This leads to clear underestimations of the CO_2-emissions.

To summarise, by the Swedish Road Administration's own assessment [6], Bypass Stockholm leads to increased emissions of the greenhouse gas CO_2. This increase is underestimated, for the following reasons:

- the increase of traffic volume is likely underestimated.
- the production of materials for the roads has not been included.
- marginal data for the emissions should have been used.
- the introduction of vehicles fuelled with electricity and renewables has been overestimated.
- it has been assumed that vehicles that can use alternative fuels will be driven exclusively with these.
- emissions from the production of fuels and electricity for the operation of vehicles, have been excluded.
- emissions from the manufacturing of vehicles have been excluded.

3.1.4. *Cost-benefit analyses*

In an earlier report [13], we have discussed the use of CBAs both from a general perspective and in previous analyses of Bypass Stockholm. The reflection built on earlier CBAs [21]. In the Swedish Road Administration's Supplementary Report [6], a new CBA is made. The conclusion is reached that the CBA of Bypass Stockholm yields a positive result. There are, however, a number of deficiencies and uncertainties in the calculation. One is the underestimation of the CO_2-emissions as discussed above. Another is the zero value given to encroachment onto natural and cultural environments, some with national importance. Another important aspect is how the future developments are included. In the analysis, future powerful economic instruments that are required to reach the Reduced climate change objective are not included. It is likely that if such policy changes were included, the benefits of a new road would decrease. This is because powerful economic instruments would probably reduce traffic volumes and thus reduce benefits from time savings. In an earlier CBA [21] it was also showed that an increased oil prices would significantly reduce the benefits of a new road.

3.2 National infrastructure plan

The national infrastructure plan includes suggestions for new investments and maintenance for the Swedish transport system corresponding to approximately 50 billion euro. It was developed by the Swedish transport agencies and submitted to the government [4]. An environmental assessment of the plan was also submitted [5].

There are two overarching aspects of the Swedish transport policy, it should be economically efficient and it should support a sustainable provision of transport services. However, these two goals do not seem to have the same importance in the planning. In the plan, it is stated that the economic efficiency, measured by cost-benefit analyses, has been guiding the work [4]. The corresponding comment is not made regarding sustainable transport service. One reason for this may be the existence of established methods for evaluating the economic efficiency. For sustainability, corresponding tools are according to the plan lacking, and it is therefore difficult to evaluate [4].

The environmental assessment [5] concludes that the national infrastructure plan will

- lead to increased impacts on the biological diversity (which is relevant for the environmental quality objective A Rich Diversity of Plant and Animal Life),
- only in a limited way contribute to the achievement of the environmental quality objective Clean Air,
- not lead to a decreased number of people being affected by noise above reference values decided by the parliament and thus not contribute to a sustainable development with regards to human health and a good environment.

In relation to emissions of greenhouse gases, it is claimed that the plan will lead to small emission reductions [4, 5]. It is thus clear that the planned projects do not contribute to the significantly decreased emissions that are required. Furthermore, the agencies have underestimated the energy use and greenhouse gas emissions in several ways. They have

- not at all, or only to a limited extent, included energy use and emissions from building of infrastructure.
- assumed large fractions of vehicles which can use renewable fuels or electricity.
- assumed that all vehicles that can use renewable fuels do that all the time.
- assumed zero emissions from production of renewable fuels.
- assumed low emissions from electricity when electricity use is increasing and high emissions when electricity use is decreasing.
- only partially included the increased transport volume caused by new infrastructure.

It is therefore likely that the plan instead will lead to increased emissions of greenhouse gases.

The plan was accompanied by an environmental assessment[5] in line with European directives [24]. It is however unclear to what extent the assessment has influenced the plan since it is noted in the assessment that the suggestions in the plan is in conflict with the environmental quality objectives and thus in conflict with the transport policy.

The environmental assessment also has some limitations in relation to the requirements formulated in the directive [24]. One such requirement is that the plan should be compared with a zero-alternative that is the likely development without the plan. The zero-development (as well as the plan) includes the so called EET-strategy, a strategy until 2020 for efficient energy and transport systems developed by several Swedish agencies. In the infrastructure plan it is however concluded that it is not likely that this strategy will be implemented. Thus the zero-alternative includes a non-likely development. Furthermore, no policy measures are assumed after 2020. Although it is clear that in order to reach the Reduced climate change goal, significant policy measures are required, no such measures are assumed in the plan. Thus the transport agencies either do not believe in the goals the Parliament has decided on, or the zero-alternative does not represent the likely development. This has implications for the comparisons between the plan and the zero alternative, and also for the cost-benefit analysis

performed. Another requirement is that the environmental assessment should include also other reasonable alternatives. The proposed document did however only include an alternative with minor modifications.

4 Conclusions

The National Road Authority suggested the Bypass Stockholm in spite of this alternative being worse than other alternatives from a climate and environmental perspective and according to their own evaluation leading to increased emissions of greenhouse gases. Also the suggested infrastructure plans do not fulfill important environmental quality objectives. Since these two cases do not contribute to the fulfillment of relevant environmental quality objectives, we conclude that the two cases do not contribute to a sustainable transport system and are thus not in line with the transport policy objectives.

Another interesting aspect of the planning processes is that the long-term climate goals, or other sustainability issues, are not included in the planning processes, neither as a clear goal nor as factor which will influence the future transport system. In this way the long-term sustainability aspects are not present in the planning. Thus, several changes must be made in the processes. Examples of such changes are:

- When goals for projects and plans are formulated, environmental and sustainability aspects should be included.
- If environmental and sustainability project or policy goals are not met, new alternatives should be developed and analysed.
- Project goals should not define the solutions (as for example the goal to find a road corridor in the Bypass Stockholm case), but be open to different possibilities.
- Environmental assessments should be performed using state-of-the art methods and data.
- Long-term environmental and sustainability goals should be included in the planning as a factor that might influence the future transport system.
- Methods for assessing the sustainability of transport systems should be developed.

Sustainable bus transports through less detailed contracts

Helene Lidestam[1,*]

Abstract: The purpose of this paper is to investigate both environmental effects and cost effects of using less specified contracts regarding bus sizes in public bus transports. The process of choosing the best bid in the public procurement of bus transports is easier if the demands of the qualifications are well specified and detailed. On the other hand, detailed contracts can force the entrepreneurs to use less environmentally friendly and uneconomical alternatives. The process of choosing the best bid in the public procurement process will be more complicated when the contracts are less detailed compared to current situations. Indeed, using less detailed contracts leads to decreased emissions and probably costs for all parts involved. A mathematical model with binary variables is developed in order to evaluate the environmental and the economic effects of using less detailed contracts in the public procurement of bus transports and in turn more suitable bus sizes. Computational results with data from a Swedish bus service provider are presented. The results of the model indicate that the emissions decrease considerably by using less detailed contracts. The results of a sub case indicate that the costs could be reduced as well, depending on how efficient the additional buses can be planned.

Keywords: *Environmental sustainability, Bus transports, Public procurement, Mathematical modeling*

1. Introduction

Many nations have converted their public transport systems from monopoly transit systems to competitive tendering. One of the first regions to use fully-tendering regime was London in 1985 [1]. An overview of international successful and less successful ways to use competitive tendering as a possibility to decrease the subsidies within the business of public bus transports has been presented [1]. The competitive tendering system has worked satisfactory in most of the European countries. Two exceptions are Italy and France where the transfer to the competitive tendering system has not affected the transports costs at all [2]. However, the costs have a tendency to be low at the first time competitive tendering is used and then instead increase for the second and third time the system is used [1]. This form of tendering often leads to changes of the structure of the actors involved in the process. Going from a market including many small actors, the actors are now few and large [1]. The system for public procurement in Sweden started through a national resolution in 1985, which led to a law coming into effect in 1989 [3]. The process for the regulations for procurement of public bus transport in Sweden is based on EU public-procurement guidelines. The most common form of contracts used in Sweden is gross contracts, where the bus entrepreneur only gets paid for the costs and is not involved in the ticket revenues. The most common way to choose the winning bid is to use so called first-price auction, which is to choose the bid with the lowest price as a winner. By using this combination the final contracts will often be very detailed. An earlier study showed that the CO_2-emissions can be reduced considerably by using less specified contracts with respect to bus sizes in the public bus transports [4]. The part of traffic being involved in the public procurement processes has increased drastically since and is now (2010) around 90%. The process of choosing the best part in the public procurement of bus transports is easier if the demands of the qualifications are well specified and detailed. On the other hand, detailed contracts will lead to limitations and could force the entrepreneurs to use uneconomical, but most of all, less environmentally friendly alternatives. The resulting contracts are indeed very detailed and there is not much inbuilt flexibility regarding for example the bus sizes. Using large buses with many bus seats for transporting few persons is

expensive, both in economic terms and most important in emission terms The trade organizations within the public bus transports area in Sweden have a common goal to double the public transports to 2020 and this ambition is in line with the aim in EU declaring that the emissions should decrease considerably. The purpose of this research was to study the cost effects of using more environmental-friendly bus traffic. The economic and environmental consequences are two of three essential aspects in sustainability. The third aspect concerns the social area. As increased emissions can lead to diseases, also this aspect is affected negatively when using non environment-friendly solutions. The outline of the paper is as follows. The methodology is presented in Section 2 and in Section 3 the mathematical model for the problem is formulated. Data from a real-life case is studied and presented in Section 4. The computational results are presented in Section 4 and finally, in Section 6, some concluding remarks are viewed.

2. Methodology

A mathematical optimization model with binary variables is developed to evaluate the environmental and cost effects of more optimized bus sizes. The mathematical model is carefully described in Section 3. We have used the program, AMPL, for modeling the problem and the commercial program CPLEX, version 10.2.0, is used to solve the model. These programs are suitable when the mathematical models include binary or integer variables. Data needed for the study is collected for one region in Sweden and is provided by a large Swedish bus entrepreneur, called Nobina Bus AB. All distances from one stopping place to the next stopping place on all chosen bus tours have been used as well as different kind of buses and their capacity in terms of number of seats. Finally, the levels of CO_2-emissions (kilogram per kilometers) and costs (Swedish crowns per kilometers) for each kinds of bus type are considered. Two opposite scenarios have been tested in order to evaluate the environmental effects of more details in contracts. The scenarios are shortly described below:

Scenario A – This is the basic scenario and it shows the current situation in the chosen region. The contract for bus traffic in the area defines which type of buses those have to be used on which bus tours.

Scenario B– The possibility to use additional buses along the lines is tested. Sometimes a large bus can drive empty from the starting place to the second last stopping place and then it can get a lot of passengers for the last part of the line. No restrictions regarding the choice of bus type. The results in this scenario show the level of CO_2-emissions when as small buses as possible, with respect to CO_2 emissions, are used. The possibility to use other bus types is also tested.

The economic effects of using more flexible and less detailed contracts in the public procurement process are evaluated in the specific case described in Section 4. This case is a sub case of the general case. In order to get a more lifelike situation, some restrictions are added into the relevant scenarios. They are further described in Subsection 4. The results from the sub case are compared to the current daily planning by the involved bus entrepreneur. The results of the model will give a solution that uses as small bus sizes as possible with respect to the costs.

3. Mathematical model

In this section we present the mathematical model for the problem of evaluation of public procurement of bus transports. The model is used in order to find as small buses as possible to use of each part of the bus tours. The model consists of an objective function, binary

variables, parameters and constraints. We first describe the parameters and the variables. Thereafter the objective function is presented and finally, the constraints are described. The original model is earlier presented [4].

Parameters

$h_i = CO_2$ emissions measured in kilogram per kilometer from bus type i.

a_{jk} = the distance from stopping place k to the next stopping place at line j.

e_{jk} = the number of people getting on the bus at stopping place k at line j.

r_{jk} = the number of people getting off the bus at stopping place k at line j.

P_i = the capacity for bus type i measured in number of seating places.

Variables

$$\boldsymbol{B_{ijk}} = \begin{cases} 1, & \text{if bus type } \boldsymbol{i} \text{ is used from stopping place } \boldsymbol{k} \text{ to the next stopping place on line } \boldsymbol{j} \\ 0, & \text{else.} \end{cases}$$

i = 1..m, j =1..n, k = 1..h

Objective function

$$\text{Min} \sum_{\boldsymbol{i}} \sum_{\boldsymbol{j}} \sum_{\boldsymbol{k}} \boldsymbol{a_{jk} h_i B_{ijk}}$$

Constraints

$$\sum_i P_i B_{ijk} \geq e_{j1} \quad \forall j, \forall k : k = 1 \quad (1)$$

$$\sum_i P_i B_{ijk} - \sum_{k=1}^{k-1} e_{jk} + \sum_{k=1}^{k} r_{jk} \geq e_{jk} \quad \forall j, \ \forall k : k \geq 2 \quad (2)$$

$$B_{ijk} \geq B_{ijk-1} \quad \forall k \geq 2, \forall i, \forall j \quad (3)$$

$$B_{ijk} \in \{0,1\} \quad (4)$$

The objective function minimizes the CO_2-emissions. The distance between all stopping places at the lines is multiplied with the CO_2-emissions from the different bus types, respectively. The constraints (1) make sure that the capacity of the used buses is enough that is that all of the people that get on the bus at the starting point have a seat place on the bus. The constraints (2) ensure that all the people getting on the buses at the forthcoming stopping places gets a seat place on the used buses. The fact that one bus has to following the whole line after it has started is described in the constraints (3). The constraints (4) express that all variables are binary, that is they could either be 1 or 0. Constraints (3) also allow buses to start on a later stopping place along the line, but it has to continue to drive to the end of the line. If there is no possibility to add buses along the line the constraints (3) can instead be described as constraints (5) given below:

$$B_{ijk} = B_{ijk-1} \quad \forall k \geq 2, \ \forall i, \ \forall j \quad (5)$$

To evaluate the specific case and to reach the lowest level of included costs, the objective function in the model is modified in the following way:

$$\text{Min} \sum_{i} \sum_{j} \sum_{k} a_{jk} c_i B_{ijk} ,$$

where c_i = costs measured in Swedish crowns per kilometer regarding bus type *i*. The costs refer to variable driving costs. The fixed capital costs, mainly for depreciations, are added afterwards in order to compare different scenarios. The constraints used for the specific case are the same as above (1-4). The model does not consider any limitations of the number of buses that can be used for different lines. The distance between one stopping place at a line and a starting place at another line and the distance to the bus garage is not regarded in the problem. The different times for the lines are counted only as different lines so the time aspect and any possible limitations of the use of different bus types has not been considered as well in the problem.

4. Case study

Nobina AB, earlier called Concordia Nordic Bus AB, is the largest bus transport company in the Nordic countries and one of the ten largest in Europe. Nobina AB works for different public authorities in Sweden. The name of the public authority for the region considered in this study is Västtrafik. The general case included 103 different lines. The lines are divided into several sub lines depending on the number of stopping places along the line. For each line there are different variants of the line. The variants differ regarding the included stopping places and their order. Each variant of a line is used several times in a 24 hour. In total it is 2 044 tours including 2 037 stopping places during a day in the selected area and the number of counted people getting on (and off) the buses is 34 312. Seven types of buses are used by Västtrafik and taken into account in the scenarios. The capacity of the different type of buses is from 23 seats to 56 seats and the levels of CO_2-emissions range from 0,83 kg/km to 0,99 kg/km. For each bus type, the related seat capacity and CO_2-emissions are given. The CO_2-emissions are defined by kilogram per kilometer. The presented model will minimize the level of CO_2-emissions.

The calculations of the emissions are based on road driving with few stops. The most important factor to consider in this paper is the difference in emissions due to the size of the bus type, which in this case is measured in number of seats in each bus type. Therefore the other depending factors, for example type of engine and driving properties are equal in of all the bus types. The considered engine in all of the bus type is a euro3 engine. The newer engine euro5 has fewer emissions but the difference is mostly related to the NOx-emissions and SOx. The figures on CO_2-emissions are considered proportionate to fuel-consumption. The fact that a full bus has more CO_2-emissions compared to an empty bus has not been considered in the optimization, however, it can be calculated and evaluated after the optimization has been made if needed. In scenario B, two additional bus types are possible to use; one large bus taking 65 passengers with 1,15 kg/km of CO_2-emissions and one small bus taking only eight passengers with 0,3 kg/km of CO_2-emissions.

An area of bus traffic is chosen from the general case in order to investigate the economic effects on a given real planning situation. One hundred tours (around 5 %) of 2 044 in total

are included in the specific case. The total length of these tours is 5 750 kilometers to compare to the total length of the general case which is 44 790 kilometers. The bus traffic for the specific case is chosen in cooperation with the planning manager at the involved company Nobina AB. One reason for choosing this area and these tours was that the traffic is expected to be heavy and the buses are supposed to be more full compared to an average tour in the area of the general case. The 100 used tours are divided into 14 bus trips. The bus trips describe the day of each bus. The current situation at the chosen region is that 14 large buses (Express buses) are used on the 100 tours. The bus goes from the garage in the morning and back to the garage at the evening. The bus trips can include from five to nine different tours. A typical example of a bus trip is illustrated in Figure 4.1. This bus trip (on the x-axis) includes seven different bus tours (the piles) represented in time order, that is the first tour represents the early morning and the last tour represents the late afternoon or evening for the bus trip. The y-axis shows the number of passengers on each tour. Each bus tour includes a number of lines between the stopping places and the number of passengers in Figure 4.1 refers to the highest number of passengers on the each tour. That means that the situation can be that the bus drives empty most of the distances and drives with many passengers, for example 50, only on one of the included lines. Then the number of passengers, in Figure 4.1 below, will be 50 on that tour. Most of the bus trips look like the one below in that sense that number of passengers on the tours included varies a lot. As mentioned before only type of large buses are used today in this area. The average number of the highest level of passengers is 24 on the 100 included tours.

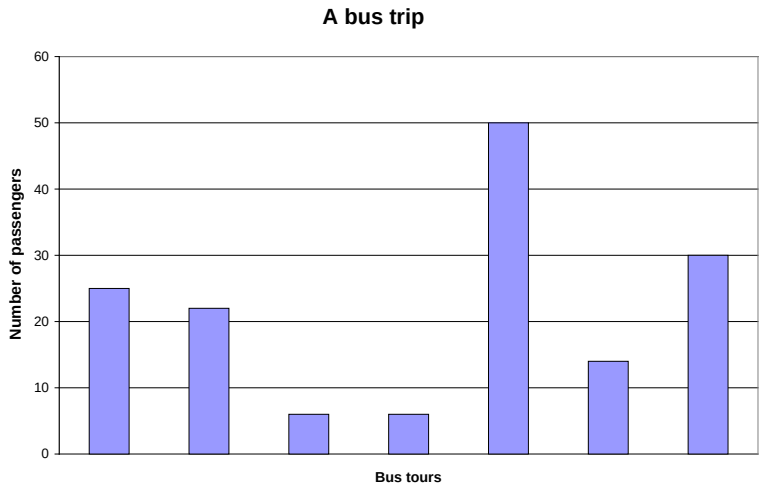

Figure 4.1 Example of a bus trip

Alternatives to use only large Express-buses can be to use as small buses as possible on the fourteen tours. That is further on called using adaptive bus sizes and that will of course also lead to the use of fourteen buses. Another alternative that will be investigated on the specific case is to use another bus type, here called Middle-bus, as a standard bus and then use smaller buses, here called Mini-buses, as additional buses that can be used whenever needed between one or several stopping places. The capacity of the Middle-bus, in terms of seats, is 32 and the capacity of the Mini-bus is 15. The CO_2-emissions from the Middle-bus and the Mini-bus are 0,45 and 0,35 kilogram per kilometers, respectively, compared to the level of 0,96 kilogram per kilometers from the Express-bus. Regarding the alternative of using adaptive bus sizes, the bus type Ordinary is also taken into account. The level of CO_2-emissions from that bus type is 0,93 kilogram per kilometers and the number of seats is 46. The considered variable costs are referred to costs for operating the bus and costs regarding the bus driver. The

included fixed costs are capital costs, mainly with respect to the depreciations and based on the purchase cost. The levels of the different costs are collected and evaluated by the planning manager for Nobina AB in the area of the specific case.

5. Results

The resulted levels of CO_2-emissions from the scenarios in the general and the specific case are presented in Table 5.1. The level of CO_2-emissions is calculated based on the level of emissions per 24 hours workday. The bus traffic on workdays is on average four times more intense compared to the bus traffic on Saturdays and Sundays. We have estimated the number of workdays in a year to 245 and the official holidays, including Saturdays and bridges days, to 120. The differences compared to Scenario A are given in percent.

Table 5.1 Comparison of the two cases.

Case	Scenario	CO_2 kg/year	Difference
General	A	11 765 150	0 %
General	B	7 653 800	- 34 %
Specific	A	1 554 300	0 %
Specific	B	1 183 050	- 24 %

The results from the two scenarios, indicate a clear relation between CO_2-emissions and contract-flexibility. By letting the number of passengers decide which bus size to use instead of following the contract regulations, the CO_2-emissions can be decreased by 34 %. The possibility to add buses along the tours create a need for more small buses. A disadvantage by using smaller buses is the fact that more buses have to be used. The buses will in total be used on shorter distances but indeed more buses on a line results of course in more bus drivers. It is a trade-off between the fixed costs of having several bus drivers and the ambition to drive as small buses as possible in order to reduce the CO_2-emissions. The fact that the difference between Scenario A and Scenario B in the general case is larger compared to the difference between the same scenarios in the specific case indicates that the chosen area for the specific case is not fully representative for the general case. The results above also tell that there are other areas in the general case that would gain more, with respect to lower CO_2-emissions, by using more flexible and less regulated contracts. The solution times regarding the general case are less than 20 minutes and the solution times for the specific case are all very small, below one minute.

The current situation, only use Express-buses, is compared to other alternatives regarding the specific case. The first alternative to investigate was to adaptive bus sizes. To find and use the smallest bus for each trip resulted in seven Express-buses, six Ordinary-buses and one Middle-bus and these changes would lead to 5 % lower CO_2-emissions on the same number of active kilometers compare to the current situation. The second alternative investigated was to use another type of base bus, Middle-bus on all trips and then when necessary use additional, Mini-buses, on parts of the tours. By using fourteen Middle-buses and seventeen Mini-buses the CO_2-emissions can be reduced by as much as 47 %.

The results, however, only present the CO_2-emissions from the active driving in the tours. The driving from the bus garage to the first tour in the morning and the driving from the last tour in the evening back to the bus garage are not taken into account. Also the fact that the buses used on one or several sub distances between stopping places on one tour also are used for other sub distances on other tours lead to additional CO_2-emissions. These extra CO_2-

emissions are not been taken into consideration in the above table. The circumstances of using additional buses on the trips lead to a larger number of active kilometers, 6 677 compared to 5 750. The plan of where different buses will be used has been showed to the planning manager. He has, from his point of view, estimated the practical need for buses in the current area to be 10 additional Mini-buses. Therefore the calculations regarding costs are made for using 10 additional buses. The results measured in emissions and costs for using different kind of combinations of bus types on the fourteen bus trips are presented in Table 5.2.

Table 5.2 The results regarding CO_2-emissions and costs from the specific case.

Used buses	Active kilometers	CO_2 kg/year	Difference	Total costs (SEK/year)	Difference
14 Express	5 750	1 518 000	0 %	30 449 000	0 %
7 Express 6 Ordinary 1 Middle	5 750	1 438 000	- 5 %	28 009 000	- 8 %
14 Middle 10 Mini	6 677	800 786	- 47%	24 997 660	- 18 %

The calculations made by the planning manager showed that adding 10 more buses in the current situation will increase the costs by 10 %. There is apparently a gap from decreasing the costs by 18 % to increasing the costs by 10 % due to how the additional buses can be scheduled. However, the value of lowering the emissions and in turn improving the environment is hard to measure and compare to the increasing related costs.

6. Conclusions

The results of the mathematical model indicate that all parts involved in the public procurement process, the public authority, the entrepreneur and the customers, will gain from more flexible and less detailed contracts. The results from the general case expose notable lower levels of CO_2-emissions when the contracts are more flexible and without detailed restrictions. The levels of CO_2-emissions decrease by 34 % from the current situation to the most flexible scenario (Scenario B). The results from the specific case indicate that the costs could be reduced as well, depending on how efficient the additional smaller buses can be planned. The results indicate that the emissions can be reduced up to 47 % by using smaller buses in traffic and the costs can in worst case increase by 10 %. Anyway, there are possibilities to decrease the costs as well if the operations planning changes. That could be done for example by expanding the planning area for the buses in order to increase the possibility to make use of returns to scale and coordination advantages. Other kinds of entrepreneurs, such as taxicabs, could also be used in addition to the ordinary buses. That will lead to more flexibility. Another base for getting lower cost could be to plan the bus trips in a different way. The occupancy level on the buses in general could probably be higher if the tours for a bus trip have more equal occupancy levels. The number of on and off-going people in the studied bus trips in the specific case varies a lot along the trip. The possibility to use parking places for the buses along the tours in addition to the bus garage could also decrease the bus driving. Directions for future research could therefore include the above suggestions in order to show the possibility to reduce both the CO_2-emissions as well as the costs considerably. In order to get a more complete view, other aspects, for example the traveler behavior connected to the level of occupied buses should be further investigated. The results from the optimization model show that detailed rules in the public procurement process lead to increased CO_2-emissions and probably higher overall costs, and therefore it would be

highly motivated by the politicians to evaluate the Swedish system. The research will therefore contribute to the operation management planning in order to achieve the overall aim to reduce CO_2-emissions. The actors in the public bus transport business should as well be interested in getting insight in how fewer restrictions in the contracts will affect them.

Abstract: The large amount of CO_2 emissions and of fossil fuel consumption by the transportation sector makes the sector central for attaining the EU energy and climate policy targets. Consequently, new propulsion systems are developed in the automotive industry, which currently have cost disadvantages compared to conventional internal combustion engines (ICE). The article provides a review on support measures for electric vehicles which have been currently implemented within the European Union. In a case study analysis for Austria, we analyze different policy instruments including a CO_2 tax aiming to support the introduction of electric vehicles in Austria. We have calculated and compared total costs of ownership (TCO), which includes all costs associated with the ownership of an automobile including costs of purchasing, operating and maintaining, charges and taxes as well as costs of recycling and disposal. A survey on main specifications of electric vehicles has been conducted among the main automobile manufacturers and importers in Austria. Based on this survey, TCO have been calculated dynamically from 2011 to 2020 for a business as usual (BAU) scenario considering currently implemented taxes and subsidies for ICE and electric vehicle systems. Three alternative policy support measures have been assessed to promote EV to ICE until 2015. We conclude that an up-front price support seems to be favorable over taxation systems. The paper focuses only of the effectiveness of the three policy support measures but does not analyze their efficiency.

Keywords: *Electric vehicles, Total cost of ownership (TCO), Fiscal policy instruments, Break-even*

1. Introduction

Currently, 98% of the transportation sector in the EU depends on fossil fuels. The sector is responsible for approx. 21% of the greenhouse gas (GHG) emissions, with more than half of the emissions produced by passenger cars [1]. The EU Directive (2009/33/EC) on the promotion of clean and energy efficient road transport vehicles has been released to foster a broad market penetration of environmentally-friendly vehicles in order to decarbonize the transportation sector and to reduce oil dependency.

Several new propulsion systems as plug-in hybrids, range extenders as well as electric vehicles have emerged and entered the market or are ready to enter the market in the near future [2]. However, in order to achieve a shift in the transportation sector the cost disadvantages of the newly emerged propulsion systems have to be overcome. Economic viability and a successful introduction of alternative propulsion systems will mainly depend on economic aspects such as relative costs. The gap between the total cost of ownership (TCO) of alternative transportation systems and ICE should be temporarily closed by appropriate policy interventions to promote environmentally-friendly vehicles.

Current research regarding the economic viability of electric vehicles (EV) focused mainly on lifecycle cost analysis [3,4,5]. Thiel et al. [3] compared the well-to-wheel CO_2 emissions, costs and CO_2 abatement costs of passenger light duty vehicles including gasoline vehicles, diesel vehicles, diesel hybrid vehicles, plug-in hybrid and battery electric vehicles [3]. A static comparison has been conducted for the years 2010, 2020 and 2030 under a new energy policy scenario for Europe. They conclude that electric vehicles can clearly contribute to a decarbonization of the transportation system if renewable electricity is used. According to [3],

current cost disadvantages of electric vehicles can be overcome by adequate policy support instruments to attain payback periods of less than five years.

Ogden et al. [4] conducted an analysis of the societal lifecycle cost of transportation including the purchase price, fuel costs, externality costs of securing oil supply and damage costs for emissions of air pollutants and greenhouse gases which are calculated over the full fuel cycle. Thomas [5] developed a dynamic computer simulation model that compares the societal benefits of replacing conventional gasoline cars with vehicles that are partially electrified, including hybrid electric vehicles. He concludes that electric vehicles in combination with hybrids, plug-in hybrids and biofuels will be necessary to achieve an 80% reduction in greenhouse gas emissions below 1990 levels by simultaneously cutting dependence on imported oil and eliminating nearly all controllable urban air pollution from the light duty vehicle fleet. However, to increase market shares, market barriers have to be overcome. Therefore, the consumer perspective and thus effective and efficient policy instruments should be the focus of further research. Taxation systems regarding vehicles vary strongly between countries.

The aim of the article is to analyze different policy instruments by comparing total cost of ownership (TCO) of EV and ICE in Austria. TCO are calculated dynamically from 2011 to 2020 for a business as usual (BAU) scenario considering currently implemented taxes and subsidies for ICE and EV in Austria. In contrast to lifecycle cost analysis of alternative propulsion systems, our analysis focuses mainly on the total cost of ownership and places the consumer perspective in the center of the analysis. The consumer perspective is placed in the center of our analysis as only early adopters are willing to accept the current cost differential between ICE and EV. As such instruments necessary to close the gap are considered to be necessary in order to achieve a mass market introduction.

The article is structured as follows. Section 2 provides an overview of the support schemes currently launched in the EU-15. Section 3 presents the methodology and data. An analysis on different policy support instruments to equalize the TCO of EV and ICE in Austria is shown in Section 4 and section 5 presents major conclusions from our analysis.

2. Implemented support schemes for EV in the EU-15

Many EU member states have introduced national targets for the EV driving stock, the expansion of charging infrastructure, or production targets of electric vehicles [6]. Most EU member states overcome the cost disadvantage of alternative vehicles by introducing policy instruments such as an up-front price support in order to increase the affordability of electric vehicles by reducing the marginal capital cost, which is considered as one of the key barriers for consumers [7]. Within the EU-15, passenger cars have mainly been the target of a tax reform that takes into account the CO_2 emissions of vehicles. Policy instruments that are currently implemented in order to stimulate the up-take of alternative propulsion systems consist of [7]:

- *Registration or purchase taxes*
  Registration or purchase taxes are an up-front cost and can have a strong impact on CO_2 emissions and the market, if costs are differentiated with regard to the specific CO_2 emissions of the vehicles. In France, a bonus/malus system has been introduced whereby vehicles above certain CO_2 emission thresholds have to pay a malus and vehicles under the threshold receive a bonus. Such a system may increase the political acceptability as well as of consumers, because it can be designed in a revenue neutral manner [7].

- *Circulation or motor taxes*
  Circulation or motor taxes have according to [7] a limited effect on the purchase decision as they are annual or monthly charges. Although they are considered to be politically acceptable, their impact to promote EV is rather low as the cost range of such measures is limited.
- *Fuel taxes*
  Fuel charges have limited short-term effects, because they do not change the purchasing decision of consumers in the longer term [8]. Furthermore, they are considered to be politically prohibitive.

Policy instruments to stimulate the up-take of alternative propulsion systems are subsidies, taxation of benefits in kind and treatment of depreciation (relevant for company cars) and in use and parking charges [8]. Table 1 provides an overview of the currently implemented support measures [7-10].

Table 1: Policy instruments to supporting EV in the EU-15

Country	**Economic instruments for the support of EV**
Austria	Exemption from fuel consumption tax Exemption from monthly vehicle tax
Belgium	Purchasers of electric cars receive a personal income tax reduction of 30% of the purchase price (with a maximum of EUR 9,000)
Finland	Exemption of fuel tax
Italy	A tax incentive of EUR800 and a two year exemption from annual circulation tax is granted for the purchase of a new passenger.
Denmark	Exemption from registration tax and annual circulation tax. Further EV qualify for free parking
Germany	EV exempt from the annual road tax for a period of five years from the date of the first registration
Spain	Various regional governments grant tax incentives for the purchase of alternative fuel vehicles including EV – approx. EUR 6,000
France	Bonus-Malus System; New Cars with CO2 emissions below 125 g/km receive a premium. EV receive currently EUR 5,000
Greece	EV exempt from registration tax. If engine capacity below 1929 cc, exemption from road tax. Further EV are even allowed to drive in Athens when parts of the city are restricted to ICE to reduce traffic congestion.
Ireland	EV exempt from registration tax – approx. EUR 2,500.
The Netherlands	approx. EUR 6,400 reduction from the registration tax
Portugal	Exemption from registration tax
Sweden	Exemption from annual road tax for a period of 5 years upon first registration
United Kingdom	Exemption from annual road tax
Ireland	Exemption from registration tax
Luxemburg	Annual circulation taxes based on CO_2 emissions

3. Data and Methodology

Total cost of ownership (TCO) includes all costs arising with the ownership of an automobile including costs of purchasing, operating and maintaining, charges and taxes as well as costs of recycling and disposal over a specified timeframe under consideration of opportunity costs. TCO is defined as following:

$$TCO = -I + \sum_{t=1}^{N} c\,(1+r)^{-t} + R\,(1+r)^{-N} \quad , \qquad (1)$$

where *I* represents the purchase price, *c* maintenance and operating costs, *r* the discount factor and *R* the resale price. Maintenance and operating costs include infrastructure charges, insurance, fuel consumption tax (NoVA) and the monthly engine related vehicle tax (motorbezogene Versicherungssteuer).

TCO have been calculated for limited vehicle options based on a survey conducted with the main automobile manufacturers and importers in Austria. The survey includes data on technical specifications and costs. The EVs included in the analysis are either already available for sale or will be in the near future. The survey has been conducted with the automotive offices of Nissan, Peugot, Renault, Mitsubishi and Think City in Austria. The ICE have been chosen of similar size and technical specifications, which are the most often sold cars in the vehicle class [11]. Technology and performance assumptions for ICE have been derived from the respective automobile manufacturers [12,13]. Table 2 provides an overview of the main specifications as well as the main resulting performance and cost figures of EV and ICE for which the TCO have been calculated dynamically over the period 2011 until 2020.

Table 2: Technical, performance and cost assumptions of analyzed vehicles

	VW Golf Rabbit	**VW Golf Rabbit**	**Nissan Leaf**	**Peugeot iOn**	**Mitsubishi i-Miev**
Technology					
ICE engine displacement (l)	1.6	1.2	-	-	-
Turbocharger (yes/no)	yes	yes	-	-	-
PT power (kW)	77	77	-	-	-
Electric motor power (kW)	-	-	80	47	49
Battery capacity (kWh)	-	-	24	16	16
Energy source	Diesel	Gasoline	Electricity	Electricity	Electricity
Performance					
Weight (kg)	1,314	1,314	1,545	1,120	1080
Acceleration 0-100 km/h (in s)	11.3	10.6	-	-	-
Top speed (km/h)	190	190	140	130	130
Fuel consumption (l/100km)	4.1	5.2	-	-	-
Electricity consumption (kWh/100km)	-	0	15	15	15
Tailpipe CO_2 emissions (g/km)	107	121	-	-	-
Costs					
Vehicle incl. VAT and NoVA (EUR)	20,350	22,120	39,600	36,000	35,900
NoVA (fuel consumption tax in % of purchase price)	4%	4%	0%	0%	0%
Battery cost (EUR/kWh)	-	-	600	600	600
Battery cost (EUR)	-	-	14,400	9,600	9,600
Loss in value p.a.	17%	16%	32%	32%	32%
Maintenance cost (EUR/100km)	4.6	4.1	2.5	2.5	2.5

The TCO have been calculated over a period of five years assuming that 15,000 km are traveled annually. According to the survey, automobile manufacturers expect that the battery of EV needs to be replaced after approx. 75,000 km. We assume that vehicles are sold after

five years, because no estimates on battery replacement costs are currently available. Both assumptions refer to results of [13] and have been confirmed by the survey. The percentage loss in value p.a. as well as maintenance costs are guesstimates of manufacturers received in the survey. Average figures are applied to all EV, because the guesstimates from the respective manufacturers differ slightly and empirical values are not available yet. We also assume that the purchase price of ICE will not change over time, because further efficiency gains in ICE are costly [2]. Furthermore, learning effects from increased production volumes decrease the purchase price. The learning effects have been depicted from an analysis conducted by [15] and are consistent with [3,14,16]. Currently, battery costs amount to approx. 600 EUR/kWh and shall decrease to approx. 300 EUR/kWh by 2015 if the projected production volumes are reached. Projected productions volumes are reflected in the assumed learning rate and have not been separately been calculated. As such price reductions resulting from an increase in production volume are already reflected in the calculation of the TCO.

The current gasoline price in Austria amounts to 1.3 EUR/l and for diesel to 1.1 EUR/l including taxes and charges. The gasoline and diesel prices are assumed to be consistent with the projected oil prices in the Annual Energy Outlook. The electricity price for Austrian households amounts currently to 0.15 EUR/kWh including taxes and charges. The average increase in the electricity price (EEX Phelix baseload) from 2000 until now has been approx. 2.8% p.a. Similar price developments are assumed to 2020.

4. Results

The three policy scenarios consist of an up-front price support, a CO_2-tax as well as a fuel consumption tax for ICE, respectively. The level of incentive to make EV competitive from 2011 onwards is shown for each policy instrument.

In a BAU-scenario, the EV becomes cost-competitive with ICE in the year 2015. TCO of ICE are increasing over time mainly due to rising fuel costs. The decrease in TCO of EV is mainly attributed to the projected decreases in battery costs. The TCO time line for EV and ICE is shown in Fig. 1.

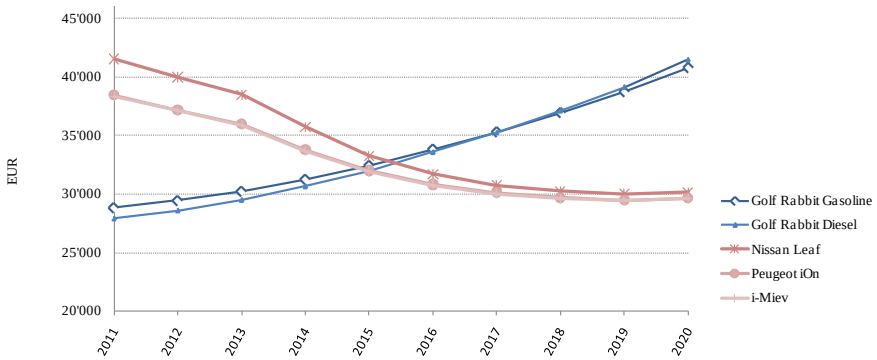

Fig. 1: TCO – BAU-scenario

The BAU scenario implies that TCO of ICE and EV will converge in 2015. However, it only may convergence if the projected volumes are produced to realize the necessary economies of scales. Consequently, subsidies may be necessary to realize the projected production volumes. As shown in Section 2, many countries have currently implemented or are considering to implement an up-front price support (e.g. usually in the form of an exemption of the registration tax) for alternative propulsion systems. An up-front price support is considered as an effective policy instrument, because consumers put much larger emphasis on the purchase

price of a vehicle than on the resulting maintenance and operating costs [8]. However, by introducing an up-front price support for EV, the question arises of how much price support is necessary to incentivize sufficient uptake of EV.

In our analysis, we have calculated alternative levels of upfront price support to offset the gap between ICE and EV TCO (table 3). It is assumed that covering the entire price differential would require large amounts of subsidies despite remaining technical limitations such as limited range that may lead to higher costs [8]. However, a regressive price support system would minimize windfall profits. Nevertheless, the interviewed representatives of automotive manufacturers clearly stated that final purchase prices are set under consideration of governmental support and that EV will be available for sale only in countries with governmental support measures at a level that is considered sufficient from the perspective of car manufacturers. The level of price support should be adjusted annually to account for learning effects. High political and public acceptability is attributed to an up-front price, however some moral hazard problem will remain [7].

Table 3: Levels of up-front price support until 2015 in Euro

	2011	2012	2013	2014	2015
up-front price support	10'000	8'000	5'500	3'000	0

In a second scenario, we have analyzed the level of a CO_2 tax for the transportation sector in order to promote EV. A CO_2-tax is generally considered to be an effective policy instrument from an environmental point of view, because it contributes to lowering CO_2 emissions. Furthermore, it is a cost-effective policy instrument as it generates revenues for the government that can be used to subsidize cleaner technologies [18]. Besides reducing greenhouse gas emissions, a CO_2-tax has the capacity to reduce other external costs of ICE such as changing driving habits, reducing traffic congestions and other emissions e.g. fine dust [18].

A CO_2 tax can be levied by directly taxing gasoline and diesel corresponding to the carbon content of the respective fuel. This implies that a CO_2 tax would result in an increase in the respective fuel price. The level of CO_2 price necessary to sufficiently promote EV is shown in Table 4 and Table 5 shows the resulting gasoline and diesel prices.

In our analysis, the implementation of a CO_2 tax becomes effective, if the CO_2 price is approx. 2’000 EUR/t. Currently, the CO_2 price on the EU Emission Allowances spot market trades at 15 EUR/t. Increasing the CO_2 tax to up to 2’000 EUR/t is seen as politically infeasible. Therefore, the introduction of a CO_2 tax as sole policy instrument to reduce the price differential and to achieve a certain market penetration of EV is not considered viable.

Table 4: Required levels of CO_2 tax until 2015 in EUR/t

	2011	2012	2013	2014	2015
CO_2 tax	2'500	2'300	2'250	1'000	0

Table 5: Resulting gasoline and diesel prices until 2015

	2011	2012	2013	2014	2015
Golf Rabbit Gasoline					
CO_2 emission g/km	121	121	121	121	121
Fuel consumption l/ km	0.052	0.052	0.052	0.052	0.052
CO_2 emission g/l	2'327	2'327	2'327	2'327	2'327
CO_2 tax ct/g	0.250	0.230	0.225	0.100	0.050
ct/l	581.7	535.2	523.6	232.7	116.3
Golf Rabbit Diesel					
CO_2 emission g/km	107	107	107	107	107
Fuel consumption l/ km	0.041	0.041	0.041	0.041	0.041
CO_2 emission g/l	2'610	2'610	2'610	2'610	2'610
CO_2 tax ct/g	0.250	0.230	0.225	0.100	0.050
ct/l	652.4	600.2	587.2	261.0	130.5

The necessary levels of the fuel consumption tax (NoVA) have been analyzed as third policy option. Currently the NoVA amounts to 4% of the purchase price for the cases under consideration. As shown in Table 6, the NoVA would need to be increased by up to 45% in order to sufficiently support EVs from 2011 onwards. Similarly to the CO_2-tax, an increase in the NoVA as sole policy instrument is considered to be politically infeasible and it may cause adverse effects on the total automotive market.

Table 6: Required level of NoVA in %

	2011	2012	2013	2014	2015
NoVA	45	40	35	30	0

5. Concluding Remarks

Several TCO have been calculated for EV and ICE. The BAU-scenario shows that EV shall be competitive with ICE in the year 2015 if no additional policy actions are taken. However, significant learning effects are assumed to decrease costs of electric cars. Such learning effects can be mainly triggered if policy makers sufficiently support research and development of new environmentally friendly vehicle technologies. The analysis shows that both CO2 and NoVA taxes, which increase the costs of ICE, have to be prohibitive to make electric cars competitive. Introducing such levels of taxes seems not politically feasible besides other adverse effects on the vehicle market. Therefore, up-front price support systems (e.g. direct financial support, exemption from registration tax, bonus/malus system, etc.) seem to be favorable over the taxation systems. These results are confirmed by literature. Even though cost disadvantages can be overcome by policy support instruments, technical limitations of EV such as limited range and relatively long charging times remain. In addition to closing the TCO gap between EV and ICE and to overcoming technical limitations, policy makers shall focus on providing infrastructures for a large-scale take-up of EV.

Abstract: The present study analyzes the performance and combustion characteristics of 10%, 20%, 30% and 40% blending of Koroch Seed Oil Methyl Ester (KSOME) and Jatropha Methyl Ester (JME) with diesel as fuels in a diesel engine. The brake specific fuel consumption (BSFC) was more for the methyl ester blends and particularly for the JME blends. The brake thermal efficiency (BTE) was slightly lower for the biodiesel blends and for the JME blends it was less compared to that of the KSOME blends. The indicated power was more in case of the blends; however it reduced significantly for the 40% blend of KSOME. Both the KSOME and JME blends exhibited similar combustion trend with that of diesel, however, the blends showed an earlier start of combustion with shorter ignition delay. The ignition delay was less and the combustion duration was more for the JME blends as compared to the KSOME blends. The overall observation was that the KSOME blending up to 30% showed an acceptable performance and combustion trend whereas the JME blends showed favorable combustion trend but due its comparatively higher fuel consumption characteristics, finally the engine BTE was less with the JME fuel blends.

Keywords: *Biodiesel, diesel engine, Koroch seed oil, Jatropha*

1. Introduction

Biodiesel obtained from non edible plant species such as Jatropha *curcas (Ratanjot), Pongamia pinnata (karanj)*, *Calophyllum inophyllum (Nagchampa)*, *Madhuca indica* (*Mahua*), *Hevea brasiliensis* (*Rubber seed)* are gaining importance as possible renewable alternate fuels in India. Biodiesel is non toxic, biodegradable, and environmentally friendly as it contains minimum sulfur and aromatics. However, its higher viscosity leads to poor atomization of the fuel spray and incomplete combustion, coking of the injector tips, oil ring sticking and thickening and gelling of the engine lubricant oil. Its lower calorific value and lower volatility are regarded as its disadvantages. Therefore, the 5-20% (by volume) blending with standard diesel has been considered as suitable at present for using in existing diesel engines without any modifications. Many researchers have evaluated the performance of conventional diesel engines fuelled by bio-diesel and its blends. Raheman and Ghadge [1] while evaluating the performance of a single cylinder, four stroke Ricardo E6 engine with various biodiesel blends and pure biodiesel from Mahua seed oil found higher BSFC and lower BTE in case of the blends. Ramadhas et al. [2] used Rubber seed oil and its blend in a single cylinder diesel engine and observed that the blends containing 20–40% of rubber seed oil in the blend yielded an engine performance closely matching that of diesel oil. Raheman and Phadatare [3] used karanja methyl ester and its blends in a single cylinder, four-stroke, direct injection (DI) diesel engine and observed slightly higher torque in case of 20% blending (B20) and 40% blending (B40) while lower torque was observed with 60% blending (B60) to pure biodiesel (B100) when compared to diesel. BSFC was lower for B20 and B40 and found to be higher for blends ranging from B60–B100. The BTEs were also higher for B20 and B40. Sahoo and Das [4] made a combustion analysis using neat biodiesel from Jatropha, Karanja and Polanga; and their blends (B20 and B40) at various loads. Saravana et al. [5] observed lower delay period, lower maximum rate of pressure rise and heat release with 20% blending of crude rice bran oil methyl ester (CRBME) in a stationary small duty DI diesel engine. The BSFC of CRBME blend was found to be only marginally different from

that of the diesel. Qi et al. [6] evaluated combustion and performance of a single cylinder four stroke diesel engine (rated power 11.03 kW, rated speed 2000 rpm) with biodiesel produced from crude soybean oil. However, the performance and combustion trend vary depending upon the type of biodiesel used, engine configurations, test conditions, and the method of analysis. Also, the appropriate blend that would give optimum engine performance and best combustion characteristics may vary from biodiesel feedstock to feedstock, its production processes and the type of engine in which it is used. For the present investigation, biodiesel was prepared from Koroch seed and Jatropha curcus oil using a two step acid base catalyzed trans-esterification process in a laboratory scale. The properties of the various blends prepared by mixing biodiesel in various volumetric proportions with diesel obtained from Numaligarh refinery limited (NRL) are summarized in Table 1. The properties were determined at the Quality and Control Laboratory of NRL. Koroch is a tree found in abundance in the forests of north east India and oil obtained from Koroch seed has its own unique characteristics as a potential source of biodiesel. The author of this paper has not come across any study on diesel engine performance and combustion involving KSOME and its diesel blends. Although related literatures are available for JME, still blends of JME have been chosen as fuels for a comparative analysis.

Table 1. Properties of NRL diesel and various biodiesel blends

Fuel	NRL diesel	KB10	JB10	KB20	JB20	KB30	JB30	KB40	JB40

2. Methodology

Tests were performed in a single-cylinder; four-stroke, naturally aspirated, DI diesel engine and its specifications are given in Table 2. The test engine is provided with necessary instruments for combustion pressure, fuel pressure and crank-angle measurements. The in-cylinder and the fuel pressure are sensed by two piezo sensors. Signals from these pressure transducers are fed to a charge amplifier. A high precision CA encoder is used to give signals for top dead centre (TDC) and the CA. The signals from the charge amplifier and the CA encoder are supplied to a data acquisition system which is interfaced to a computer through engine indicator for obtaining pressure CA diagram. There are provisions in set up also for interfacing airflow, fuel flow and load measurement. The engine is coupled with an eddy current dynamometer for controlling the engine torque through computer. A Lab view based engine performance analysis software package evaluates the on line engine performance. The tests were conducted at steady state and 100% load at average engine speed of 1,535 rpm where the average engine torque was 21.85 Nm. This yielded an average brake power (BP) of 3.5 kW in each fuel test. Three test runs were performed under identical conditions to check for the repeatability of all the results. The repeatability of the results was found to be within an acceptable limit. The test results were then averaged and the average test results have been reported.

Table 2. Engine Specifications

Make and Model	Kirloskar –TV1
Rated power and speed	3.5 kW and 1500 rpm
Type of Engine	1 cylinder, DI type, 4Stroke
Compression ratio (CR)	12-18:1
IV Opening	4.5° before TDC
IV Closing	35.5° after BDC
EV Opening	35.5° before BDC
EV Closing	4.5° after TDC
Bore & Stroke	87.5mm and 110mm
Nozzle opening pressure	220 bar
Cooling Medium	Water cooled

3. Results and Discussion

3.1. Performance Characteristics

3.1.1. Brake thermal efficiency

Fig. 1 shows the BTE of the test engine for the tested fuels. It was observed that the BTE with the methyl ester fuel blends were comparatively less. The BTE decreased with increasing proportion of methyl ester in the blends. Further, the BTE for the JME blends were less compared to that for the KSOME blends. The BTE values with NRL diesel, KB10, JB10, KB20, JB20, KB30, JB30, KB40 and JB40 are 25.63%, 24.86%, 23.89%, 24.34%, 23.24%, 24.13%, 22.41%, 22.35% and 22.18% respectively. K and J here refer to KSOME and JME respectively. Compared to KSOME blends, slightly lower BTEs for the JME blends was mainly due to their increased fuel consumption rates for maintaining a constant BP output. Since the density and viscosity values of the JME blends were lower and the HHVs were higher compared to their corresponding KSOME blends, fuel consumption for the JME blends should have been lower than those of KSOME blends. Similarly the BTEs of the JME blends should also be more due to better combustion resulting from lower viscosities of JME blends compared to their KSOME counterparts. But the opposite trend in fuel consumption and BTE could not be understood. An energy balance study determining the various energy losses could be an appropriate future work for confirming this opposing trend.

3.1.2. Brake specific fuel consumption

The BSFC for the blends of JME and KSOME are compared with NRL diesel and is shown in Fig. 2. It was seen that the BSFC for the biodiesel blends was more. BSFC was marginally higher in case of the JME blends. This is due to higher fuel consumption rate in case of the JME blends. The fuel consumption rate for NRL diesel, KB10, JB10, KB20, JB20, KB30, JB30, KB40 and JB40 are 1.15 kg/h, 1.187 kg/h, 1.23 kg/h, 1.214 kg/h, 1.27 kg/h, 1.228 kg/h, 1.32 kg/h, 1.328 kg/h and 1.34 kg/h respectively.

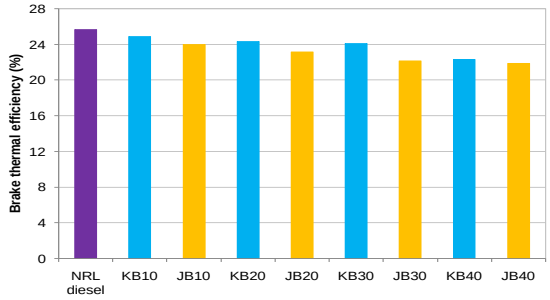

Fig. 1. BTE for the tested fuels

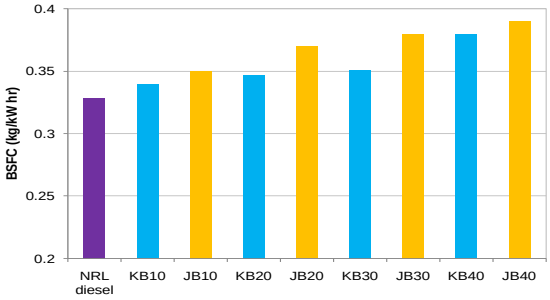

Fig. 2: BSFC for the tested fuels

3.1.3. Indicated power

From Fig. 3 it is observed that the engine IP operated with the blends is slightly more except for the blend KB40. The engine IP produced with NRL diesel, KB10, JB10, KB20, JB20, KB30, JB30, KB40 and JB40 are 5.6 kW, 5.76 kW, 5.7kW, 5.80 kW, 5.83kW, 5.92 kW, 6.02kW, 5.42 kW and 6.09kW respectively. It was observed that the loop work i.e. the work done during the gas exchange process and the compression work were less while the combustion and expansion work were more in case of the blends. Hence the net work done during the cycle was more and this resulted in higher IP. Slightly higher IP with the methyl ester blends may also be due to combustion of relatively more amount of fuel in case of the blends. Although the calorific values of blended fuels were lower than that of NRL diesel, the fuel energy was more for the blends and particularly for the JME blends due to relatively higher fuel consumption rate. Lower IP with KB40 was due to increase in the compression and loop works and decrease in the expansion work. The viscosity of KB40 was higher and may be due to poor combustion of this fuel blend it resulted in cylinder pressure variation leading to lower IP. Again, the IP with the JME blends was comparatively more than that with the KSOME fuel blends. It was due to higher energy input in respect of these blends and also due to higher net works done during the cycle as can be seen from the Table 3 shown below.

Table 3. Various works done during the cycle

Fuel	NRL diesel	KB10	JB10	KB20	JB20	KB30	JB30	KB40	JB40
Combustion and Expansion work (kJ)	724.13	728.18	721.84	719.64	734.99	743.05	748.1	692.86	749.90
Comprssion work (kJ)	309.80	300.51	285.98	286.15	288.43	294.92	288.63	311.35	280.55
Loop work (kJ)	24.16	20.12	10.42	18.32	8.48	14.64	13.84	42.97	8.55
Net work (kJ)	390.17	407.55	425.44	415.17	438.08	433.49	445.63	338.54	460.80

4. Combustion characteristics

4.1. Pressure crank angle diagram, peak pressure and rate of pressure rise

The pressure CA variation at full load is shown in Fig. 4 for the tested fuels. It was observed that pressure rise takes place early in case of the biodiesel blends. As compared to the KSOME blends, the pressure rise was earlier in case of the JME blends. Early pressure rise for the JME and KSOME blends may be due to their lower ignition delay which can be found out and will be discussed separately in section 3.2.4. Early pressure rise with JME blends in comparison to that with the KSOME blends implies relatively lesser ignition delay for the JME blends. It was also seen that more the amount of biodiesel in the blend, early is the pressure rise that occurs. Fig. 5 shows the peak cylinder pressure for the tested fuels. The peak pressure depends on the amount of fuel taking part during premixed combustion which in turn depends upon the delay period and the spray envelope of the injected fuel. Larger the ignition delay more will be the fuel accumulation, which finally results in a higher peak pressure. It was seen that the peak pressure for NRL diesel as well as the KSOME blends was almost the same at full load, the peak pressure values for KB10, KB20, KB30 and KB40 being 57.35, 57.62, 57.31 and 57.16 bar respectively, as against a peak pressure value of 57.43 bar for NRL diesel. However, the peak pressure for the JME blends were slightly less and these being 57.02, 56.98, 56.04 and 55.93 bar for JB10, JB20, JB30 and JB40 respectively. This is again due to combustion of relatively less amount of fuel during premixed phase of combustion as a result of lesser ignition delay period associated with the JME blends. The CAs at which these peak pressures occurred were 370, 370, 370, 370, 370, 369, 370, 369 and 369 degree CA for NRL diesel, KB10, JB10, KB20, JB20, KB30, JB30,

KB40 and JB40 respectively. Even though the pressure rise was occurring earlier in case of the JME and KSOME blends, but the peak values occurred almost at the same CA for these blends at full load. This may be due to lower rate of pressure rise in case of the biodiesel blends which is shown in Fig. 6. Rate of pressure rise was slightly more in case of the biodiesel blends towards the end of compression and it was more in case of the JME blends as compared to the KSOME blends. The pressure rise rate first decreased during the delay period for all the fuels and then it increased before the start of combustion (SOC) with a sharp rate of rise after SOC. However the peak of the rate of pressure rise was less and it also advanced in case of the biodiesel blends. Compared to the KSOME blends, the peak of the rate of pressure rise was less in case of the JME blends with early occurrence of the same.

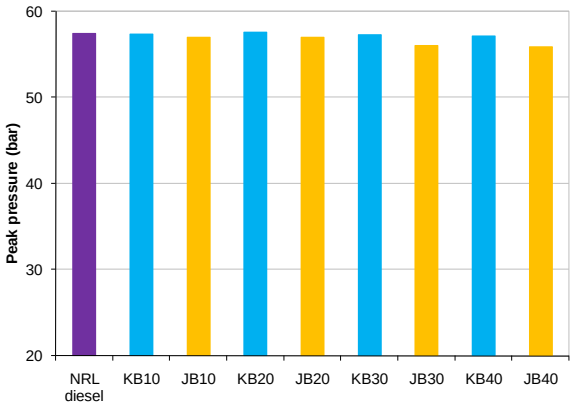

Fig. 5. Peak pressure for the tested fuels

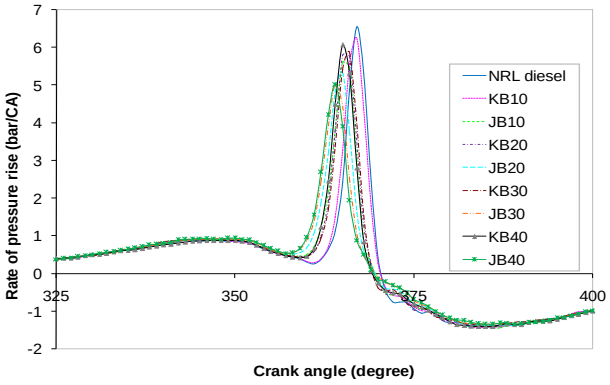

Fig. 6. Rate of pressure rise for the tested fuels

4.2. Net heat release rate

The heat release rate was calculated by first law analysis of the pressure CA data. The apparent net heat release rate which is the difference between the apparent gross heat release rate and the heat transfer rate to the walls is given by Equation (1) as given below.

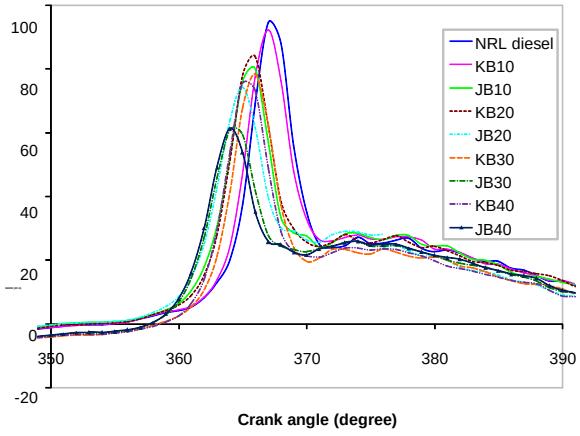
$$\frac{dQ_n}{d\theta} = \frac{\gamma}{\gamma - 1} p \frac{dV}{d\theta} + \frac{1}{\gamma - 1} V \frac{dp}{d\theta} \qquad (1)$$

An approximate range for γ (specific heat ratio) for diesel engine heat release analysis is 1.3 to 1.35. However the values of γ which will give more accurate heat release information are not well defined [7]. In the present analysis value of γ for all the fuels were taken as 1.35. Lower heat release rate was observed in case of methyl ester blends at full load as can be seen from Fig. 7. In the equation (1), it is the second term in the right hand side which mainly influences it over a w ide range of TDC and therefore the rate of heat release is directly

proportional to the rate of pressure rise. Since the pressure rise was earlier in case of the biodiesel blends and also due to the early occurrence of the peak of the rate of pressure rise which was also lower for the blends it is seen in Fig. 7 that the net heat release rate also followed the same trend. As obviously the rate of net heat release raised early in case of the JME blends as compared to that of the KSOME blends. Similarly the peak of net heat release rate was also less for the JME blends. It was also seen that the net heat release rate was higher particularly for the JME blends during the reaction controlled diffusion and late combustion phases.

4.3. Cumulative heat release

Cumulative heat release is shown in fig. 8 for the tested fuels. It was observed that cumulative heat release was more for most of the biodiesel blends towards the later part of the combustion process which means that greater amount of heat was released in case of the blends for producing a given output. This was due to greater heat release as a result of diffusion combustion in case of the blends. As the amount of fuel taking part in combustion was more in the case of the KSOME and JME blends therefore it resulted in higher amount of heat release with the biodiesel blends. This is also the reason of higher IP associated with these blends. Although the calorific value of the KSOME and JME blends was less compared to that of NRL diesel but the lower calorific value of these fuel blends were compensated by their higher fuel flow rate and hence cumulative heat release increased in case of the blends. In case of the JME blends both the fuel consumption rates and the calorific values were more compared to their KSOME counterpart. Therefore the cumulative heat release was also more for the JME blends. Slightly lower cumulative heat release in case of JB10 was due to lower heat release during later part of its diffusion combustion. Exceptionally the cumulative heat release for the blend KB40 was significantly lower towards the later part of combustion. Although the fuel consumption rate was higher but may be due to incomplete burning of this particular fuel blend together with its lower calorific value it resulted in low cylinder pressure and low rate of pressure rise during the later part of combustion. This ultimately affected the cumulative heat release. The reason for incomplete burning can be its higher viscosity due to which it led to poor atomization and ultimately resulted in lower heat release. The same can also be the reason of lower engine IP produced with this particular fuel blend.



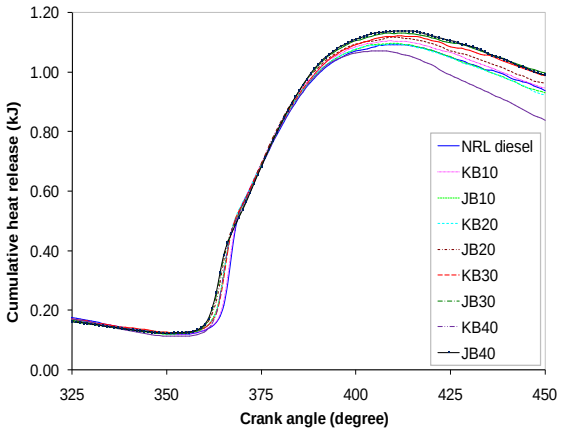


Fig.7. Net heat release rate for the tested fuels *Fig.8. Cumulative heat release for the tested fuels*

4.4. Igniton delay

Ignition delay is the time period between start of injection (SOI) and SOC. The point of SOI was determined from measurement of the fuel injection pressure profile. SOI is usually taken

as the time when the injector needle lifts off its seat. As no needle lift sensor was fitted to the injector, therefore the CA at which the fuel pressure in the fuel line reached its maximum value followed by a sudden drop in pressure, was considered as the SOI. Criterion based on $\max\left(d^2p/d\theta^2\right)$ is widely used to predict SOC [7] and was also used in the present study to determine SOC. Fig. 9 shows the ignition delay for NRL diesel and various biodiesel blends at full load. It was found that the ignition delay period for the KSOME and JME blends was less. Further, the delay period was found to be less for the JME blends compared to the KSOME blends and the prediction made in pressure CA and heat release analyses was found to be correct. Cetane index of the KSOME and JME blends were higher and therefore the ignition delays were less for the biodiesel blends. Cetane index of the JME blends were comparatively higher and hence delay periods were lower for the JME blends compared to KSOME blends. Moreover, biodiesel typically contains unsaturated fatty acids and these get oxidized when exposed to oxygen environment. May be due to presence of higher oxygen content, biodiesel blends get ignited earlier than that of diesel. Another reason could be the rapid preflame chemical reaction of the biodiesel mixed fuel with high temperature air during injection and also the thermal cracking due to which the high molecular weight ester (biodiesel) breaks down to lighter compounds and ignites earlier resulting in shorter ignition delay.

4.5. Combustion duration

Determination of combustion duration of a diesel engine is a difficult task because the total combustion process consists of phases such as rapid premixed combustion, mixing controlled combustion and the late combustion of fuel present in the fuel rich combustion products. It can be defined as the time interval from the start of heat release to the end of heat release [4]. Banapurmath et al. [8] evaluated the combustion duration considering the CA interval between the SOC and 90% cumulative heat release. They observed higher combustion duration with Honge, Jatropha and Sesame oil methyl esters which they attributed to the longer diffusion combustion phase of the esters. Rao et al. [9] however observed lower combustion duration with JME blends and it was stated to be due to early start and faster rate of combustion. In the present study the CA at which the cumulative heat release is the maximum has been considered as the end of combustion. Fig. 10 shows the combustion duration for NRL diesel and the various methyl ester blends at full engine load. It was seen that, the combustion durations of KB30 and NRL diesel were the same (47° CA duration) and it was slightly less for the other KSOME blends. Even though the amount of injected fuel was more for the KSOME blends but slightly lesser combustion duration may be due to fact that biodiesel is oxygenated in nature which helps in early completion of combustion of the blends as it was the case for KB10. But with the increase in the amount of biodiesel in the blend, combustion duration increased for KB20 and KB30 which may be due to increase in the amount of fuel injected. But again the combustion duration decreased in case of KB40, which may be due to higher viscosity of this particular blend. However for the JME blends, the combustion durations were slightly more compared to the KSOME blends and these were 46, 47, 50 and 50° CA for JB10, JB20, JB30 and JB40 respectively. Slightly higher duration of combustion particularly with respect to JB30 and JB40 could be due to earlier start of combustion and relatively longer diffusion combustion for these blends.

5. Summary and Conclusion

Compared to NRL diesel operation, the KSOME and JME blends resulted in slightly poor performance in terms of BTE and BSFC. However the IP produced with the methyl ester

blends was more except for the blend KB40. Although the fuel consumption with KB40 was higher, but may be due to higher viscosity it resulted in poor fuel atomization leading to incomplete combustion, lower heat release and hence lower IP. All the blends revealed almost similar pressure CA characteristics, however early pressure rise and lower ignition delay was observed in case of the blends. Compared to the KSOME blends, the ignition delay period and the pressure rise were early in case of the JME blends. The JME blends also showed better combustion trend with improved rate of pressure rise and heat release due its lower viscosity, increased fuel consumption and slightly higher calorific value. However, BTE values were slightly lower for the JME blends.

Abstract: Of all the alternative sources of energy for rural areas, producer gas from biomass appears to have the greatest potential. As an agricultural country, India has large supply of biomass resources. It is estimated that about 40 to 60 percent of agricultural residues are either lost or put to inefficient use. This calls for better utilization of these resources by thermo-chemically converting into producer gas in the current context of limitedness of petroleum based fuels for use in internal combustion engines. Diesel engines are widely used in Indian agricultural farms for a variety of stationary and mobile operations. The usual approach of producer gas utilization in diesel engines consists of operating existing compression ignition engines on producer gas cum diesel dual-fuel mode. There is also a lack of information on the use of different types and conditions of biomass to generate producer gas as a supplement fuel for diesel engines. Therefore, an effort was made to develop a gas producer system utilizing the locally available biomass materials to power a diesel engine that can be used on small horse power tractors and stationary machines. Experiments were conducted to study the performance of a diesel engine (four stroke, single cylinder, 5.25 kW) with respect to its thermal efficiency, specific fuel consumption and diesel substitution by use of diesel alone and producer gas-cum-diesel (dual fuel mode) through a downdraft gasifier. Performance of the engine was studied by keeping biomass moisture contents as 8%, 12%, 16%, and 21%, engine speed as 1600 rpm and with variable engine loads. The gas producer system developed for a 5.25 kW diesel engine was found to perform satisfactorily by using three types of biomass such as wood chips, pigeon pea stalks and corn cobs. The average value of thermal efficiency on dual fuel mode was found slightly lower than that of diesel mode. The specific diesel consumption was found to be 60 to 64 % less in dual fuel mode than that in diesel mode for same amount of energy output. The average diesel substitution of 64% was observed with pigeon pea stalks followed by corn cobs (63%) and wood chips (62%). Based on the performance studied, the producer gas may be used as a substitute or as a supplementary fuel for diesel conservation, particularly for stationary engines in agricultural operations in the farm.

Keywords: *Biomass gasification, Producer gas, Downdraft gasifier, Diesel engine.*

1. Introduction

The escalating oil prices and scarcity of fuel oils coupled with exploding population have resulted in serious energy crisis. There is thus a pressing need to develop technology for utilizing the renewable energy sources that can make significant contribution to the economy and the well being of the rural people.

Of all the alternative sources of energy for rural areas, producer gas from biomass appears to have the greatest potential. As an agricultural country, India has large supply of biomass resources. It is estimated that about 40 to 60 percent of agricultural residues are either lost or put to inefficient use. This calls for better utilization of these resources by thermo-chemically converting into producer gas in the current context of limitedness of petroleum based fuels for use in internal combustion engines. Producer gas is generated from solid carbonaceous fuels such as wood, charcoal, coal, agricultural and forest residues and also animal wastes by gasification process (Hindsgaul C et.al., 2000, Dogru M. et.al., 2000, Bhattacharya S.C. et.al., 2001, G. Sridhar et.al., 2001, Das and Pandey, 1993 and Pathak and Jain, 2004). Gasification is an irreversible thermo-chemical process by which feed stock is thermally decomposed and the end products are principally in gaseous form, the main combustible components being carbon monoxide and hydrogen. The main advantages of gases as a fuel over liquid or solid

fuels are that (i) gases burns with higher efficiency than the solid or liquid fuels, (ii) they have a higher rate of heat release (iii) the rate of energy output is easily controlled and adjustable, and (iv) gaseous fuels with good energy utilization can be used for power sources. A good quality producer gas has an energy content of about 5200 kJ/Nm^3. A gas producer requires 2.5 to 3 kg of wood to generate about the same energy as 1 liter of diesel (Tiwari and Ghosal, 2007).

Diesel engines are widely used in Indian agricultural farms for a variety of stationary and mobile operations. The usual approach of producer gas utilization in diesel engines consists of operating existing compression ignition engines on producer gas cum diesel dual-fuel mode. The thermal efficiency of gasifiers in which producer gas is produced has been found to be 70-80 per cent and that of the gasifier-engine system to be 16-20 percent (Tiwari and Ghosal, 2007). The problem is more acute and serious in nature when producer gas is used to run motor vehicles particularly for agricultural operations. Past studies indicate that a very little effort has been made in this direction. There is also a lack of information on the use of different types and conditions of biomass to generate producer gas as a supplement fuel for diesel engines. Therefore an effort was made to develop a gas producer system utilizing the locally available raw materials to power a 5.25 kW (7 hp), single cylinder diesel engine that can be used on small horse power tractors, known as power tillers. The major objectives in this study were as follows:

(i) To fabricate the different components of a gas producer system to operate a 5.25 kW (7 hp) diesel engine.
(ii) To evaluate the performance of the above engine with respect to thermal efficiency, specific diesel consumption and diesel substitution by using different types of biomass.

2. Fabrication of gas producer system

A gas producer system consisting of a gasifier, a cooler cum cleaner unit, a filtration unit and a mixing device was designed and fabricated to operate a 5.25 kW diesel engine on dual fuel mode (Fig.1). A downdraft type gasifier operating under suction induced flow was designed for a maximum engine gas requirement of 10.70 Nm^3/h taking a maximum hearth load of 0.9 Nm^3/cm^2-h. The upper part of the gasifier was the fuel container and the lower part was the hearth with ash pit. The hearth section of the gasifier was V-shaped.

The primary air intake was through a pipe extended from top to the hearth with a provision to adjust the air inlet height. The ignition tube was passed through the hearth which was closed during gasification and opened only while starting to introduce fire. Ash pit was covered with a metal filter known as grate through which ash and soot particles were collected. A hand blower was attached to the gasifier for initial charging. The cooler-cum-cleaner unit consisted of a radiator to radiate heat from hot water, a venturi to provide sufficient space for cooling the gas and a water tank. The other attachments to the cooling system were a fan driven by a 0.375 kW motor to lift water from the tank to the radiator. A two stage filtering unit was developed to filter the dust and soot particles. The first stage consisted of gravel, charcoal, coconut coir and cotton layers each of 15 cm thickness where as the second stage consisted of only two layers of cotton each of 15 cm thickness. Both the filtering units were packed in different boxes.

3. Methodology

A single-cylinder 4-stroke 5.25 kW diesel engine of a commercial power tiller was used for the experiment. The intake manifold of the engine was modified using a T-section to introduce the mixture of air and gas into the engine during suction stroke. The quantities of gas and air flowing to the engine were measured separately with the help of two venturi sections provided in the T-section. The U-tube manometers were connected to the venturi section with polythene tube to measure the pressure drop across them. The original fuel supply of the engine from its fuel tank was cut-off for the operation on dual fuel mode and the diesel fuel was supplied from an auxiliary tank provided with a fuel measuring set-up. In order to measure the load applied to the engine, a prony brake dynamometer was used. A strain gauge transducer was used to measure the temperatures of oxidation and reduction zones in the gasifier and the exit gas from the gasifier and the filtration unit.

3.1. Performance evaluation of engine

The diesel engine (specifications given in Table-1) was tested on diesel as well as on dual fuel mode at the engine speed 1600 r/min and six loads (7.5N, 12.5N, 20N, 30N, 40N and 50N). The composition of the gas was also studied (CO=22.8%; CO_2= 7.2%; O_2=0.5% and other gases= 69.50%). For dual fuel operation, the types of biomass used were wood chips, pigeon pea stalks and corn cobs. Three materials were used at four different moisture contents (8, 12, 16 and 21 percent on wet basis). Each test was conducted for a period of 5 minutes with two replications. During each test on diesel, the engine load, engine speed and fuel consumption were measured. The observed data were utilized to calculate the engine thermal efficiency, specific diesel consumption and percent diesel substitution. The performance of a diesel engine operated on dual-fuel mode was generally evaluated in terms of specific diesel consumption, engine thermal efficiency and per cent diesel substitution. These parameters were determined as follows,

a) Specific diesel consumption (SCD) : SDC is given by

$$\text{SDC} = \frac{3600 v_d \rho_d}{1000 t\ p} = 3.6 \frac{v_d \rho_d}{t\ p} \quad (1)$$

where SDC = specific diesel consumption, g $kW^{-1}h^{-1}$; v_d = volume of diesel consumed, cm^3, ρ_d = specific weight of diesel, kg/l; t = time required to consume v_d in second; and p = engine power, kw.

b) Thermal efficiency: The thermal efficiency is expressed as the ratio of output power to the power supplied by the fuel.

i) Thermal efficiency of engine on diesel alone: Thermal efficiency of engine on diesel alone is given by

$$\eta_t = \frac{\text{Brake power}}{\text{Power input from fuel}} \quad (2)$$

The power input from fuel in eqn. (2) is given by

$$p_f = \frac{cv_d \times \rho_d \times f_c}{3600} \quad (3)$$

Where p_f = Power input from fuel, kW; cv_d = calorific value of diesel = 39 MJ/kg ρ_d = densityof diesel = 640 kg/m^3; and f_c = fuel consumed, cm^3/h. Substituting the values of cv_d and ρ_d, the eqn (3) yields

$$\text{P}_\text{f} = \frac{39 \times 840 \times \text{f}_\text{c}}{3600} = 9.1\ f_c \quad (4)$$

Using eqn (4.), eqn (2) gives

$$\eta_t = \frac{\textit{Brake}\ \text{power}}{9.1 f_c} \quad (5)$$

ii)Thermal efficiency of engine on dual fuel mode

The formula used for calculating the thermal efficiency of engine on dual fuel mode is given by

$$\eta_t = \frac{\text{Brake power}}{\text{Power input from pilot diesel} + \text{power input from gas}} \quad (6)$$

Power input from producer gas is given by

$$p_g = \frac{CV_g \times g_c}{3.6} \quad (7)$$

where p_g = power from producer gas, kW; cv_g = calorific value of producer gas, KJ/Nm^3; and g_c = gas consumption, Nm^3/h. Substituting eqns. (5) and (7) in eqn. (6),

$$\eta_t = \frac{\textit{Brake}\ \text{power}}{9.1 f_c + \frac{CV_g \times g_c}{3.6}} \quad (8)$$

iii) Diesel substitution: The per cent diesel substitution is given by

$$ds = \frac{D_d - D_{dg}}{D_d} \times 100 \qquad (9)$$

Where ds = diesel substitution, per cent; D_d = diesel consumption by the engine on diesel alone, cm^3/h; and D_{dg} = diesel consumption by the engine on dual fuel mode, cm^3/h.

Table-1 Specifications of gas producer engine system under test

I. Engine		
(a)	Type	4-stroke cycle diesel engine
(b)	Number of cylinder	1
(c)	Cylinder capacity (cc)	450
(d)	Bore (mm)	80
(e)	Stroke (mm)	90
(f)	Crank shaft speed (rated), r/min	2200
(g)	Rated capacity (kW)	5.25
(h)	Grade of oil	SAE 30
(i)	Fuel	High speed diesel
(j)	Cooling system	Water-cooled
II. Gasifier		
(a)	Type	Moving bed, co-current Down draft
(b)	Material of construction	Mild steel
(c)	Hearth opening (mm)	60
(d)	Grate mesh size (mm)	10
(e)	Total weight (kg)	37

4. Results and discussion

The relationship between engine load and thermal efficiency at the four levels of moisture content (8%, 12%, 16% and 21%) for the different types of biomass (wood chips, pigeon pea stalks, corn cobs) is shown in Figs. 2 , 3 and 4 at engine speed of 1600 r/min. The trend shows that the thermal efficiency increased with a decreasing rate with increase in engine load for all the biomass fuels at all the biomass moisture levels tested. This may be due to better combustion of relatively rich gas-air mixture at higher loads. It is also observed that with increase in biomass moisture from 8 to 21 per cent, the thermal efficiency also increased marginally from 28 to 31 per cent with wood chips, 30 to 32 per cent with pigeon pea stalks and 29 to 32 per cent with corn cobs. The slight increase in thermal efficiency from 8 to 21 per cent moisture range might have been caused due to better combustion of premixed mixture of gas and air on dual-fuel mode resulting in reduced requirement of total energy input at different loads.

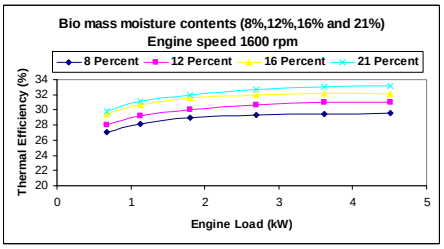

Fig. 2 Variation of thermal efficiency with engine load on dual fuel mode at different moisture contents of wood chips

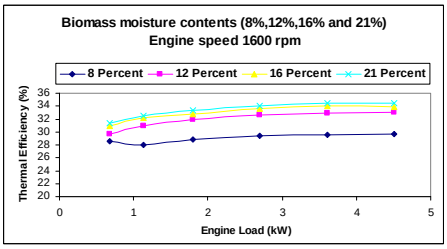

Fig. 3 Variation of thermal efficiency with engine load on dual fuel mode at different moisture contents of pigeon pea stalks

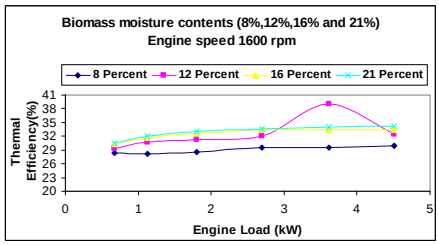

Fig. 4. Variation of thermal efficiency with engine load on dual fuel mode at different moisture contents of corn cobs

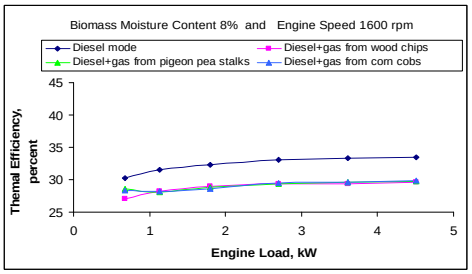

Fig. 5 Effect of engine load on thermal efficiency with different types of fuel

The effect of different types of fuel on engine thermal efficiency at 1600 r/min is shown in Fig. 5. The trend showed that there was a slight drop in thermal efficiency of engine on dual-fuel mode, compared to that on diesel alone. Based on mean values, it may be reported that the thermal efficiency of diesel engine when tested, dropped from 32.3 per cent on diesel fuel mode to 30.5 per cent on dual-fuel mode using wood chips. However, the efficiency of engine on dual-fuel mode using pigeon pea stalks and corn cobs was found almost at par with that on diesel mode. This showed that the combustion of air-gas mixture while using pigeon pea stalks and corn cobs was better compared to wood chips, even though the energy content of wood chips was relatively high. The variation of specific diesel consumption and diesel substitution with engine load on dual-fuel mode of a diesel engine at different biomass moisture levels has been shown in Figs. 6 through 11. The trend of the curves showed that the specific diesel consumption, in general, decreased with increase in engine load at different moisture levels for all the three types of biomass used. However, a definite trend of variation of diesel substitution with engine load has not been established. It has shown increasing trend with load in most of the cases, whereas in a few cases a decreasing pattern has also been observed. This kind of trend is not uncommon in the existing literatures. It is usually reported that if the energy content of the gas remains relatively stable, a higher load means a higher consumption of diesel fuel and thus a lower percentage of diesel fuel displacement. But if the quality of the gas in terms of its energy content is not stable, an increase in load can also increase the percentage of diesel fuel substitution. The decrease in specific diesel consumption with load is primarily due to increase in diesel fuel consumption at a decreasing rate. From the mean values of specific diesel consumption and diesel substitution in the test engine at different operational parameters (taking all loads into consideration), it was observed that the specific diesel consumption of engine on dual-fuel mode using wood chips decreased from 87.9 g/kWh at 8 per cent moisture level to 75.9 g/kWh at 12 per cent moisture level beyond which it again increased and rose to 161.8 g/kWh at a biomass moisture level of 21 per cent. The diesel substitution on the other hand, varied from 50.5 to 68.8 per cent in the same moisture range showing maximum value of 72.3 per cent at a moisture level of 12 per cent. Similar trends of variation of specific diesel consumption and diesel substitution were also noticed in case of the other two biomass fuels. For the sake of comparison, the minimum values of specific diesel consumption using pigeon pea stalks and corn cobs were observed to be 82 and 87 g/kWh respectively, whereas the maximum values of diesel substitution for these fuels was found to be about 71.3 per cent at a moisture level of 12 per cent. This showed that the minimum values of specific diesel consumption were derived at a particular biomass moisture level (12 per cent) where diesel substitution was maximum. This was perhaps due to better quality of gas obtained at this moisture level as reflected by its higher CO content resulting in better combustion of air gas mixture. The variation of specific diesel consumption with engine load for the test engine on diesel mode as well as on dual-fuel mode using different types of biomass is shown in Fig. 12 for a particular set of operating

parameters. The data indicated a slight decrease in specific diesel consumption with engine load both on diesel as well as on dual fuel operations. As expected, the specific diesel consumption on diesel mode is much higher than that on dual-fuel mode for all the engine loads tested. Comparing the performance of engine on the basis of the mean values of specific diesel consumption, it was observed that the engine consumed 60 to 64 per cent less diesel on dual-fuel mode than that on diesel mode for the same amount of energy output. The effect of engine load on per cent diesel substitution for different types of biomass is shown in Fig. 13. The trend showed increasing pattern of diesel substitution with engine load as explained earlier. Based on the mean values of diesel substitution, it can be pointed out that the average diesel substitution of 64 per cent was found with pigeon pea stalks followed by corn cobs (63 per cent) and wood chips (62 per cent) throughout the range of biomass moisture. From the results discussed above, it can be stated that the gasifier system developed for 5.25 kW diesel engine has indicated satisfactory performance by showing, on an average 60 to 65 percent saving in diesel consumption while utilizing three types of locally available biomass fuels.

5. Conclusions

Based on the studies conducted, the following conclusions may be drawn.

(i) The gas producer system designed and developed for a 5.25 kW diesel engine was found to perform satisfactorily by using different types of biomass such as wood chips, pigeon pea stalks and corn cobs.

(ii) The average value of thermal efficiency of engine was found to drop slightly from 32.3 percent on diesel mode to 28.7 percent on dual fuel mode using wood chips as biomass fuel. However the efficiency found on dual fuel mode with pigeon pea stalks and corn cobs was comparable to that on diesel mode.

(iii) The mean values of specific diesel consumption of engine on dual-fuel mode for all the three biomass fuels were less compared to diesel mode and their diesel substitution was more.

(iv) The average diesel substitution in a 5.25 kW diesel engine was found in the range of 62 to 64 percent using three types of biomass fuels.

The above findings presented in this paper would provide useful information to all those engaged in design, manufacture and use of gasifier system for satisfactory and mobile operation of stationary engine used in agricultural purposes.

Abstract: A comparative study has been carried out on the performance of compression ignition engine (CI) using common diesel fuel (CDF) blended with both refined soybean (Glycin max) and sunflower (Helianthus annus) oil as straight vegetable oil (SVO) as well as their corresponding fatty acid methyl esters (FAME) with respect to CDF. Low cost methyl esters of vegetable oil were prepared using own patented technique where ultrasonic energy has been found to be beneficial. SVOs and corresponding FAMEs were blended with CDF separately at different proportion to act as fuel for research CI engine. Both engine performance and fuel combustion characteristics were evaluated from the present study at different loads with varying compression ratios. Graphical relationships of load (kg) in engine against various engine performance parameters such as: brake thermal efficiency (%), brake specific fuel consumption ((kg/kWh), brake mean effective pressure (bar), cumulative heat release (kJ) and emission characteristics have been plotted for each set of fuels with respect to CDF. The relationship developed identifies the advantages of using blended FAME prepared with the patented processes over their corresponding SVO and CDF in the CI engine.

Keywords: *CI engine, Straight vegetable oil, FAME, Blended fuel, CDF*

1. Introduction

The Energy and Environment will determine the fate of mankind in this century. The alarming rise of energy demand in the growing civilization is mainly met by fast depleting fossil fuel. The transport sector is the highest consumer of fossil fuel as common diesel fuel (CDF) requiring more than 29 per cent of its total consumption. Due to its high sulphur, aromatics and nitrogen content the CDF is considered to be the single largest polluter of the environment. As the agro based vegetable oil is carbon neutral of renewable energy source and free of sulphur as well as aromatics, it behaves environmental friendly biofuel. However, the straight vegetable oil (SVO) fails to act as ideal fuel primarily because of its high viscosity and poor atomization in fuel spray for its low volatility. It often leads to deposit and chocking of injector, combustion chamber and valves [1]. These hurdles are reduced to minimum by subjecting the vegetable oil mainly to the process of dispersion or Transesterification. Dispersion of SVO with common diesel fuel, also called blending is to provide a simple as well as cheap fuel for the CI engine.

1.1. Transesterification of vegetable oil and animal fats

Chemically, vegetable oil and animal fat are triglycerides in which one glycerol molecule is esterified with three molecules of different long chain fatty acids [2] each with 15-20 carbon numbers raising its average molecular mass over 800amu. This reason might be responsible to inherit high kinematic viscosity and lowers vapour pressure. The process adopted to transfer one heavier ester to three lighter esters (esters of three different fatty acids with lower aliphatic alcohols) is called Transesterification reaction. Combination of these different

FAME molecules with viscosity and carbon equivalent to CDF is able to replace fossil fuel as ideal fuel for CI engine, popularly called Biodiesel [3].

1.2. Fuel for the performance of Unmodified Compression Ignition Engine:

CDF is a mixture of hydrocarbon molecules with varying carbon chain of C_6-C_{18}. The presence of smaller hydrocarbon chains with their high vapour pressure contributes to lower flash point of CDF to below 60^0C which is ideal to start ignition under common compression. While FAME of particular fatty acid (biodiesel), a compound of fixed carbon number 15-18 acquires very low volatility is contributing high flash point (>130^0C) thus fails to get atomized in unmodified CI engine for early ignition. The hurdle is minimized by blending the biodiesel with CDF. A system known as the "B" factor is generally used to state the amount of biodiesel in CDF fuel mixture such as: 100% biodiesel is referred to as B100, while 20% biodiesel when mixed with 80% CDF is labeled B20 and so on. Obviously, the higher the percentage of biodiesel, the more eco-friendly is the fuel. Blended fuel up to B20 has successfully used in unmodified engines [4-7].

The aim of the article is to evaluate the acceptability of biodiesel prepared at reduced parameters by employing ultrasonication at various steps of the composite process such as the purification of crude vegetable oil, transesterification, separation of FAME from the reaction mixture and purification of crude FAME to make ASTM standard. An unmodified CI engine setup with variable compression ratio is adopted to study the engine performance and combustion of fuel for different fuel and evaluate brake power (kW), brake thermal efficiency (%), brake specific fuel consumption (kJ/kW-hr), brake mean effective pressure (bar), of engine against various engine loads (especially lower loads). A comparative statement would be prepared for each set of four combinations of SVO-CDF, their corresponding FAME-CDF in different ration against CDF to find out the most acceptable fuel for the CI engine.

2. Methodology

2.1. Materials

Refined Soybean oil of Nature fresh (India) and refined sunflower oil of Fortune brand (India) are collected from retail outlets and analysed to evaluate the free fatty acid (FFA), phospholipids and moisture content following ASTM 6751 method. Refined varieties of soybean oil and sunflower oil were found to contain such impurities within permissible limit to prepare biodiesel. Fatty acid methyl esters (FAME) of refined soybean oil and sunflower oils were prepared following in house patented process [8]. CDF collected found to have the acceptable range of fuel specification for CI engine [9]. Low energetic (1kW) Ultrasonic Processor Sonapros PR-1000 model (M/s Oscar Pvt. Ltd., Mumbai, India) was used for transesterification at various steps of the composite process.

2.2. Preparation of fuels for the comparative studies

Four sets each of both soybean oil and sunflower oil were prepared by blending 5% and 10% of the two SVOs and their corresponding FAMEs with rest quantity of common diesel fuel (CDF). Samples of soybean and sunflower oil blends (as shown in ***Table 1***) were taken to evaluate the fuel properties in CI engine and make a comparative study with 100% CDF. Physical properties of this fuel were measured following ASTM 6751 method. Results within a range for both the fuels were reported in ***Table 2***.

Table 1. Set of fuels for the comparative study in CI engine

Vegetable oil	CDF %	Percentage of SVO in blended common diesel fuel		Percentage of FAME in blended common diesel fuel	
		05% SVO	10% SVO	05% FAME	10% FAME
Soybean oil	100	SVO SB B05	SVO SB B10	FAME SB B05	FAME SB B10
Sunflower oil	100	SVO SF B05	SVO SF B10	FAME SF B05	FAME SF B10

Table 2. Physical properties for Common Diesel Fuel (CDF), SVOs (soybean and sunflower oil) and corresponding methyl esters (Biodiesel)

Sl. No.	Properties of Fuel	CDF	Vegetable oil	Biodiesel
01	Kinematic Viscosity(cSt) at 40^0 C	2.5-5.5	35-65	5-8
02	Gross caloric value (kJ/kg)	42000	39,000-48,000	30000-39477
03	Density at 20^0 C, kg/m^3	0.835	0.825-0.894	0.865-0.877
04	Flash Point (^{0} C)	38	>200	130-175
05	Cetane Number	45	40-50	40-58

A Research engine, make Kirloskar type, 1 cylinder, 4 strokes diesel, water cooled with variable compression ratio (VCR) of M/s Apex Innovation Pvt. Ltd., Sangril, Maharashtra, India was procured to study the CI engine performance. The engine is of constant speed (1500 rpm) type having maximum load 12kg with a capacity of 661.1cm^3. The engine performance with various sets of fuels (shown in Table 1) was studied at lower loads of 2, 4, 6 and 8 kg under different compression ratios (16, 17 &18). The data acquisition system was used to create pressure-crank angle plot for both diesel and cylinder pressure. Also the pressure-volume plot was obtained to study the power generated by the engine at various compression ratios. Brake Specific Fuel Consumption and Brake Thermal Efficiency were obtained from load and fuel consumed etc. The engine Brake Power was measured by Eddy current dynamometer. Air inlet flow was measured using pressure transmitter and water flow by rotameter. Exhaust emission analysis was done with a multi gas analyser, M/s Netel (India) Ltd. under varying operating conditions.

3. Results and Discussion

3.1. Brake Specific Fuel Consumption (BSFC) of Soybean and Sunflower oil

Results on BSFC (i.e. the ratio of fuel mass flow of an engine to its output power) for all four sets of both soybean and sunflower fuel blends and CDF with engine loads of 2 to 8 kg against each compression ratio (16-18) are drawn but only CR 18 is shown in ***Fig. 1*** and ***Fig. 2*** respectively. It is observed that the BSFC(kg/kWh) is highest for B05 of both FAMEs when the engine load is only 2kg and CR 16, which further decreases linearly at higher CRs (17 and 18). BSFC for all fuels decrease uniformly when engine load increases to 8 kg because combustion improves due to increases in pressure and temperature.

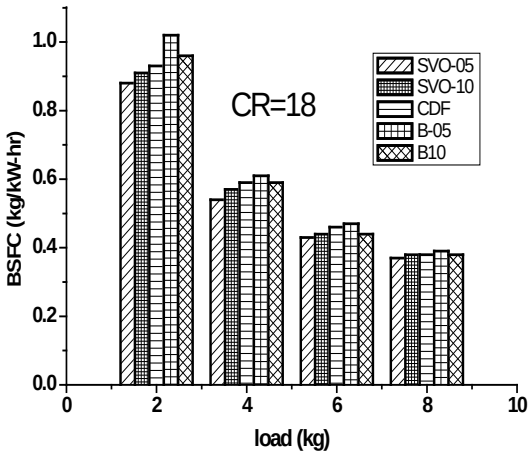

Fig.1. BSFC (kg/kWh) vs variable engine loads (kg) plot at CR-18 for four fuel blends of soybean oil and CDF

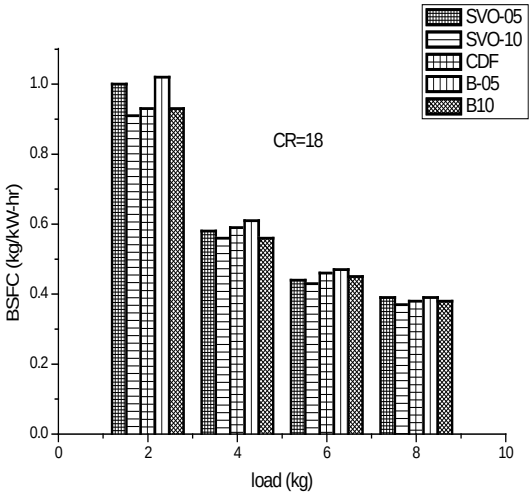

Fig. 2. BSFC (kg/kWh) vs variable engine loads (kg) plot at CR-18 for four fuel blends of sunflower oil and CDF

On comparing the results of ***Fig. 1*** (soybean oil) with ***Fig. 2*** (sunflower oil) it is observed that BSFC values for both fuel sets are almost identical at engine load 8 kg. Values for B10 of both fuel blends are less than that of B05 but almost equal to CDF. With low gross calorific values of biodiesel, it is expected to have high BSFC for the B10 blended fuel. The presence of easily combustible linoleic and oleic acids with unconjugated and unsaturated fatty acids in respective FAME probably balanced such negative effect.

3.2. Brake mean effective pressure for soybean oil and sunflower oil

Brake mean effective power (BMEP) is the measure of the useful power output of the engine and may be represented by the equation (1).

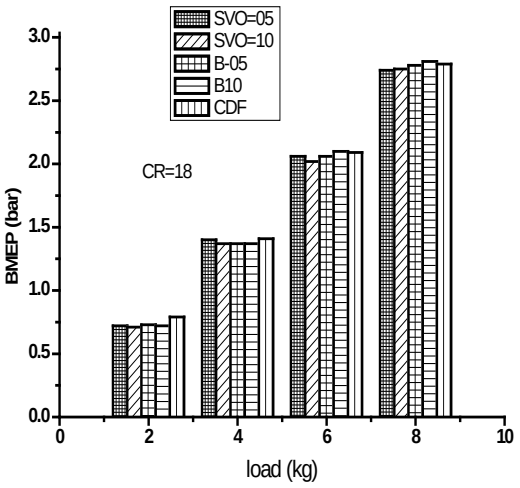

Fig. 3. BMEP (bar) vs variable engine load s(kg) plot at CR-18 for four fuel blends of soybean oil and CDF

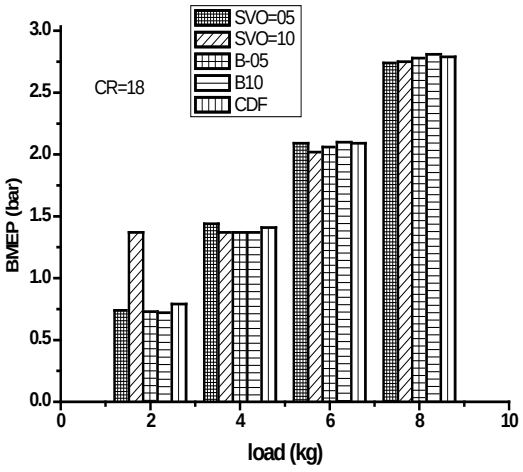

Fig. 4. BMEP (bar) vs variable engine loads (kg) at CR-18 plot at CR-18 for four fuel blends of sunflower oil and CDF

$$BMEP = 2\pi T n_C / V_d \quad (1)$$

where T = torque(Nm), n_c = number of revolution per cycle and for 4 stroke engine it is 2, and V_d = displacement in volume.

Experimental results of brake mean effective pressure for each fuel of soybean set are drawn against engine load of 2-8 kg for each CR values of 16-18. The power outputs for all fuels are increasing with rise of engine load but shows same trend for all compression ratios. The BMEP comparison plots with respect to CDF at CR 18 for soybean and sunflower fuel blends are shown in ***Fig. 3*** & ***4*** respectively. BMEP is found to be much high for B10 of both soybean-FAME and sunflower-FAME at compression ratio 18 with 8 kg engine load.

3.3. Brake thermal efficiency

The variation of brake thermal efficiency with engine load of 2-8 kg at compression ratio 18 for both soybean and sunflower fuel sets are presented in ***Fig. 5*** and ***6*** respectively. It increases with increase in load under all compression ratios for both the fuel systems along with that of CDF. This may be due to the reduction in heat loss and increase in power with increase in load. The brake thermal efficiency for B05 and B10 for both fuel systems are less than that of CDF. This lower brake thermal efficiency obtained could be attributed to lower GCV values of biofuels. Hence it may be concluded that the performance of the unmodified CI engine with biodiesel prepared [10] with less operating parameter is comparable with conventional common diesel fuel.

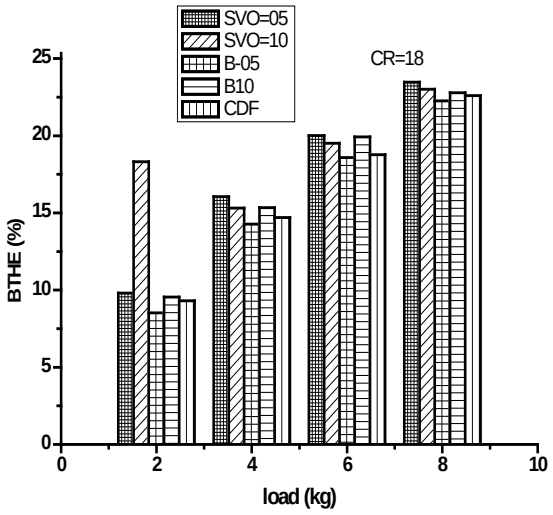

Fig. 5. BTHE (%) vs va riable engine loads (kg) plot at CR-18 for four fuel blends of soybean oil and CDF

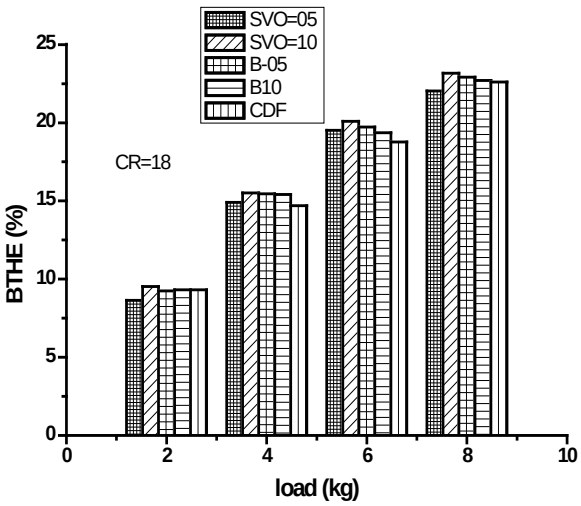

Fig. 6. BTHE (%) vs va riable engine loads (kg) plot at CR-18 for four fuel blends of sunflower oil and CDF

3.4. Brake power

The power output for all fuels increase with rise of engine load but shows same trend for all compression ratio at higher loads. ***Fig. 7*** shows FAMEs give slightly better power with respect to SVOs.

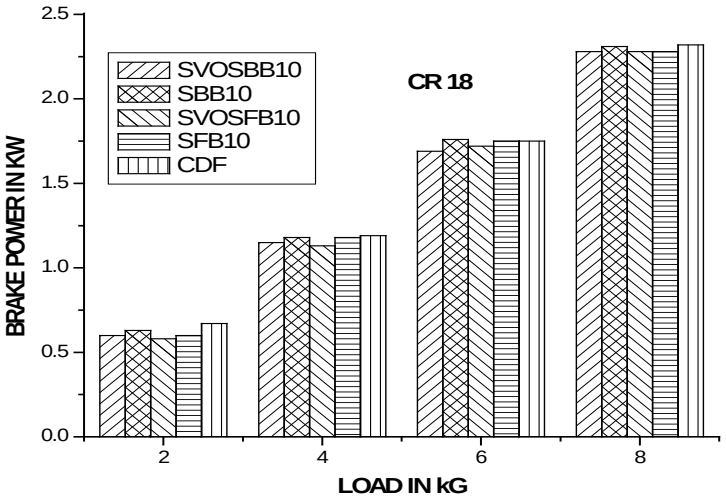

Fig.7. Brake power (kW) vs various engine loads (kg) plot at CR-18 for SVO and FAME (Biodiesel 10) fuel blends of soybean and sunflower oil with respect to CDF

3.5. Cumulative Heat Release

From ***Fig. 8*** it is clear that heat release of CDF is more than soybean SB B10 and slightly lower than sunflower SF B10 since biodiesels have less calorific value whereas out of these two biodiesels sunflower derivative is easily combustible than that of soybean.

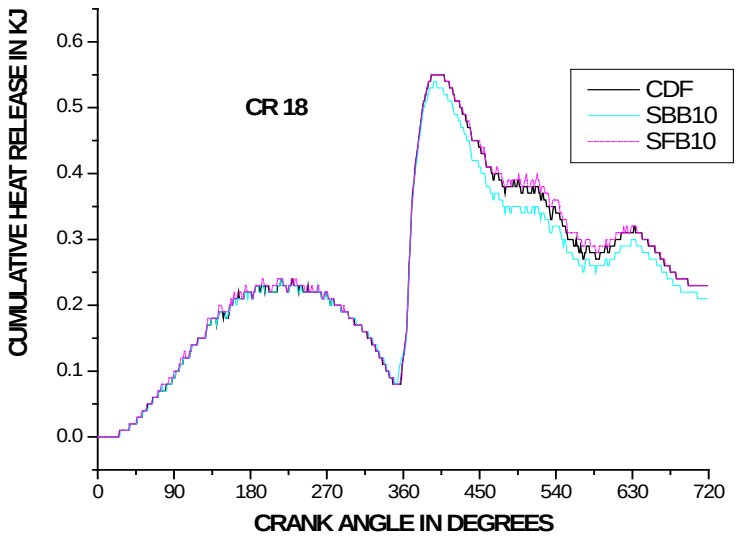

Fig.8. Cumulative heat Release (kJ) vs Crank angle (degrees) at 8kg engine load with CR-18 for CDF, soybean B10 and Sunflower B10

3.6. Exhaust emission characteristics

Exhaust emission profile for Common Diesel Fuel (CDF), and methyl esters (Biodiesel) of soybean and sunflower (B10) at CR 18 were studied and the results are given in Table 3. Combustion efficiency of these fuels under study increases with rise in engine load. It is seen that the combustion efficiency of B10 of both soybean and sunflower FAME are much better than that of CDF. SB B10 FAME is found to be more efficient fuel than SF B10. However, NO_x emission increases at higher loads due to rise in temperature in the compressor.

Table 3. Exhaust emission characteristics for Common Diesel Fuel (CDF), and methyl esters (Biodiesel) of soybean and sunflower (B10) at CR 18

Engine Load (kg)	CDF			Soybean (SB B10)			Sunflower (SF B10)		
	% CO_2	% O_2	NO_X (ppm)	% CO_2	% O_2	NO_X (ppm)	% CO_2	% O_2	NO_X (ppm)
2	1.7	18.2	72	2.9	16.1	144	2.4	17.2	106
4	2.0	17.5	116	3.5	15.6	235	2.8	16.6	162
6	2.6	16.8	161	3.9	15.0	290	3.1	16.1	226
8	2.9	16.2	208	4.6	14.0	321	3.4	15.7	269

4. Conclusion

The fatty acid methyl esters prepared from soybean and sunflower oil with own patented composite process employing ultrasonication has been successfully tested in unmodified compression ignition engine. Amongst various engine performance data evaluated, the BSFC parameters although suggest biofuel to be inefficient than CDF, however, considering the exhaust emission factor biofuel is acceptable. SVOs possess better performance, but taking the viscocity into account FAMEs look better fuel from the present study. From BMEP studies biofuels show better performance than CDF. With reference to the studies on BTHE, brake power and emission characteristics B10 soybean-FAME fuel is most acceptable fuel amongst the all studied nine fuels including CDF for the CI engine with lower load up to 8 kg at compression ratio 18. Hence it may be recommended as renewable fuel and prominent replacement for CDF in unmodified compression ignition engine.

Abstract: Diesel engines are major contributors of air pollution by its exhaust gasses such as particular matter, carbon oxides, oxides of nitrogen, and sulfur compounds. Also, the diesel as a fossil fuel is threatened to decay with depletion of its sources. Hydrogen as a renewal energy and promising fuel might use to solve that troubles and crisis. A multi cylinder, natural aspiration, four stroke, compression ignition, and water cooled engine is tested under hydrogen diesel different blends and at different operating conditions. A hydrogen induction set up is built in the lab with all of the acquitting sensors and measuring instruments. The safety rules are considered. A continuous hydrogen induction in the inlet manifold is selected technique for this investigation. Experimental tests are done to investigate engine thermal performance and exhaust emission constituents under those blends circumstances. The optimum operating conditions and optimum parameters for those blends are found. The investigation led to find that, the optimum rate of hydrogen induction is 7.5 lpm. This optimum rate reduced the diesel fuel consumption by 20 % and increased the brake thermal efficiency by about 8-9%. The NO_X emission is reduced.

1. Introduction

Since 1878 to this day, diesel engine played the role of one primary source of power in human life. Many life sectors are depended on diesel engine such as agriculture and transportation. Diesel engine possesses a high reliability and durability with reasonable fuel consumption. Unfortunately, diesel engine is the main contributor to world's pollution. It has smoke and NO_X as major exhaust emissions. Numerous research efforts are concentrated on finding solutions to this problem. In 1970, the energy crisis ignited the competitions and research to find new energy sources or renewable energies. For both challenges, save our environment and save the energy sources, hydrogen is found as a promising solution. Hydrogen is nearly ideally suited as energy carrier because of its physical and chemical properties. It can be produced from water and conversely, on combustion forms water again in a closed cycle with very low formation of NO_X. It seems that the improvement in the engine performance under steady conditions is mainly attributed to the contribution of the hydrogen properties to the combustion process. The use of hydrogen with diesel engine might supplement wholly or partially without substantial hardware modification in arrangement of diesel engine [1]. The replacement of diesel by hydrogen totally needs high compression ratio above 29 along with a drop in the engine power and efficiency. Duel fuel mode or hydrogen diesel blends are more preferable [2]. The idea of using hot diesel drops as an igniter to air- hydrogen blend is applied. Many techniques have been studied and tested to inject or induct the hydrogen in air manifold or air intake passage. Carburetions, timing intake injection and induction, continuous injection or induction are the techniques mostly used [3].

Each technique has advantage and disadvantage. However, indirect injection or induction techniques pose no requirement of high compression ratio to run the engine under hydrogen-diesel blend. Verhelst at el. [4] used air port injection method to investigate the hydrogen effect on SI engine which might apply in diesel engine as well. Masood et al [5, 6] investigated direct injection and in port induction with modeling to those blends. Saravanan et

al. [7-10] investigated different techniques in the hydrogen injection and induction with recycling to exhaust gas and tested the timing and duration of hydrogen injection.

In this paper, a continuous induction of hydrogen in the air inlet manifold of a multi cylinder, compression ignition engine is adopted to investigate engine performance and exhaust gas emission constituents experimentally under different hydrogen induction rates and loads.

2. Experimental set-up

The experimental set up used for the present investigation consists of a four cylinder, four stroke, water cooled, indirect injection, naturally aspirated, and compression ignition engine developing a rated maximum power of 37 hp or 26.7 kW and running at varied speed equipped with a hydrogen induction system and an eddy current dynamometer with variable loading arrangement. The eddy current dynamometer gives the value of load in terms of Amp. only. The engine is coupled directly to the dynamometer and is mounted on a test bed with suitable connections for lubricating and cooling systems. The specification of the engine used for the study is given in Table 1.

Fig. 1 illustrates the schematic of the set up. Hydrogen induction system consists of high pressure hydrogen gas cylinder at 14.6 bar pressure, regulating valves, fine valve and digital mass flow meter to measure hydrogen flow rate. Nitrogen gas cylinder, flame arrestor, flame trap, non-return valve are used as a protection devices. PT 100 thermometer type is used to measure the exhaust temperature. Diesel weight flow rate is measured using strain gauge. Air surge tank with vertical water manometer is used to measure air pressure difference and to calculate the airflow rate in inlet manifold pipe. While a non contact tachometer is used to measure the engine speed. All the instruments are calibrated against traceable standards.

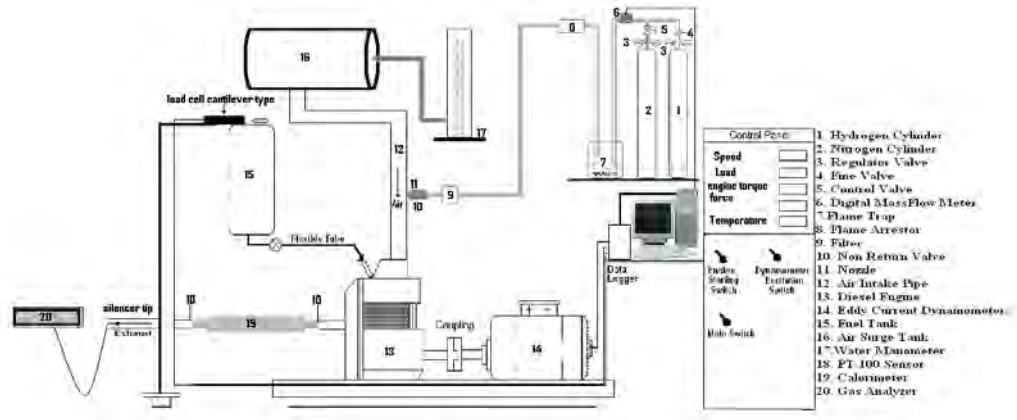

Fig. 1. The experimental setup

Table 1. Engine specification

Make and model	Stride Engine 1.5 E2 DSL
General details	Four cylinder, four stroke, compression ignition, vertical, water cooled, indirect injection
Bore	73 mm
Stroke	88.9 mm
Compression ratio	23:1
Max. power	27.6 kW @ 4000 rpm
Max. torque	83.4 Nm @2250 rpm
Capacity	1489 cm^3

3. Experimental procedure

The following step by step procedure is followed during the experimental investigation:
Start and run the diesel engine at 1500 rpm (most of previous investigations tested the diesel engine at this rate speed) for about 15 minutes to warm the engine and attain steady state condition before the data is acquired.

1. Set the fuel supply system in only diesel mode and record the data of fuel consumption rate, air difference pressure, engine speed, exhaust gas temperature, and exhaust gas constituents under no-load condition.
2. Repeat the observations under different load conditions at the eddy current dynamometer with loadings at 0.5, 1, 1.5, and 2 Amp. of load.
3. Run the engine on diesel mode. Then, set the induction of hydrogen in the an inlet manifold at a specified rate of 1 lpm and run the engine under dual fuel mode to attain steady state condition.
4. Record the data of fuel consumption rate, air pressure difference, engine speed, exhaust gas temperature, and exhaust gas constituents under 0.5 Amp. load condition.
5. Repeat the procedure in steps 4 and 5 under different load conditions at the dynamometer with loadings at 1, 1.5 and 2 Amp.
6. Repeat the experiment for different hydrogen induction rates of 2, 3,…, up to 18 lpm.
7. Close the hydrogen cylinder valve and open the nitrogen cylinder valve and purge the hydrogen gas from the induction system to avoid any burning of residual hydrogen gas.
8. Stop the induction of nitrogen and bring the engine to no load condition before switching off the engine.

4. Results and discussion

From an initial experimental study, it is found that the maximum rate of hydrogen induction at a given loading is to be restricted up to 18 lpm and the maximum loading possible on the engine is 2 Amp. due to engine load capacity restriction. This is the constraint within which the present experimental investigation is carried out.

Fig. 2 illustrates the relation between brake thermal efficiency and hydrogen induction rate at 1500 rpm speed and various loads. The brake thermal efficiency calculated by [1]:

$$brake\ thermal\ efficiency\ (\%) = \frac{Brake\ Power}{(m_f \times CV_D + m_{H2} \times CV_{H2})} \quad (1)$$

It is seen that, the brake thermal efficiency significantly increases with hydrogen induction rate. The rate of increase in brake thermal efficiency with continuous hydrogen induction is found to be higher at higher loads of 1, 1.5, and 2 Amp. load, while, there is no significant change in the efficiency with load of 0.5 Amp. The reason may be attributed to the higher caloric value of hydrogen which is approximately twice that of diesel. For a given load and speed condition, the influence of extra energy addition due to hydrogen induction on brake thermal efficiency is apparent from Eq. (1). The extra energy induction decreases the need of diesel fuel required. At full load, there is 20% increasing in brake thermal efficiency when the hydrogen induction rate changed between 0 lpm and 18 lpm.

Fig. 3 gives the variation in diesel fuel consumption with hydrogen induction rate for various loading (0, 0.5, 1, 1.5, and 2 Amp.) of diesel engine running at 1500 rpm. The engine running at constant speed needs less amount of diesel at a specified brake load due to extra energy available from hydrogen. It can also be noticed that the rate of reduction in diesel fuel consumption is higher at higher loading. At high load condition, the rate of reduction in diesel

fuel consumption is found to be about 40% between hydrogen induction rate from 0 to 18 lpm. This is observed to be true for higher loading of 1, 1.5, and 2 Amp. However, at no loading or light loadings of 0 and 0.5 Amp respectively, the reduction in diesel fuel consumption for hydrogen induction rate from 0 to 18 lpm is found to be about 25-30 %.

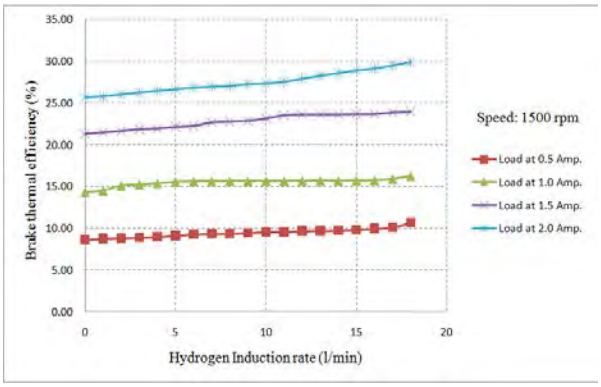

Fig. 2 Variation of brake thermal efficiency with hydrogen induction rate for various loading of diesel engine

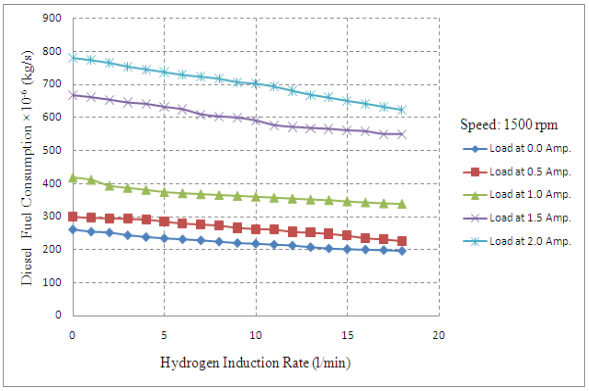

Fig.3 Variation of diesel fuel consumption with hydrogen induction rate for various loading of diesel engine

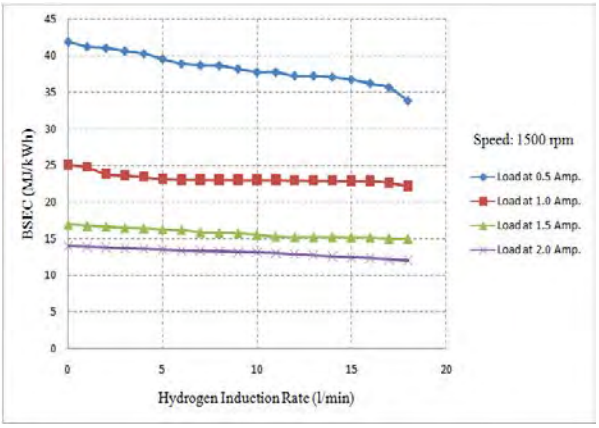

Fig. 4 Variation of brake thermal efficiencywith hydrogen induction rate for variousloading of diesel engine

The variation of the brake specific energy consumption (BSEC) with hydrogen induction rate at different loading conditions is shown in Fig. 4. It is seen that the hydrogen induction in the atmospheric air intake manifold of the engine enhances the consumption of energy to produce more usable power. Basically, the BSEC decreases with increase in load with the engine running at a given constant speed. The same trend is observed with various hydrogen induction rate also. With the induction of hydrogen, the decrease in BSEC is more significant when the load applied is beyond 1.0 Amp. At constant induction rate, the decrease in BSEC is of the order of about 3 times when the load is increased from 0.5 Amp. to 2.0 Amp.

Fig. 5 illustrates the effect of hydrogen induction rate on the exhaust temperature of diesel engine at different loading conditions with speed held at 1500 rpm. The increase in exhaust temperature is an indicator of combustion process behavior. The increment in exhaust temperature is directly indicating to the increment in the energy released increment in the combustion chamber. It can be noticed a margin increase in exhaust temperature due to the high caloric value of hydrogen.

The effect of hydrogen induction rate on volumetric efficiency is represented in Fig. 6. It is observed that irrespective of the loading condition, volumetric efficiency decreases by about 10% when the hydrogen induction rate increased from 0 to 18 lpm. The reason for such a trend may be attributed to the following. A naturally aspirated diesel engine working at a constant speed is found to operate with constant air suction rate. The rate of suction air decreases with increase of load resulting in a decrease of volumetric efficiency. In the range

of loading under consideration, the decrease is found to be a maximum of about 5%. However, at a constant speed and load, the volume intake of air decreases when hydrogen induction rate is increased which results in decrease of volumetric efficiency. The reduction in suction air rate leads to incomplete combustion affecting obviously the emission characteristics.

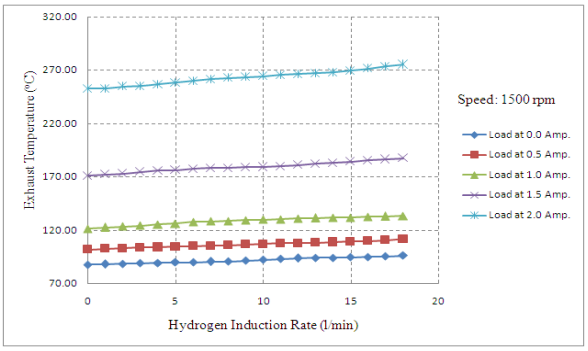

Fig. 5 Variation of exhaust temperature with hydrogen induction rate for various loading of diesel engine

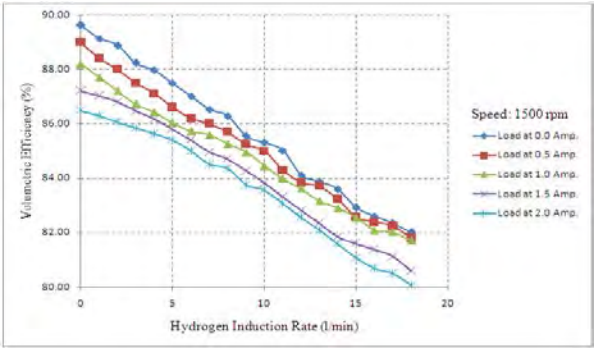

Fig. 6 Variation of volumetric efficiency with hydrogen induction rate for various loading of diesel engine

Fig. 7 shows the variation of equivalence ratio with continuous hydrogen induction rate for various loading of diesel engine running at constant speed. The trend is in consistent with that observed in Fig. 3. For diesel hydrogen duel fuel system, the equivalence ratio is calculated using Eq. (2) [12]. The equivalence ratio increases with loading increase. The equivalence ratio decreased as hydrogen induction rate increased for a given load.

$$\emptyset = \frac{\frac{[G]}{[Air]-\frac{[H_2]}{\left(\frac{[H_2]}{[Air]}\right)_{st}}}}{\left(\frac{[G]}{[Air]}\right)_{st}} \qquad (2)$$

Where, ϕ is equivalence ratio, [G], [Air], and [H_2] are respectively diesel, air, and hydrogen molar concentrations. Subscript 'st' stands for stoichiometric. The thermal performance evaluation of the effect of continuous hydrogen induction in inlet manifold to naturally aspirated multi cylinder water cooled diesel engine running at a constant speed of 1500 rpm indicates improvement in brake thermal efficiency. The notable feature of the effect of the hydrogen induction is the significant reduction in diesel consumption rate required. However, an optimum hydrogen induction rate could not be ascertained for maximizing thermal efficiency and minimizing diesel consumption rate as hydrogen induction rate beyond 18 lpm poses serious flash back problems.

In view of the above observations, experimental investigations are further carried out to quantitatively estimate the emission characteristics and evaluate whether there should be an optimum hydrogen induction rate, which does not seriously affect pollutant emission rates. Figs. 8-12 represent the effect of continuous hydrogen induction rate on the emission of the various exhaust constituent gases such as CO, CO_2, HC, NO_X, and O_2 when the engine is run at different load.

It is seen from Fig. 8 that, the hydrogen induction rate has significant effect on CO emission. The reason for such a trend is due to the proportionate decrease in the content of inlet manifold air. In the case of fuel rich mixture, the CO emission increases while for that of lean

fuel mixture, it remains fairly constant. As diesel engines are operated with lean fuel mixture, CO emission is generally low [13]. However, with hydrogen induction rate increased from no induction to 18 lpm, the CO percentage emissions increases from about 0.15% to 0.95% with the loading of 2 Amp. Similarly, it is found that there is significant effect of hydrogen induction rate on CO emission for the engine running at 0, 0.5, 1 and 1.5 Amp. loads.

Since diesel consumption rate increases with increase in loading. There is an increase in CO_2 emission by about three times (i.e from about 2.5% to 7.5%) with no hydrogen induction. Further, similar trends are observed with hydrogen induction rate, Fig. 9. Further, it is seen that there is no significant effect on CO_2 emission when hydrogen induction rate increased from 0 to 18 lpm for engine running at constant speed and load.

Fig. 10 illustrates the effect of hydrogen induction rate on unburned hydrocarbon (HC) emission. It is observed that there is a considerable increase in HC emission when hydrogen induction rate is increased beyond 7.5 lpm. At 18 lpm hydrogen induction rate the HC decreased by about 8 times when the load varied between 0 and 2 Amp.

Hydrocarbons, or more appropiately organic emissions, are the consequence of incomplete combustion of the hydrocarbon fuel. The level of HC in the exhaust gases is generally specified in terms of total hydrocarbon concentration expressed in parts per million carbon atome or volume percentage (as in present work). While total hydrocarbon emission is a useful measure of combustion inefficiency, it is not necessarily a significant index of pollutant emissions. Engine exhaust gases contain a wide variety of hydrocarbon compounds. Hydrocarbon compounds are divided into different categories and scales. The simplest scale, which divides the HC into classes as methane and non methane hydrocarbons, probably best approximates the end result for all HC emissions. All hydrocarbons except methane react, given enough time. In diesel the HC constituents vary from methane to the heaviest hydrocarbons. The multi gas analyzer used into present work measured the HC on basis of the methane. Unburned hydrocarbons or partially oxidized hydrocarbons emission levels from diesel vary widely with operating conditions, and different HC formation mechanisms are likely to be most important at different operating modes. Engine idling or low speed and light load operations produce significantly high hydrocarbon emissions than full load or high speed operation [11]. These notes can be observed in the Fig. 10. The increment in hydrogen induction rate causes reduction in the intake air which results in a displacement of some volume of the intake air. With increase in load , therefore, the percent content of CO in exhaust gases slightly decreases for a given hydrogen induction rate. This slight reduction in per cent content of CO in exhaust gases may be either due to the formation of lean mixture when only diesel is used as base fuel or/and due to the conversion of CO to CO2.

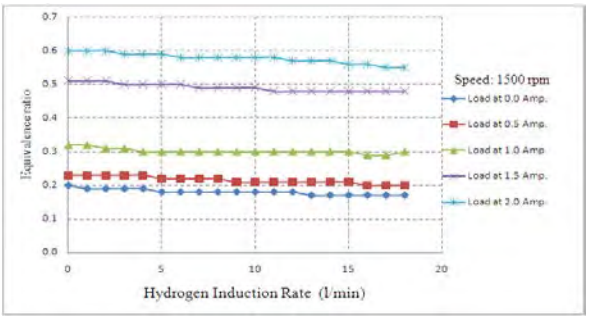

Fig. 7 Effect of hydrogen induction rate on equivalence ratio

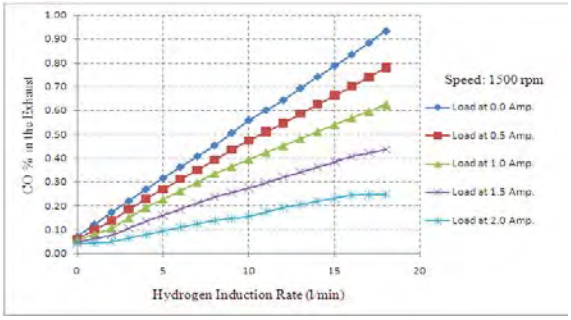

Fig. 8 Effect of hydrogen induction rate on on CO emission at difference loading

The effect of hydrogen induction rate on NO_X emission is given in Fig. 11. It is seen that there is 20% decrease in NO_X emission at smaller loading of 0, 0.5, and 1 Amp. from the condition of no induction to 7.5 lpm hydrogen induction rate. However, at higher loading, the decrease in NO_X emission is only about 6-7% between the same ranges of hydrogen induction rate. The constituent gases of NO_X emission are mainly NO and NO_2. Although the amount of the NO_2 is increased with higher hydrogen induction rate, the decrease in the amount of constituent gas NO plays a dominant role in the decrement in NO_X formation. The reduction in the amount of intake air has contributed to the reduction in NO_X emission in spite of the increase in the exhaust temperature. Fig. 12 illustrates the effect of hydrogen induction rate on O_2 emission. It is observed that there is only a marginal decrease in O_2 emission with increase in hydrogen induction rate. However, as the load on the engine is increased from 0 to 2 Amp., there is a 30 – 35 % decrease in O_2 emission.

5. Conclusion

Based on the experimental studies conducted on the thermal performance and pollutant emissions using a indirect injection multi cylinder naturally aspirated diesel engine with and without continuous hydrogen induction in the inlet manifold, the following conclusions are drawn:

1. A continuous hydrogen induction into the inlet manifold is a unique way of addressing simultaneously issues related to thermal performance and pollutant emission from diesel engine operated with diesel as a fuel. The system may be treated as hydrogen diesel dual fuel system as energy from hydrogen is also utilized.
2. There is a monotonous effect of continuous hydrogen induction rate on thermal performance parameters such as brake thermal efficiency, diesel fuel consumption rate and volumetric efficiency. And hence thermal performance tests alone cannot predict optimum hydrogen induction rate needed.

3. Based on both thermal performance and pollutants emission studies, it is seen that hydrogen induction rate about 7.5 lpm gives an optimum performance keeping the emissions level at a reasonable low levels. At 7.5 lpm, the levels of CO, CO_2 and HC are not increase significantly while the NO_X is reduced. The 7.5 lpm hydrogen induction rate approximately reduced the diesel fuel consumption by 20% and increased the brake thermal efficiency by about 8~9%.

Abstract: In this study, the influence of methanol/diesel and ethanol/diesel fuel blends on the combustion characteristic of an IDI diesel engine was investigated at different injection timings by using five different fuel blends (diesel, M5, M10, E5 and E10). The tests were conducted at three different start of injection {25°, 20° (original injection timing) and 15° CA before top dead center (BTDC)} under the same operating condition. The experimental results show that maximum cylinder gas pressure (P_{max}) and maximum heat release rate $(dQ/d\theta)_{max}$ increased with advanced fuel delivery timing for all test fuels. Although the values of P_{max} and $(dQ/d\theta)_{max}$ of E10 and M10 type fuels were observed at original injection and retarded injection (15° CA BTDC) timings, those of the diesel fuel were obtained at advanced injection (25° CA BTDC) timing. From the combustion characteristics of the test fuels, it was observed that ignition delay (ID), total combustion duration (TCD) and maximum pressure rise rate $(dP/d\theta)_{max}$ increased with advanced fuel delivery timing. The ID increased at original and advanced injection timings for ethanol/diesel and methanol/diesel fuel blends when compared to the diesel fuel. It was also found that increasing methanol or ethanol amount in the fuel blends caused to increase in ID and to decrease in TCD at all injection timings. At original injection timing, the $(dP/d\theta)_{max}$ increased with increasing methanol or ethanol amount in the fuel blends. To see the cycle to cycle variation, the fifty cycles of each fuel were also investigated at the different injection timings. It was found that, at the advanced injection timing, cyclic variability of the test fuels was higher when compared to the original and retarded injection timings. The maximum cyclic variability was observed with the M10 at the advanced injection timing.

1. Introduction

Compression ignition (CI) or diesel engines are widely used for transportation, automotive, agricultural applications and industrial sectors because of their high fuel economy and thermal efficiency. The existing CI engines operate with conventional diesel fuel derived from crude oil. It is well known that the world petroleum resources are limited and the production of crude oil is becoming more difficult and expensive. At the same time, with the increasing concern about environmental protection and more stringent government regulation, the researches on the decreasing of exhaust emissions and improving fuel economy have become a major research issue in the engine combustion and development. A lot of research related to the emissions reduction has been performed by using different injection parameters such as injection time and injection pressure, exhaust gas recirculation and oxygenated alternative fuels. In the recent years, methanol and ethanol are attractive oxygenated alternative fuels for diesel engines. The oxygenated alternative fuels such as methanol and ethanol have provided more oxygen during combustion. Therefore, the oxygenated alternative fuels and blends with gasoline and diesel fuel are more clean combustion processes than that of diesel and gasoline fuels [1-7]. The studies related to the alternative fuels should be enhanced for diesel engines especially for indirect injection (IDI) diesel engines. Because, they have a simple fuel injection system and lower injection pressure level. They do not depend upon the fuel quality and have lower ignition delay (ID) and faster combustion than direct injection (DI) diesel engines.

For a diesel engine, the fuel injection timing is a major parameter that affects the combustion and exhaust emissions. If the start of fuel injection timing is earlier, the initial air temperature and pressure will be lower, so that the ID will increase. The increase in the ID period causes to increase in the premixed burning phase, the cylinder gas temperature and the NO_x emissions. However, this trend decreases PM emissions. If the start of fuel injection timing is later (when piston is closer to TDC), the temperature and pressure will be slightly higher, therefore the ID will decrease. For this reason, injection timing variation has a strong effect on the combustion characteristics and exhaust emissions, because of changing maximum pressure and temperature in the cylinder.

Canakci et al. [2] experimentally investigated the combustion and exhaust emissions of a single cylinder diesel engine at three (25, 20 original injection timing and 15° CA BTDC) different injection timings when methanol/diesel fuel blends were used from 0 to 15%, with an increment of 5%. The results indicated that the P_{max} decreased and the ID increased with the increase of methanol mass fraction at all injection timings. The increment in the ID caused to the deteriorating combustion thereby reduced the P_{max}. Also advanced injection timing boosted the P_{max} and the rate of heat release because of the increase in ID. Huang et al. [8, 9] used the diesel/methanol blend and combustion characteristics and heat release analysis in a CI engine. According to the experimental results, the increase in methanol mass fraction in the diesel/methanol blends resulted in an increase in the heat release rate at the premixed burning phase and shortened the combustion duration of the diffusive burning phase. The ID increased with increasing of the methanol mass fraction. This trend was more obvious at low engine load and high engine speed. TCD and P_{max} increased by advancing fuel delivery timing. The P_{max}, the $(dP/d\theta)_{max}$ and the $(dQ/d\theta)_{max}$ of the diesel/methanol blends obtained a higher value than that of diesel fuel. Yao et al. [10] researched the effect of diesel/methanol compound combustion (DMCC) fuel injection method on combustion characteristics. In this fuel injection method, the methanol was injected into the air intake of each cylinder. The diesel fuel was injected into the cylinder to ignite a methanol/air mixture. This system was tested on naturally aspired diesel engine. The test results showed that the ID increased and the cylinder gas temperature reduced with the DMCC fuel injection method due to the high latent heat of methanol.

Xing-cai et al. [11] conducted research on the heat release and emissions of a high speed diesel engine fuelled with ethanol/diesel blend. They found that the ID increased and TCD shortened for ethanol/diesel fuels when compared to diesel fuel. It was observed that the maximum heat release rate of ethanol/diesel blends were lower than that of diesel fuel. In the other studies, Rakopoulos C.D. et al. [12] investigated the effect of ethanol/diesel blends with 5%, 10% and 15% (by vol.) ethanol on the combustion and emissions characteristics of a high speed direct injection diesel engine. According to the experimental results, the ID for the E15 blend was higher than pure diesel fuel; also there was no significant difference among the P_{max} for each load conditions.

The combustion characteristics of IDI diesel engines are different from the DI diesel engines, because of greater heat-transfer losses in the swirl chamber. This handicap causes the brake-specific fuel consumption (bsfc) of the IDI engine to increase and the total engine efficiency to decrease compared to that of a DI diesel engine. Because of these disadvantages of the IDI diesel engines, most engine research has focused on the DI diesel engines. However, IDI diesel engines have a simple fuel injection system and lower injection pressure level because of higher air velocity and rapidly occurring air-fuel mixture formation in both combustion chambers of the IDI diesel engines. In addition, they do not depend upon the fuel quality and produce lower exhaust emissions than DI diesel engines [13].

From the literature review, it was concluded that the combustion characteristics of an IDI diesel engine have not been clearly investigated when using methanol/diesel and ethanol/diesel fuel blends at different injection timings. For this reason, this study experimentally investigated the effects of methanol/diesel and ethanol/diesel fuel blends on the combustion characteristics of an IDI diesel engine and compared them with those of diesel fuel.

2. Materials and method

In this study, a naturally aspirated, water-cooled, four cylinders IDI diesel engine was used as a test engine. The test engine specifications are compression ratio: 21.47, the maximum brake torque (95 Nm) was obtained at 2000 rpm and the maximum power 38 kW at 4200 rpm, start of injection timing: 20^{o} CA BTDC and injector opening pressure: 130 bar. A hydraulic dynamometer was directly coupled to the engine output shaft. Fig. 1 shows the schematic diagram of the experimental setup. The following parameters were recorded during the each test: engine speed, load, fuel consumption, air flow rate, and ambient, cooling water inlet-outlet, and oil and exhaust temperatures. Conventional diesel fuel, methanol and ethanol were used, and their properties are shown in Table 1. To obtain cylinder gas pressure and fuel line pressure data, piezoelectric-type sensors were used. The cylinder gas pressure sensor was installed on the first cylinder of the engine head. The cylinder gas pressure was obtained by using a Kistler water-cooled piezoelectric sensor type 6061B. An AVL quartz pressure sensor 8QP500c was mounted on the fuel line of the first cylinder to measure the fuel line pressure. The outputs of the pressure sensors were amplified by a Kistler charge amplifier 5015A type. The output of the charge amplifier and a signal from the magnetic pick-up were converted to digital signals and recorded by an Advantech PCI 1716A data acquisition card, which has a 16-bit converter and 250 kS/s sample rate. The pressure and crank angle data were stored in a computer. A computer program was written to collect the pressure data, with a resolution of 0.25° of crankshaft angle. To analyze the cylinder gas pressure, a combustion analysis program was written. To eliminate cycle-cycle variation, the cylinder gas pressure data of 50 cycles were averaged using a computer program. Then, the pressure data was used to calculate the heat-release rate. Experiments were performed after the test engine reached to the steady-state conditions. The steady-state conditions were determined with the engine oil temperature (~70 °C). The test engine was run at least 5 min after the test engine was loaded, and then data was collected for each test. The test procedure was repeated 3 times to verify the each engine test condition, and the results were averaged.

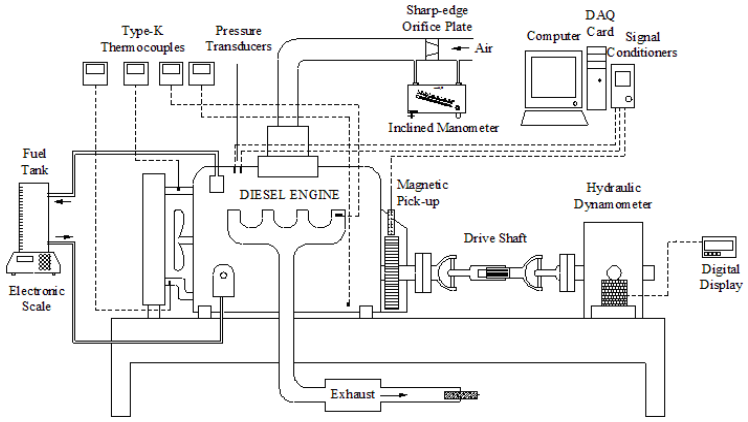

Fig. 1: Schematic diagram of the experimental set-up

Table 1. Properties of the test fuels

	Methanol	Ethanol	Diesel
Formula	CH_3OH	C_2H_5OH	$C_{10.8}H_{18.7}$
Molecular weight (kg/kmol)	32	46	170
Boiling temperature (^oC)	64.7	78	180 – 330
Density (g/cm^3, at 20 ^oC)	0.79	0.78	0.83
Auto-ignition temperature (^oC)	470	423	235
Lower heating value (MJ/kg)	20.27	26.8	43
Cetane number	4	5-8	50
Viscosity (mm^2/s, at 25^{o}C)	0.59	1.2	2.6
Heat of vaporization (MJ/kg)	1.11	0.856	0.280

3. Heat release analysis

The heat release analysis was based on the changes of the cylinder gas pressure and cylinder volume during the cycle. Therefore, some assumptions were made to calculate the heat release rate. It was assumed that no passage throttling losses exist between both chambers. Large temperature gradients, pressure waves, leakage through the piston rings, fuel vaporization and charge mixtures were ignored. Hence the intake and exhaust valves assumed to be closed. After using these assumptions, the heat release rate is calculated by using the following formula:

$$\frac{dQ}{d\theta} = \left[\frac{k}{k-1}\right] P \frac{dV}{d\theta} + \left[\frac{1}{k-1}\right] V \frac{dP}{d\theta}$$

Where: $(dQ/d\theta)$ is the combination of heat-release rate, P is cylinder gas pressure, V is cylinder volume, θ is the crank angle, k is the ratio of specific heats.

The parameters of combustion characteristics are ID, start of combustion, TCD which are obtained from heat release curve. The heat release curve in a diesel engine examines ID and TCD. The ID is defined as the time between the start of injection and the start of combustion. The start of injection time is determined by the fuel line pressure reached the injector nozzle opening pressure. The start of combustion is defined as the point where the heat release rate turns from negative to zero. The TCD is defined as the time from the start of combustion to the end of the heat release.

4. Results and discussion

In this study, the engine test was conducted at three different start of injection {25^o (advanced), 20^o (original) and 15^o (retarded) CA BTDC} under 1400 rpm and 40 Nm. The maximum fuel/air ratio was observed at 1400 rpm for diesel fuel, therefore the test condition was chosen as 1400 rpm. The relationship between the combustion characteristics and injection timings were focused by using conventional diesel fuel (D), E5, E10, M5 and M10. These fuel blends content of methanol or ethanol in different mass ratios (e.g., E5 contains 5% ethanol and 95% diesel fuel by mass). In this study, the combustion characteristics defined as the cylinder gas pressure and heat release rate were analyzed as shown in Fig. 2. The ID, TCD, $(dQ/d\theta)_{max}$, $(dP/d\theta)_{max}$, and the variation of the fifty consecutive P_{max} were also investigated as shown in Figures 3 and 4.

Fig. 2 illustrates the cylinder gas pressure and heat release rate of test fuels at three different injection timings under the same engine operating conditions. As shown in Fig. 2, it can be clearly seen that the cylinder gas pressure and heat release rate increased by advancing fuel

injection timings for all test fuels. This behavior was such that, as injection started earlier, the cylinder gas pressure and the heat release rate become higher due to more fuel injected during the ID period. In addition, the location of P_{max} and the start of combustion points occurred early with advanced fuel injection timing. Therefore the premixed combustion phases occurred earlier and also this phase finished before TDC at 25° and 20° CA injection timing. Diffusion or controlled combustion phase of the M10 and E10 formed lower burning than that of other test fuels at original injection timing. The lower viscosity and density of M10 and E10 led to high atomization and vaporization, so the lower burning was observed in the diffusion combustion phase. At the same time, the fraction of the heat release in the premixed or uncontrolled burning phase of the E10 and M10 blends decreased and the peak of premixed combustion phase of these blends increased at original injection timing. These results can be explained by increasing ethanol and methanol mass fraction in the blends.

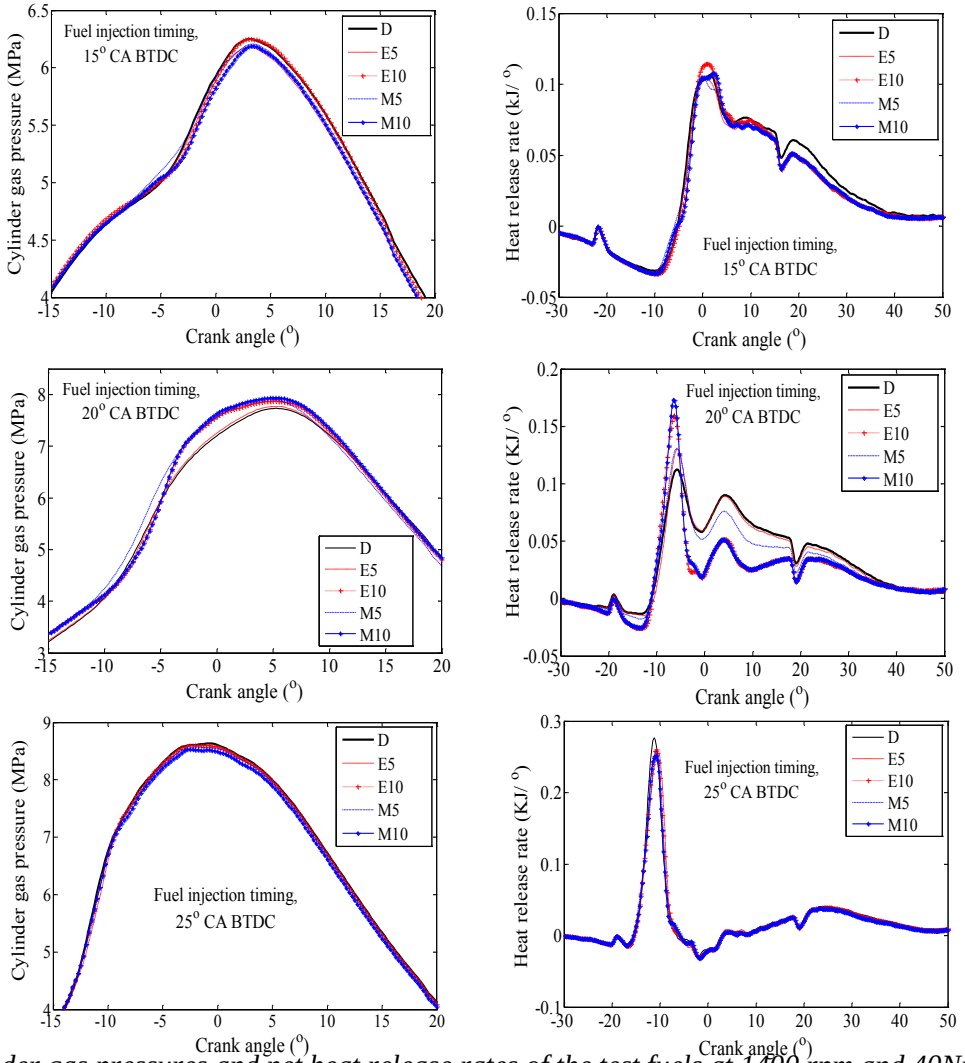

Fig.2 Cylinder gas pressures and net heat release rates of the test fuels at 1400 rpm and 40Nm

Fig. 3 shows the variation of ID, TCD, $(dQ/d\theta)_{max}$ and $(dP/d\theta)_{max}$ under three different injection timings. It was observed that the ID decreased with retarded injection timing for all test fuels. This behavior can be explained by the pressure, temperature and vaporization in the cylinder increased with retarded injection timings. It was found that, at advanced and original injection timings, the IDs of the blends are longer than that of conventional diesel fuel. This effect was interpreted by two different reasons. The first reason is that cetane numbers of the

blends which are lower than that of conventional diesel due to the cetane number decreased with the increase in methanol and ethanol mass fraction in the fuel blends. The second reason is that the methanol and ethanol have higher heat of vaporization than that of conventional diesel fuel. It was observed that the IDs of the E5 and M5 were shorter than that of E10 and M10 due to lower cetane number of the E10 and M10 blends. The TCD decreased with retarded fuel injection timing for all test fuels. The reason for the decrease in TCD is the increase in the premixed or uncontrolled combustion phase due to long ID and decrease in the diffusion or controlled combustion phase. It was revealed that, at all injection timings, TCD with blends was longer than that of conventional diesel fuel. This result can be explained by the increasing amount of the oxygen in the blends. It is known that the increase in amount of the oxygen enhances the combustion and causes to the diffusion combustion phase which becomes shorter.

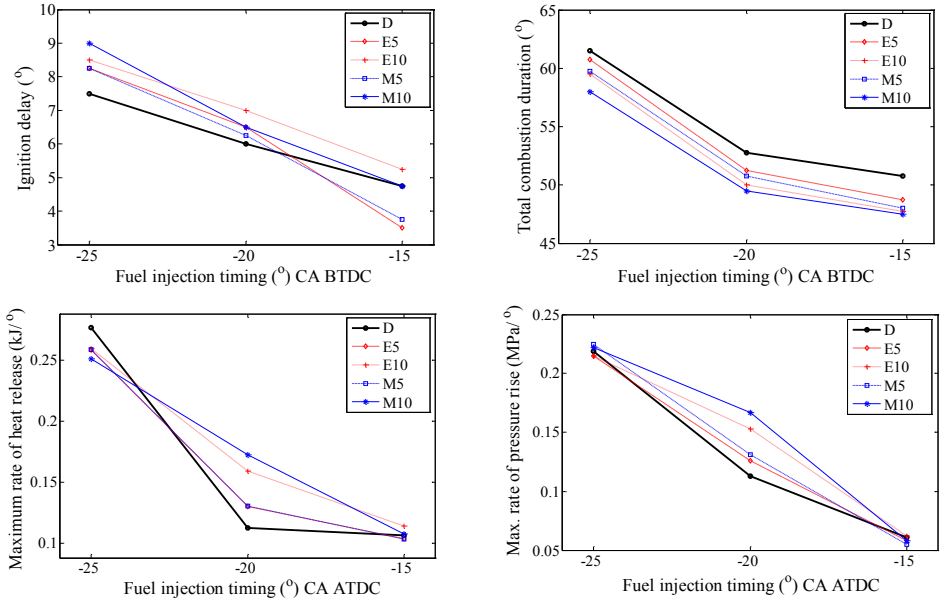

Fig.3 Effect of injection timing on the ID, TCD, $(dQ/d\theta)_{max}$ and $(dP/d\theta)_{max}$ at 1400 rpm, 40 Nm for each test fuel

As shown Fig. 2, the net heat-release profile has a slight negative dip during the ID period, which is mainly heat loss from the cylinder during the fuel vaporizing phase. It is more obvious at retarded injection timings. Because of the temperature in the cylinder increasing with retarded injection timing, the injected fuel during the ID period causes an increase in the evaporation heat. Therefore, the $(dQ/d\theta)_{max}$ decreased with retarded injection timings for all test fuels. The $(dP/d\theta)_{max}$ increased with the advancing injection timing as shown in the Fig. 3. This can be attributed to the increase in the injected fuel into the engine cylinder during the ID period, and so that produced higher the $(dP/d\theta)_{max}$ and the cylinder gas pressure. Also, there is no significant difference among the $(dQ/d\theta)_{max}$ and the $(dP/d\theta)_{max}$ of the test fuels at advanced and retarded injection timing, while at original injection timing, the $(dQ/d\theta)_{max}$ and the $(dP/d\theta)_{max}$ of the blends were higher than that of conventional diesel fuel. The main reason for this situation is that in order to obtain the same bmep from the blends, more fuel was injected into engine cylinders due to the blends have lower heating value than that of conventional diesel fuel. At the same time, it w as observed that the $(dQ/d\theta)_{max}$ and the$(dP/d\theta)_{max}$ increased with the increase in the mass fraction methanol and ethanol in the blends at original injection timing. This was caused by E10 and M10 fuel blends which have

more oxygen rate than E5, M5 and conventional diesel fuel. Thereby, the combustion became better and the $(dQ/d\theta)_{max}$ and the $(dP/d\theta)_{max}$ increased.

Fig. 4 shows the average of the P_{max} achieved from 50 consecutive cycles for all test fuels and all injection timings. It was observed that the cyclic variability decreased with the retarding fuel injection timings. Specially, at 25° CA injection timing, the cyclic variability of the M10 test fuel was higher than those of other injection timings. As shown in Fig.4, similar cyclic variability and the smooth operation of the engine can be achieved by using E5, E10, M5 and M10 blends when compared the conventional diesel fuel.

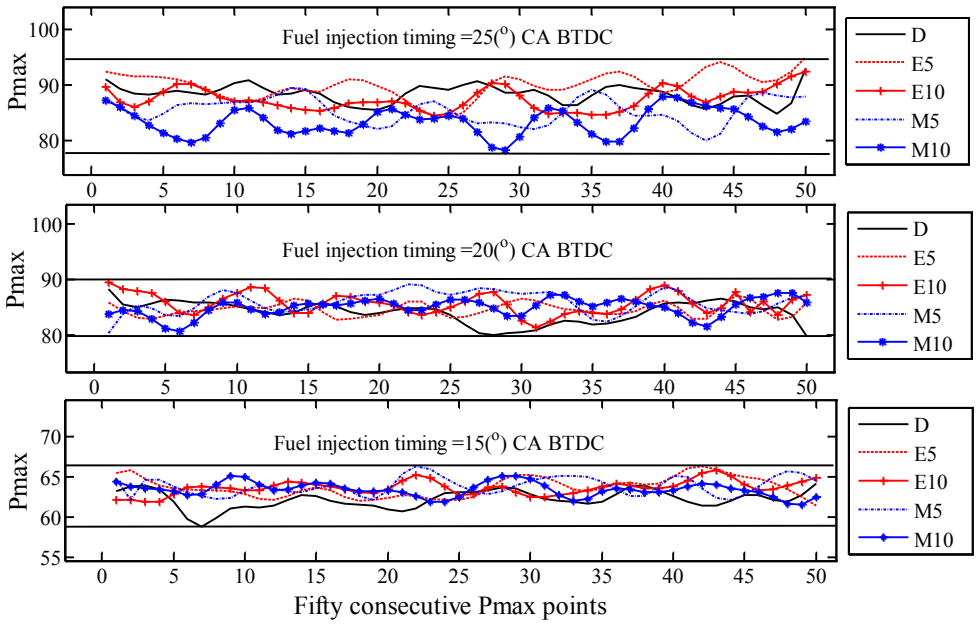

Fig.4 Effects of blends and fuel injection timing on the variation of maximum cylinder gas pressure

5. Conclusion

The paper presented the results of experimental research on the effects of injection timing on the combustion characteristics of an IDI diesel engine using the ethanol and methanol blends with diesel fuel. The following conclusions can be drawn from the current paper:

(1) The P_{max} and premixed combustion rate increased with advanced fuel injection timings for all test fuels.
(2) The location of P_{max} and the start of combustion points occurred early with advanced fuel injection timing.
(3) The ID and TCD decreased with retarded injection timing for all test fuels.
(4) It was determined that the IDs of the blends were longer than that of conventional diesel fuel at originally and advanced injection timings.
(5) An increase in the mass fraction of the methanol and ethanol in the fuel blends generally caused to increase in ID, but it decreased TCD.
(6) The retarding of injection timing decreased the $(dQ/d\theta)_{max}$ and the $(dP/d\theta)_{max}$ for all test fuels.
(7) It was found that the characteristics of $(dQ/d\theta)_{max}$ and $(dP/d\theta)_{max}$ of the blends are higher than that of conventional diesel fuel. These characteristics increased with the increase of methanol and ethanol mass fraction in the fuel blends at original injection timing.
(8) It was observed that the cyclic variability decreased with the retarding fuel injection timings. Also, the maximum cyclic variability was observed with the M10 at the advanced injection timing. The fuel blends used in the current study may replace with

conventional diesel fuel in terms of the combustion characteristics, cycle to cycle variation and smoothness of the engine operation.

Abstract: Bioenergy is one way of achieving the indicative target of 10% renewable energy outlined in the EU Directive 2009/28/EC. This paper assesses the consequences for land use, greenhouse gas (GHG) emissions and fossil fuel substitution of increasing the use of bioenergy for road transportation. Different technologies, including first and second generation fuels and electric cars fuelled by bio-electricity are assessed in relation to existing bioenergy uses for heat and power production. The paper applies a spatially explicit energy system model that is coupled with a biomass production model to allow estimating impacts of increased biomass utilization for energy production on agriculture and forestry. Uncertainty is explicitly considered with the help of Monte-Carlo simulations of input parameters. Results indicate that second generation fuels perform better with respect to land use than first generation ethanol and that costs are lower. Biodiesel is also a cheap option, although the total potential is limited at a low level due to constraints in feedstock production. Electric vehicle mobility minimizes land use, however, costs are still high and prohibitive. First generation ethanol production is effective in reducing domestic GHG emissions because it does not induce feedstock competition with existing bioenergy uses (i.e. heat and power production). However, land use change is significant.

Keywords: *biofuels, electric cars, e-mobility, 2020 goals, spatially explicit optimization*

1. Introduction

Directive 2009/28/EC requires all member states of the EU to guarantee a share of 10% of renewable fuels in transportation by 2020. The target may be reached by various measures, including an increase in the share of biofuels and an increase in the share of renewably produced electricity in the transportation sector. However, since the large scale introduction of biofuels in the US and Europe an extensive discussion has evolved because the large land requirements were identified as cause for direct and indirect greenhouse gas (GHG) emissions [1], [2] and as the driver for increasing competition between food and fuels [3], [4]. In Austria, bioenergy has played traditionally an important role. It provided around 8% of the primary energy demand in 2006, mainly for heating purposes [5]. Other uses of bioenergy developed in recent years, include biofuel and power production. Austria has complied with the 5.75% indicative EU biofuel target since late 2008 and used around 4.00 TWh of biodiesel and 0.60 TWh of ethanol in 2008 [6]. A further increase of the supply of biofuels will be difficult to achieve, particularly if only domestic biomass supply is considered. However, new technologies are emerging that aim to increase biofuel productivity and diversify feedstock supply. Second generation biofuels that may use ligno-cellulosic feedstock for fuel production are regarded as a sustainable alternative to first generation biofuels which are mainly produced from food and feed crops [2], [7]. A technological alternative is electric cars. Technical and economical barriers currently prevent the large scale introduction of electric cars, however, future potentials are considered significant [8], [9]. Electric cars will only contribute to renewable energy targets if the electricity for cars is produced in a renewable manner. Biomass is one possible source for this purpose. An existing study estimates [10] that the utilization of biomass resources for electricity generation and subsequent utilization in electric cars is a far more effective way of using limited land resources for transportation than the conversion of food and feed crops to first generation ethanol. However, the assessment relied merely on technical details without considering economics and alternative uses of biomass in

the energy sector – e.g. for heating. This paper contributes to research by applying a spatially explicit agricultural-bioenergy-system model to evaluate several technological options for the transportation sector, including first and second generation fuels and electric cars, with respect to land use, GHG emissions and fossil fuel substitution. The techno-economic characteristics of future biofuel production as well as of electric cars are not well known yet. Also, high uncertainty is attached to future price energy scenarios. We therefore apply a Monte-Carlo simulation of input parameters to explicitly include uncertainty in the modeling process.

2. Methodology

2.1. Model and Model Boundaries

A spatially explicit, techno-economic mixed integer program is developed and applied to assess the costs, land use and GHG emissions of different bioenergy conversion routes. The model minimizes the costs of supplying Austria with transportation fuels, heat and electricity from either bioenergy or fossil fuels. It is static and simulates one year of operation. The current model version considers domestic biomass supply and energy demand only and does not allow imports and exports of biomass or bioenergy commodities. The model determines which bioenergy plants of a specific size and specific location shall be built and which demand regions are supplied with bioenergy and/or with fossil fuels. Each plant produces various energy commodities, e.g. the heat produced in a combined heat and power (CHP) may be delivered to district heating networks (Figure 1). By-products of biofuel plants are sold as animal feed. Biomass supply curves endogenously determine the price of feedstock from forestry and agriculture, while prices of fossil fuels and energy demand are defined exogenously. Taxes currently applied to both fossil and bioenergy fuels are not included in the model.

2.2. Technologies

We assess several bioenergy technologies which are able to replace fossil fuels in the transportation sector along with technologies that convert biomass to heat and power. First generation biofuels are classified into ethanol produced from fermentation of starchy and sugar crops (e.g. wheat and corn) and biodiesel which is produced from vegetable oil derived

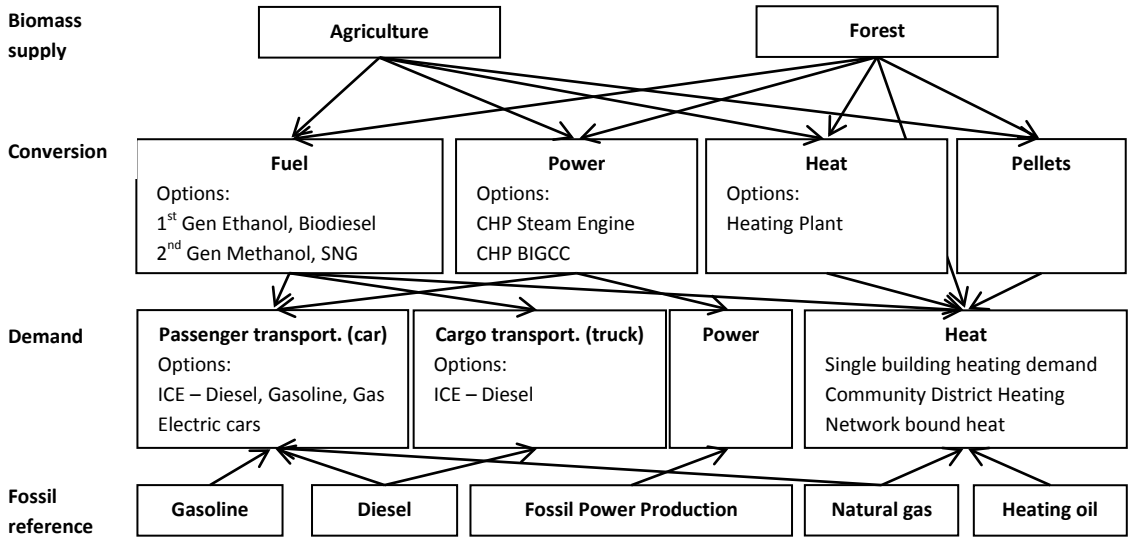

Figure 1: Diagram of the mixed integer programming model.

from oil crops (e.g. sunflower and rapeseed). Both technologies are commercially available and are currently used for the production of biofuels in Austria**.** Ethanol is blended with gasoline. A blend of 5% ethanol and 95% gasoline is considered safe to be used in all cars,

while all cars sold currently on the market are also able to handle a blend of 10% of ethanol. Similar limitations apply to biodiesel [11]. Second Generation biofuels are able to use cellulosic feedstock and even waste for the production of biofuels. There are two major technological options [7]. The biomass can be gasified and subsequently upgraded to liquid transportation fuels such as methanol or synthetic natural gas (SNG) which can also be used as transportation fuel. The second option is the hydrolysis of cellulose to sugars that are fermented to ethanol afterwards. We assess gasification only as it is estimated to be economically more viable than hydrolysis with fermentation [12], [7]. Second generation production technologies are currently under research and first pre-commercial installations are being built. US legislation requires 572 TWh of yearly cellulosic biofuel production until 2022 [13], therefore a rapid increase in the construction of second generation facilities can be expected. Current cars cannot run solely on methanol and the amount of methanol that may be blended to gasoline is, similar to ethanol, limited. SNG requires significant modifications to the car, including the installation of a gas tank. Electric cars are currently globally under research, however, costs and ranges of batteries are major economic and technical obstacles to full implementation of the technology. Ranges of above 150 km are currently only achieved at very high costs [9]. Also, electric cars need the large scale deployment of charging stations. Metering of power and billing still has to be developed. The model considers investment costs for electric cars. Costs associated with additional infrastructure necessary for electric cars are not included. With respect to power production, the model allows two technologies: steam engines and biomass integrated gasification combined cycle (BIGCC) plants. While steam engines are well established in Austria and the installed capacity exceeded 300 MW in 2007 [5], BIGCC is a technology that is still under research. It allows higher electrical conversion efficiencies than steam engines but capital costs are also significantly higher. We assume that power can be either used to fuel electric cars or that it is simply sold on the electricity market at a fixed price. Heating technologies modelled include fuel wood furnaces, pellet furnaces and heating plants for district heating networks.

2.2.1. Total Cost of Ownership – Cars

We use the concept of total cost of ownership (*tco*) to assign different costs to different cars in the model. Costs for fuels are endogenously determined by the model and are therefore not included in the calculations of *tco.* The *tco* per km is described by equations (1)-(3):

$$tco = \frac{C\frac{i(1+i)^t}{(1+i)^t-1}+B}{km} + om \qquad (1)$$

$$t = \min\left(\frac{maxKm}{km}, 10\right) \qquad (2)$$

$$B = \frac{i(1+i)^{tb}}{(1+i)^{t}b-1}\sum_{tb\in y}\frac{bc}{(1+i)^{t'}} \qquad (3)$$

The *tco* is determined by the annuity of capital costs *C* of the car, assuming an interest rate *i* and a lifetime *t*. For electric cars, the battery cost *B* is additionally considered as explained below. Total necessary yearly investment costs are divided by the kilometres *km* driven annualy. Additionally, operation & management costs per km of *om* are assumed. These costs are assumed to be lower for electric cars because maintenance of the electric motor is less complex than for an internal combustion engine (ICE) [9]. The lifetime of the car is limited to ten years, however, if the car is driven a lot (i.e. more than *maxKm*), the lifetime is further reduced as indicated by equation (2). The lifetime of a battery is significantly less than that of the carriage. A change of the battery within the lifetime is therefore probable and is modelled

by equation (3): the annuity of battery costs is derived by adding up the discounted battery costs over the whole life time, assuming that one battery costs *bc*. The battery is changed in year *y* when the driven kilometres since the last change exceed the lifetime of the battery. The *tco* depends significantly on the kilometres driven each year. A higher amount of kilometres implies lower specific capital costs per km. We therefore estimate ten classes of annual car utilization based on data provided by ÖAMTC. ÖAMTC, the biggest Austrian Automobile Association, checks approximately 10% of all cars for their technical liability each year. The total driven kilometers and the year of the first registration of the car are collected in the examination of the cars. An approximate estimate of the yearly driven kilometers can be derived from this data. We classified the cars by the annual driven kilometers into ten classes (0 km - 10,000 km, 10,001 km - 20,000 km, …, 90,000 km – 100,000 km). For each class, the mean of the yearly driven kilometers by car and the mean of the sum of driven kilometers by all cars in the class are determined. The sum of driven kilometers is linearly extrapolated from the ÖAMTC data with data of total Austrian car ownership from Statistik-Austria to allow an estimate for whole Austria as ÖAMTC data only covers around 10% of all registered cars.

2.3. Demand

We estimate current transportation demand from the ÖAMTC data and assume that the demand for transportation remains constant until 2020. We assume a total of 60 billion annual kilometres for personal transportation and total of 24 billion tonne kilometres for cargo transportation by truck. Although transportation fuel consumption has historically seen significant increases in the last years, the increase was significantly caused by "tank tourism" due to lower fuel taxes in Austria. We exclude demand from "tank tourism" from our analysis and also assume that public transportation will take a higher share of the overall transportation supply, thus allowing that road transportation remains constant. While the model allocates biomass resources to various conversion routes depending on energy prices and production costs, the demand for biomass heating is assumed to not fall under 17 TWh in the simulations. This is a possible decline of 5 TWh from current consumption levels. Setting a lower bound for biomass consumption for heating is reasonable because adjustment of individual heating devices to new economic conditions generally takes a lot of time.

2.4. Uncertainty

Most of the parameters in the study are of high uncertainty. Uncertainties on the performance and costs of various technologies as well as uncertainty about future energy prices are high. We explicitly address this issue by performing Monte-Carlo simulations of the MIP model and conducting an extensive sensitivity analysis. We first define plausible ranges for the uncertain parameters from a literature research and assume that the parameters are distributed uniformly within that range. For energy and CO_2 prices, correlation between the prices of oil, gas, gasoline and CO_2 are determined from historical spot prices**.** The input data for the Monte-Carlo simulation is generated by performing a Latin Hypercube Sampling procedure and combining it with the Iman-Conover method to guarantee correlation of correlated parameters in the procedure [14]. Latin Hypercube Sampling is used to guarantee that the whole parameter range is covered in the Monte-Carlo simulations. Results are given in form of probability distributions and a stepwise regression analysis is performed to examine the sensitivity of results to input parameters. The assumption on the distribution of the most important parameters is reported in Table 1. Further parameters modelled stochastically are biomass costs, conversion efficiencies and investment costs of bioenergy plants.

Table 1: Main model parameters and uncertainty ranges

	Lower Bound	Upper Bound
Price of oil (€ MWh^{-1})	40	60
Price of gas (€ MWh^{-1})	30	50
Price of gasoline (€ MWh^{-1})	42	62
Price of electricity (€ MWh^{-1})	54	74
Price of carbon (€ MWh^{-1} tCO_2^{-1})	21	55
Battery costs (€)	4,000	6,500
Replacement distance battery (km)	70,000	90,000
Investment costs electric cars (w/o battery) (€)	14,000	16,500
Investment costs gasoline cars (€)	16,500	16,500
Investment costs diesel cars (€)	17,000	17,000
Investment costs gas cars (€)	17,500	17,500
O&M costs electric car (€ km^{-1})	0.02	0.025
Conversion efficiency car – Gasoline (km MWh_{fuel}^{-1})	2,000	2,200
Conversion efficiency car – Diesel (km MWh_{fuel}^{-1})	2,250	2,450
Conversion efficiency electric car (km MWh_{elec}^{-1})	5,600	7,000

2.5. Scenarios

We model one baseline scenario, that assumes no policy intervention at all, and 7 policy scenarios. Three of the scenarios assume that 5% (*S5*), 10% (*S10*) and 15% (*S15*) of the transportation sector are supplied by bioenergy, allowing all technologies to be selected by the model. The other four scenarios examine the impact of a 10% target of renewable transportation fuels, if only single technologies (i.e. ethanol (*eth*), methanol (*met*), sng (*sng*), electric mobility (*emo*)) are allowed. Biodiesel is not modelled in these scenarios because domestic feedstock production is too low to supply 10% of the transportation sector with biofuels.

3. Results

3.1. Technologies and fuel utilization

The first three scenarios allow free choice of technologies. Biodiesel and methanol supply the biofuels in these scenarios. Biodiesel is however limited at around 0.5 TWh due to restrictions in feedstock supply of oil-crops. Second generation methanol is the supplement to biodiesel to complete the full target. E-Mobility plays a role in the first three scenarios - however, variation is very high and the contribution is significantly lower than that of methanol. Ethanol and SNG are not selected in the first three scenarios. These results indicate that methanol production can be considered superior to ethanol in terms of costs – although the variation of results is generally high, the dominance of methanol over ethanol is stable. Competing bioenergy technologies (i.e. heating and power production) are mainly reduced in *S15, met* and *SNG*. This is due to the high demands for woody biomass for biofuel production which increases prices for the feedstock and therefore makes production of power and heat partly unprofitable. The ethanol scenario has less influence on the woody biomass market as ethanol feedstock competes with food and feed crops. Biodiesel is mainly used in the freight sector where it substitutes diesel. Ethanol and methanol are used for personal transportation in driving classes with low annual distances because fixed capital costs contribute more to the total costs of transportation in those classes than the distance dependent fuel costs. Higher classes with higher annual driving distances are more likely to be supplied by electric cars where the influence of the high capital costs of the car and the battery decrease and the fuel costs become more important.

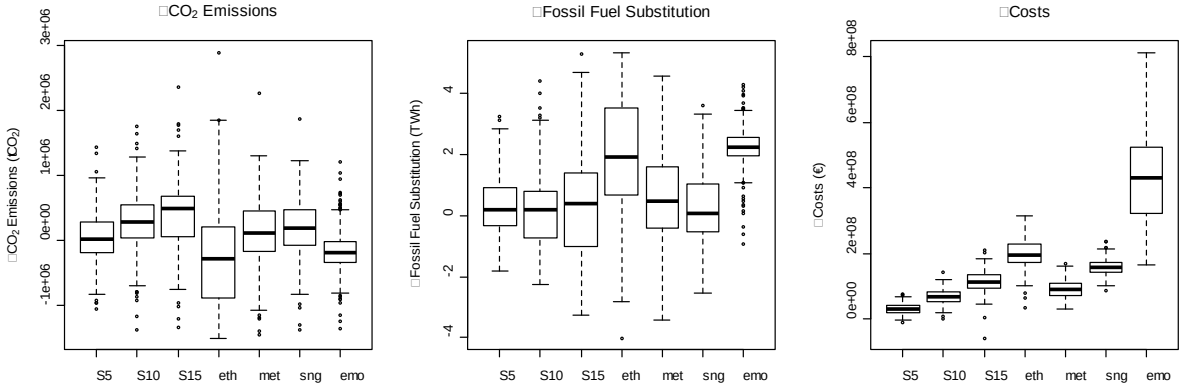

Fig. 2: Differences in CO_2-Emissions, Fossil Fuel Substitution and Costs between the baseline and the biofuel scenarios.

3.2. CO_2 Emissions, Fossil Fuel Substitution and Costs

Figure 2 shows CO_2 emissions, fossil fuel substitution and costs calculated as the difference from the baseline scenario. A significant reduction in CO_2 emissions and an increase in fossil fuel substitution are achieved by the *eth* and the *emo* scenario. These two scenarios also have highest costs. The variance of costs is highest in *emo* due to the large uncertainties in the development of the costs of electric vehicles. However, the model only considers domestic GHG emissions while effects of indirect land use change on GHG emissions are not modeled.

3.3. Land use

While the *eth* policy substitutes a lot of fossil fuels, the land use effects are also substantial in comparison to the other policy scenarios (See Figure 3). Up to 200,000 ha of agricultural land are converted to energy crop production while all other scenarios stay well below 50,000 ha. This implies that food and feed production is reduced significantly in the *eth* scenario while all other policies have rather low impacts on the production of other agricultural products. There are two reasons for this: first, productivity is higher for second generation fuels and for electric mobility due to higher total conversion efficiencies (see Figure 3). Second, these technologies rely on lignocellulose resources that may come from additional forest harvesting or that may otherwise be used for power and heat production (see Figure 3, bottom-right). There are also important differences between the *S10*, *met*, *sng* and *emo* scenarios. Combining biodiesel and methanol for the biofuel goals as in *S10* reduces land use change in comparison to the methanol only scenario. Biodiesel therefore plays a small, but important role in the technological portfolio. Figure 3 shows that *SNG* is more efficient in converting biomass than methanol. Electric mobility has by far the lowest impact on land use change and on additional forest wood utilization.

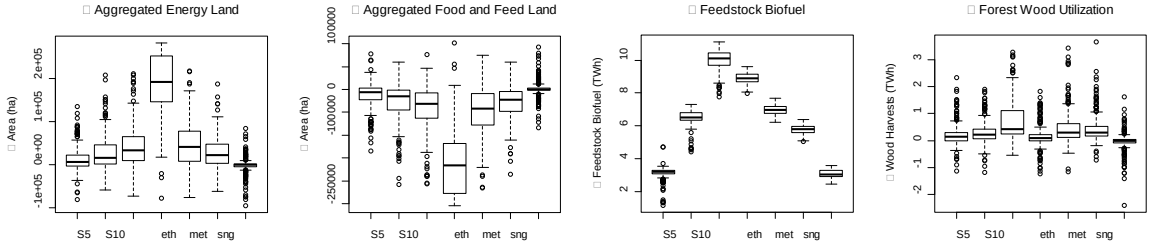

Fig. 3: Differences in Land Use, Feedstock Utilization and Forest Wood utilization between the baseline and policy scenarios.

3.4. Sensitivity Analysis

Table 2 show the results of the sensitivity analysis performed on the results of the *S15* scenario. We checked for the influence of parameters on the deployment of electric mobility to show which factors mainly influence the competition between second generation fuels and electric mobility by performing a regression of the input parameters on the output variables (a stepwise regression procedure is used). The regression coefficients are normalized. The most important input parameters regard the cost for the electric car (i.e. battery costs, investment costs, O&M). The carbon price and the kilometers until replacement of battery also prove to significantly influence the results while the gasoline price does not show significant influence on results.

4. Discussion

Results of our study are in line with other studies that estimate lower land use for bio-electric-cars than for biofuel production [10]. They are also in line with studies that come to the conclusion that battery replacement costs are currently the biggest economic barrier to the large scale introduction of electric mobility in the transportation sector [8], [9]. However, there are additional barriers to electro-mobility that were not modelled within this study: the change from cars that are refuelled at gas stations in very short time to cars that need hours of recharging and that have a comparably low driving range probably plays a more important role than sole considerations of the *tco*. The model results indicate that drivers who use their car a lot are more likely to choose electric cars than those with low car utilization because of lower fuel costs. However, technical reasons may impede the utilization of electric cars for those drivers: the low range and the high recharging times may render electric cars impractical for them. With respect to economics, renewable electricity production from wind or small water power plants may produce electricity at much more competitive costs than biomass powered thermal plants. Therefore, electric cars may be more competitive than stated in this study due to lower fuel costs from renewables. The GHG emission effects of biofuel policies have to be considered in conjunction with the land use change that is caused by the expansion of biofuel production. The GHG emissions stated in this paper do not include indirect or leakage effects of the policies. However, it can be clearly stated that fuelling electric cars with electricity produced from biomass induces by far the least change of land use and can therefore be considered to also minimize leakage effects.

*Table 2: Results of sensitivity analysis. Confidence levels: *** 0.999, ** 0.99 and * 0.95*

	Coefficient	
Amount of electric mobility (R^2 0.49)		
Battery Costs	-0.54	***
Investment costs electric car	-0.28	***
O&M costs electric car	-0.12	*
Gasoline price	0.08	
Kilometers until replacement of battery	0.15	**
Carbon price	0.17	**

5. Conclusions

Second generation biofuels have less impact on land use than first generation ethanol due to two reasons: yields of biofuel per hectare are higher for agricultural land and the feedstock may additionally come from forests. Biodiesel has high yields per hectare, but the total domestic potential is limited at a low level. The lowest land use is implied by the utilization of

electric cars, which, at current technological standards, are still very costly in comparison to cars fuelled by liquid fuels. With respect to policies for promoting second generation biofuel production, one has to consider that investments in second generation biofuel production will have a long-term effect on the utilization of biomass resources. The results of the study indicate, however, that the gains in efficiency in relation to first generation fuels are relatively low while significant efficiency increases can only be expected when developing a transportation system based on electricity. A large scale introduction of second generation biofuels has to be considered very carefully therefore and in the light of a possible total restructuring of the transportation sector within the next 20 to 30 years.

Abstract: The initial step of this analysis corresponds to the evaluation of the current state of the art (SoA) for various alternative fuels (AFs) and alternative sustainable automotive technologies (ASATs) across Europe, taking into account their detailed energetic, environmental and economic variables. The method to assess economic and environmental performance of AFs and ASATs corresponds to a well-to-tank (WTT) and tank-to-wheel (TTW) assessment complemented by scenarios until 2030, with projections of reference and high prices of major input variables of analysis. This analysis determines short and long term economic performance taking into account technology learning. 2nd generation biofuels offer potentials for meeting future fuel-energy demand, and are currently supported by main governments and programs. Initial results of this study also indicate that second generation biofuels offer promising solutions in terms of environmental performance but production costs, conversion efficiencies and by-products are major challenges that can influence the overall economic performance considerably. In addition, price volatilities for first generation biofuels feedstock play a major role on the competitiveness and economic performance of these fuels.

Keywords: *Sustainable transport, Low carbon fuels, Alternative fuels, Mobility technologies, Economic assessment*

1. Introduction

Biofuels and alternative fuels (AFs) have emerged strongly since last one decade as sustainable alternatives for the reduction of fossil fuel energy demand and emissions in the transport sector. Various AF production options include 1st generation biofuels (biodiesel and bioethanol) obtained from well established fermentation, oil extraction and trans-esterification processes, as well as emerging 2nd generation biofuels via BTL, gasification, CTL and other processes. Currently, several technological challenges and bottlenecks exist in different AF production options at different levels across the whole supply chain. Biomass supply constraints, inefficient and capital intensive production processes, fuel transportation and supply, onboard usage related problems and many others are such challenges that affect the success and proliferation of these AFs. The expected economic and environmental performance of these alternatives require not only a clear understanding of the current state of the art, but also a comparison between various alternatives along the complete supply chain as "well-to-tank" and "tank-to-wheel" analysis. Within this study, scenarios for the future development of the most important input variables in different AF production pathways have been defined with feedstock costs and production-scale effect variations that influence the overall economic performance.

2. Methods and modelling structure

The current state of the art and developments of AFs and ASATs have been studied by various authors in different projects and studies. In this study, the characterization of technologies along the whole technology cycle included an extensive literature review including research papers, studies, industrial information, etc. from 2003 until 2010, as well as expert's interviews and assessments in order to screen the state of development of alternative fuel technologies along the technology cycle curve (S-Curve) [1,4]. State of the art updates and projections until 2030 were collected for 26 different AFs pathways through

techno-economic databases including information on biomass feedstock requirements, production process input characterizations (inputs, quantities, efficiencies, costs, emissions) and other techno-economic and techno-environmental parameters. The main formulas and assessments used in this study include the annual cost of capital (ACC):

$$\mathbf{ACC} = \frac{IR}{1-\left(\frac{1}{(1+IR)^{Te}}\right)} * Ti * 1 - \left(\frac{1}{(1+IR)^{Te}}\right) * \left(\left(\frac{Tt-Te}{Tt}\right)\right)$$

Ti corresponds to total investments, *Te* to economic lifetime and *Tt* to technical lifetime while IR is the interest rate. For this particular research it was established as 8% for all AF technologies; however it could be higher for 2nd generation and other unavailable technologies due to risks related. Total costs have been estimated as the sum of capital costs and O&M costs which were either found in existing examples or estimated based on the technical configuration of plants and assuming operating conditions (e.g. annual operation hours) by taking into account maintenance due to associated risks of new technologies [1,2,4].

2.1. Technology Learning

Technology learning is projected in the future development of specific investment costs based on the cumulative number of plants in relationship to an assumed progression ratio [4,5,6,7,8]. The currently existing plants especially for 2nd generation AF technologies are either very new or with short commercial history thus making it difficult to have reliable data and technology experience. Therefore, this parameter has been built as an adjustable progress ratio (***Pr*)** as experienced in case of other industries like aviation, machinery, wind mills etc. and it reflects a maximum of 10 to 30% progress ratio differentiated in small and large scale plants. The following equation indicates the specific investment costs ***(SIC)*** taking into consideration total investments ***(Ti)*** and installed capacities ***(Ic).*** The indicator ***TPI*** corresponds to a technological progress indicator based on the assumed cumulative number of plants as function of time within 5 years periods.

$$\mathbf{SIC} = \frac{\mathbf{Ti}}{\mathbf{Ic}} * \mathbf{TPI} * \left(\frac{\mathbf{Log\ Pr}}{\mathbf{Log\ 2}}\right)$$

2.2. Well to Tank (WTT) and Tank to Wheel (TTW) assessment

The WTT assessment in this study relates to the amount of energy expended and the associated GHG emitted in various steps involved in production and delivery of the fuel. The economic assessment of the pathways considers the scale of production and revenue generated through by-products and other associated production costs. Depending on inputs, WTT economic performance [c€/kWh] and CO_2 emissions have been calculated with the steps involved in producing one kWh of alternative fuel and the corresponding inputs (like electricity, heat, fuel and biomass feedstock) as well as the corresponding emissions factors for each particular input variable. This detailed WTT analysis of the pathway(s) describes various processes involved in cultivation of the feedstock until the distribution of finished fuel at the filling station. The TTW assessment accounts for the energy expended and the associated GHG emitted by the fuel and vehicle technology combinations. In this assessment, the internal combustion engine vehicles were considered to propel with pure biofuel (such as ETBE, FT-diesel) or blended with conventional fossil fuel (E85, B5) [3,4,11]. Complete WTW CO2 emissions were assessed by combining the emission generated during the fuel production pathways WTT [gCO2eq/km] and TTW [gCO2eq/km] emissions generated by combustion of fuel at the level of vehicle. The data that WTW assessment includes are the WTT emitted GHG and expended energy (i.e. excluding the energy content of the fuel itself)

per unit energy content of the fuel [MJf/100 km] and the TTW energy consumed by the vehicle per unit of distance covered.

3. Assumptions

3.1. WTT – Technology Pathways

Biofuel technology pathways were pre-selected by carrying out a pathway analysis based on the evaluation of costs and emissions performance at various stages of production until delivering biofuel at the filling stations. Year 2010 was selected for comparison between conventional and advanced biofuels, as AFs were to have a commercial start up onwards. In the respect of WTT assessment, 26 biofuel pathways were analyzed in this research and they are described in detail below.

Biodiesel pathways stated include rapeseed and sunflower grain cultivation and transportation to the extraction of oil in small scale (SS) or large scale (LS) extraction plants, production of biodiesel in small scale (SS) or large scale (LS) plants, distribution by trucks and storage at filling station (FS). The consideration of by-products for the assessment result in *8 pathways* for the case of biodiesel as indicated below.

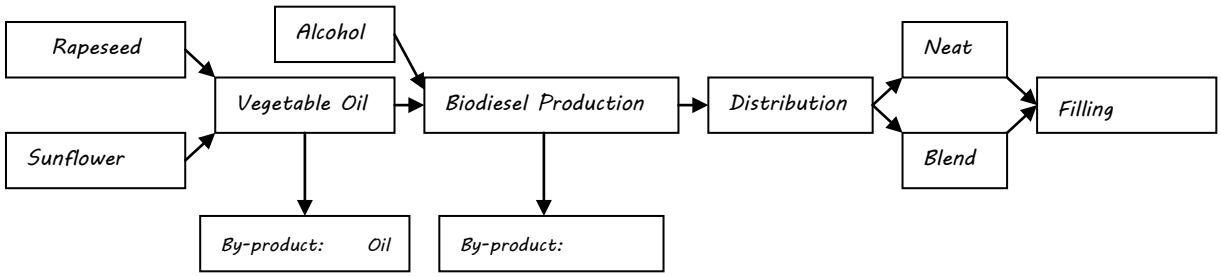

Figure 1: Biodiesel WTT pathways
Source: [1,2]

For bioethanol, *12 WTT pathways* were analysed for both conventional (1st generation) and advanced options (2nd generation) considering biomass production and transport, bioethanol production and distribution until the filling station (FS). Bioethanol production is modelled in small scale (SS) and large scale (LS) plants and the revenues generated from by-products were considered for the assessment (separate pathways for by-products revenues). For lignocellulosic ethanol, by-products have been considered along all the pathways but the differences lie among the feedstock used.

The six BTL Pathways (Figure 3*)* take into account the scale of production plants (small scale, medium scale and large scale) as well as the use of by-products (electricity, heat) however, the differences lie on the biomass pre-treatment techniques using either pyrolysis oil or woodchips pre-gasification in small, medium and large scale F-T Diesel production plants. Power generation data is currently based on demonstration or CHP standard configurations on efficiency and costs. The use of power generation by BTL has the highest contribution to reduce emissions and increase competitiveness.

Source: [1,2]

3.2. Scenarios definition

One *reference and* one *high price* scenarios are defined in this research including the projection of the most important drivers for the production development of alternative fuels AF (e.g. feedstock prices, input prices, co-products). This is a new approach combining not only a mere techno-economic characterization of several technologies but simulating future economic performance under changing the most important parameters dynamically in 5 years steps until 2030. The scenario I (reference) projects until 2030 the most important input materials for alternative fuels production such as biomass feedstock prices, electricity, heat and fuels. The projection reflects conditions before the economic crisis for scenario I considered as a *reference* projection. Scenario II reflects a high prices environment for the same parameters.

With respect to the technology learning the progress ratio, shown as indexed changes in percentage below, reflects enhanced learning as cumulative capacities and production are achieved (scenario II). However, the technology learning projections partially simulate a normal and enhanced learning conditions for AF technologies not directly correlated with the price development of scenario I and II. The values for the major inputs projections for both scenarios and progress ratios are shown in Figure 4 in [c/kWh] and Figure 2 in [%].The projections have been cross checked with experts' assessments and the review of several studies on feedstock prices since 2004 until 2010 [1,2,4,9,10,11]; however, Figure 4 projections assumptions have been made based in correlation with the development of the

projected diesel prices for both reference and high price environments. Two progress ratios changes for technology learning are assumed for modelling technology learning possibilities as shown in Figure 5.

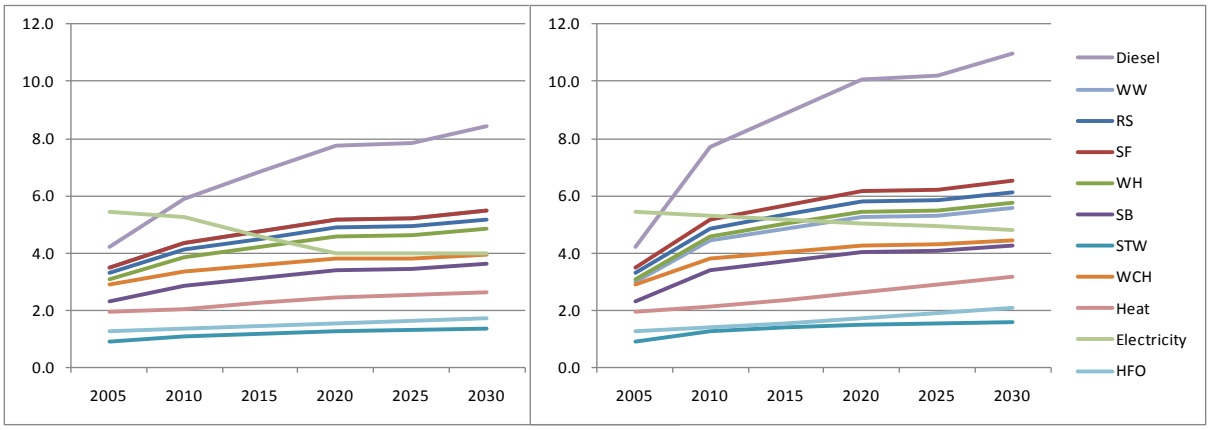

Figure 4: Assumed price changes for AF technologies inputs for scenario I (left) and II (right) until 2030 – [c/kWh]

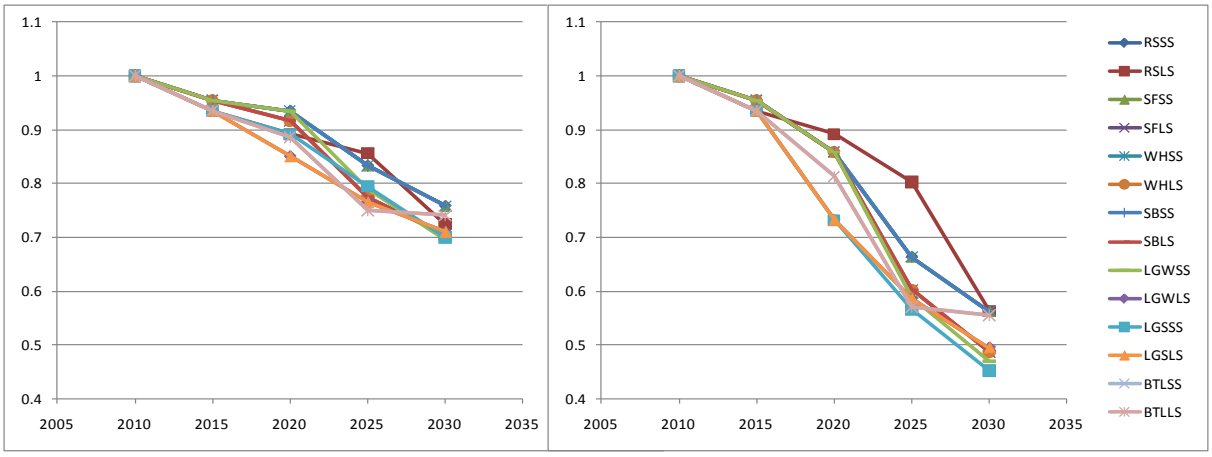

Figure 5: Changes in progress ratios (PR) for AF technologies (large and small scales) for scenario I (left) and II (right) until 2030- [% - index year 2010]

The scenario assumptions should be carefully interpreted as they have strong interaction with other variables (e.g. yields, climate conditions, dietary changes, etc) not directly modelled in the present construct. These scenarios have been defined for all pre-selected pathways, in particular with their inputs such as feedstock for 1st and 2nd generation biofuels, heat, electricity or heavy fuel oil (HFO) among others. In addition, a further assumption is done for technology learning with lower or higher progress ratios in 5 years steps differentiated for small and large scale units.

4. Results and discussion

Results of WTT assessment are illustrated for biodiesel and bioethanol pathways in Figure 6 and Figure 7. BTL results are also available but omitted in graph form due to space limitation. Both figures illustrate the economic performance changes of AFs pathways for both the *reference and high price* scenarios as well as due to the considerations in enhanced technology learning progress ratios for the years 2010 until 2030 in 5 years steps. The number below the graphs corresponds to the number assigned to the pathway for each particular

alternative fuel analysed. Pathway 1[1] (2010) and 27 (2030) for example are identical in configuration but 27 reflects 2030 results. Production economic performance increases 17% in scenario *reference* while almost 20% in scenario II compared to 2010 values. A 2.5% annual increase of rapeseed prices until 2030 (high prices) increases in 16% the costs for oil extraction and biodiesel production when compared to the *reference scenario*. The learning effects are observed in the right side graphs where pathway number 27 reduces its cost performance in further 2% by learning with high progress (experience) ratios of 75% for large scale plants and 80% for small scale plants.

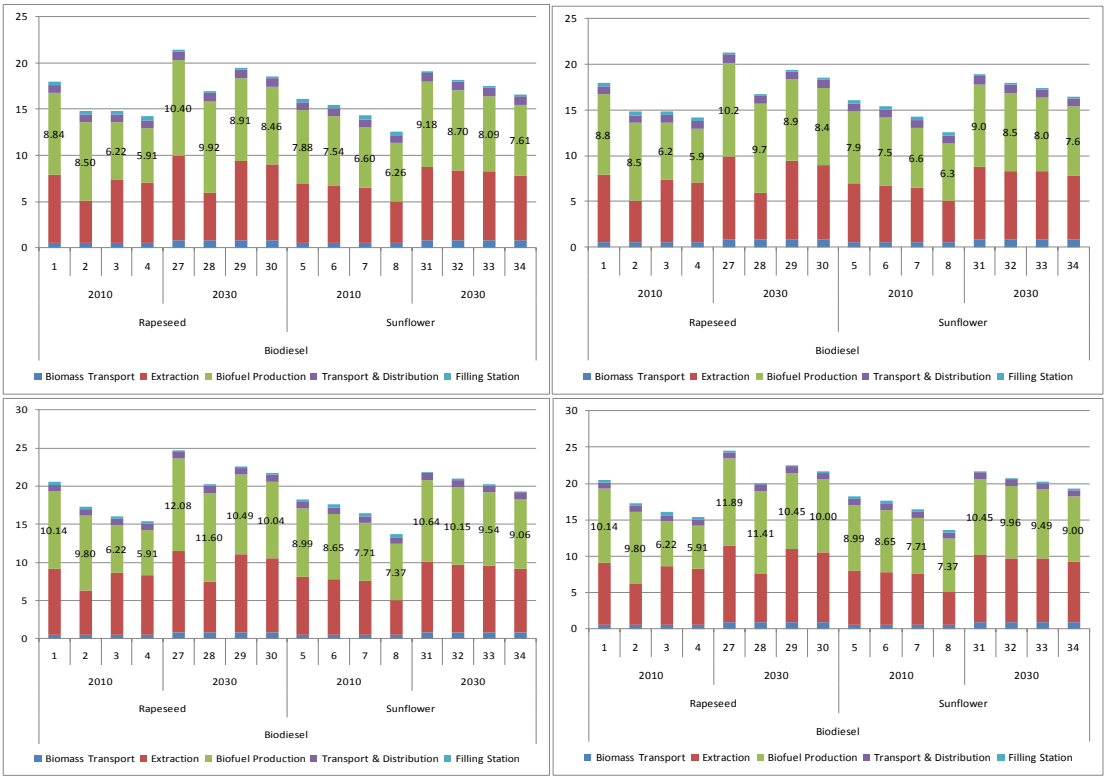

Figure 6: Results of the integrated WTT analysis (economic performance) for Biodiesel pathways for scenario I and II (up) and technology learning (right side graphs)- [c/kWh]

For biodiesel, as observed in the figures, pathways corresponding to large scale facility production, taking into account by-products credits, perform better with respect to economics (and emissions). The major part of the costs for all pathways corresponds to the extraction and production, especially the biomass feedstock prices varying from 50 to 85% of total producing costs. Oil extraction and subsequent biodiesel production are highly sensible to the variation on agricultural production costs.

Bioethanol pathways are grouped for starch (cereals) and sugar-beet crops and lignocellulosic biomass options (straw-2nd generation). The results indicate that the largest part of the costs for all options correspond to bioethanol production, of which the biggest share corresponds to the biomass costs and delivery at the bioethanol production facilities. Non-agricultural biomass feedstock (e.g. Straw) is less vulnerable to feedstock prices changes than the agricultural feedstock for 1st generation bioethanol, exhibiting higher vulnerability to volatile sugar and cereals markets. The benefits from increased learning rates remain marginal for

[1] Biodiesel from Rapeseed in *large scale* facility without by-products credits. Pathway 2 considers by-products also large scale. Pathway 3 and 4 are small scales with the same by-products considerations.

most of the producing options despite of a strong increase in experience (lower ratios) and therefore lower costs.

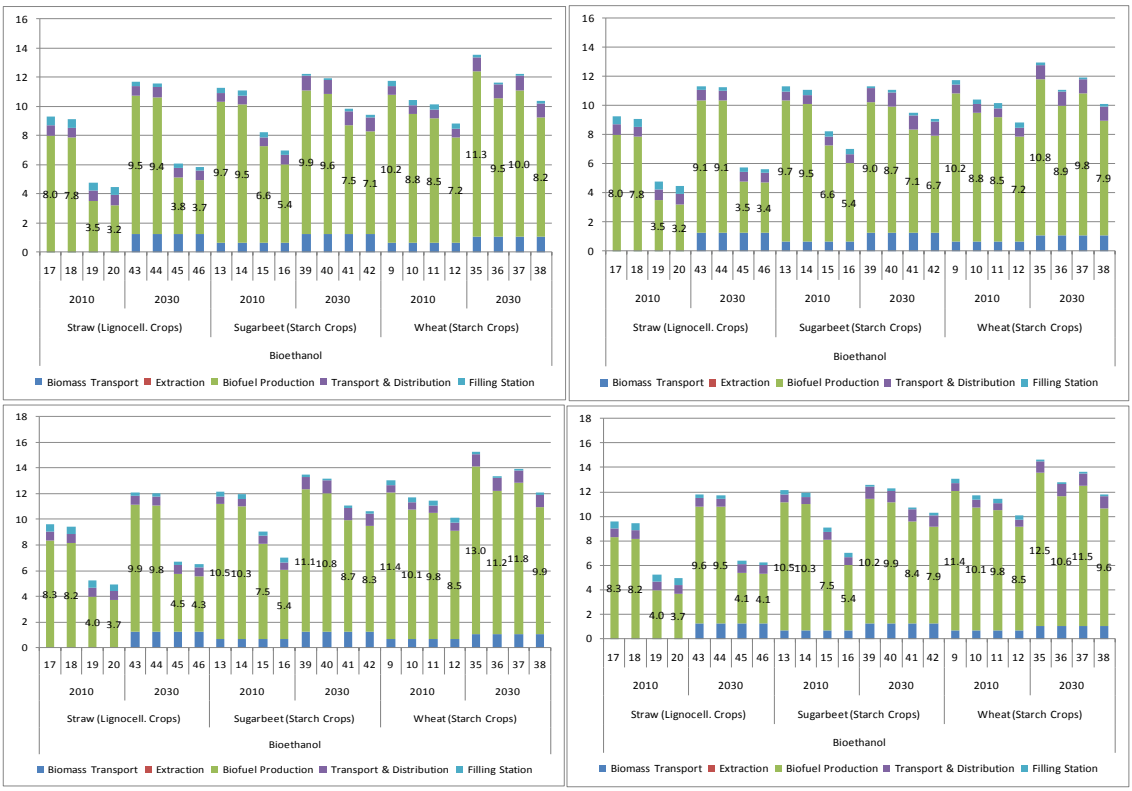

Figure 7: Results of the integrated WTT analysis (costs) for Bioethanol pathways for scenario I and II and technology learning (right side graphs)

The best cost performance corresponds to large scale plants considering by-products credits for animal feed substitution for both cereal and sugar crops. Large scale lignocellulosic bioethanol performs also better in 2010 while in 2030 it also demands logistically an organized supply of straw, however outperform compared to 1st generation options in *reference and high price* scenarios. However, such a facility does not exist currently in the market and this is just an indicative value of the cost ranges of these technologies. Furthermore, short rotation crops (wood) as feedstock for the production of bioethanol with similar plant characteristics have been used in the analysis. This technology is still in development phase and it could mean that higher capital expenditures, especially for large capacities are needed. This technology will enter the market only around 2010 and onwards, and efficiency improvements as well as capacity enlargements are expected to reduce costs in the future. Within the results, the highest emission reduction potentials are obtained for BTL facilities as the energy spent in the process is recovered using the co-generated gas to produce electricity and heat that can be reused internally in the process (self-sufficiency). Followed by the BTL facilities, the second highest reduction potentials are obtained from lignocellulosic ethanol. For biodiesel and bioethanol further emissions improvements are achieved when considering by-products credits as they substitute other materials.

5. Conclusions

The strong dependency of 1st generation alternative fuels on agricultural feedstock is observed in the results for their reference and high price scenarios developments. These technologies have still the potential to achieve costs reductions through learning, increase production, economies of scale; however, the results presented here only show a marginal benefit to increase economic performance. The high volatility of agricultural markets combined with

strong climatic changes and increase in food demand poses higher pressures to producers to develop strategies that keep supply prices down. However, the results of this analysis indicate that large scales plants might have the possibility to perform better than smaller producers, partially also reflected on the possibility to have stocks (not modeled here), however, there are high direct increases in the economic performances of these options in these kind of fuels in high price scenarios prospects. Bioethanol pathways (2^{nd} generation (4-9.5 c/kWh) and starch/cereals 8-11 c/kWh) are close to get competitive with diesel projected prices in 2030 for both large and small scale configurations with by-products credits. Biodiesel inputs are strongly correlated with diesel prices increases and therefore results indicate that these pathways remain uncompetitive. BTL results for high price scenario considering stronger technology learning (ca. 7.8 - 12 c/kWh) are closer to be competitive to diesel projected prices in 2030 for large scale configurations with centralized biomass treatment concepts.

Furthermore, advanced AFs (2^{nd} generation biofuels) that are in R&D and Demonstration phase (non commercial technologies) pose higher risks for investors despite of the fact that they could have faster technology learning when entering the markets especially for certain portions of second generation routes such as lignocellulosic, BTL and Hydrogen. These options are high capital intensive with still unresolved technological challenges on biomass supply possibilities; meet end-use properties like energy content, chemical stability, refueling infrastructure, storage and ex-ante feedstock price projections. The better economic performance observed in these results are partially true in case lower biomass waste streams are used or high value by-products (co-generation) add to the income flows. However, these results should be considered cautiously as the input data for the simulation is based on data that is to be proved in real operating conditions that at the moment can only be obtained by demonstration or pilot projects. In emissions terms, pathways performing better relate to the ones where by-products credits are taken into account especially co-generation plants which definitely will reflect emissions reductions, requiring on the other hand more investments for additional facilities.

Abstract: Hybrid electric vehicles (HEVs) are commercialized and plug-in hybrid electric vehicles (PHEVs) are becoming more popular. PHEVs are charged by plugging into electric outlets or on-board electricity generation. These vehicles can drive at full power in electric-only mode over a limited range. As such, PHEVs offer valuable fuel flexibility. The charging of PHEVs has an impact on the distribution grid because these vehicles consume a large amount of electrical energy and this demand of electrical power can lead to extra large and undesirable peaks in the electrical consumption. The improvements in power quality that are possible by using coordinated charging are emphasized in. It also indicates that not coordinating the charging of PHEVs decreases the efficiency of the distribution grid operation. Several automakers are preparing for the next generation of passenger transportation, Plug-in Hybrid Electric Vehicles (PHEVs). Using data from the Tehran Regional Electric Company (T.R.E.C), this study sought to understand how different charging scenarios for PHEVs could impact electricity demand in Tehran.

Keywords: *Plug-in hybrid electric vehicles; Charging scenario; Distribution grid*

1. Introduction

Plug-in hybrid electric vehicles (PHEVs) are a new and upcoming technology in the transportation and power sector. As they are defined by the IEEE, these vehicles have a battery storage system of 4 kWh or more, a means of recharging the battery from an external source, and the ability to drive at least 10 miles in all electric mode [1]. These vehicles are able to run on fossil fuels, electricity, or a combination of both leading to a wide variety of advantages including reduced dependence on foreign oil, increased fuel economy, increased power efficiency, lowered greenhouse gas (GHG) emissions and vehicle-to-grid (V2G) technology [2–4]. These claims are backed by data suggesting that fueling a PHEV would cost the equivalent of 70 cents per gallon of gasoline when electricity costs 10 cents per kWh [4] and that an all electric driving range of 40 miles could lower oil consumption by two-thirds [4]. Currently, there is little storage available in the power grid so demand and generation must be perfectly matched and continuously managed to avoid frequency instabilities. PHEVs have an energy storage capacity which is rather small for each individual vehicle, but the number of vehicles will be large, yielding a significant energy storage capacity. At any given time, at least 90% of the vehicles are theoretically available for V2G [5,6]. These vehicles must be connected to the grid when idle. There must be enough vehicles plugged in during the day to provide grid services therefore it could be beneficial to give incentives to vehicle owners to stay plugged in. Most of the weekdays, vehicles follow a schedule which does not vary much from week to week [5]. The electrical storage of PHEVs could provide grid services via V2G concept and add a surplus value to the vehicle owner [7]. The reason for choosing Tehran for this study is the air pollution. Cut oil subsides in Iran is another reason for choosing Tehran for this study. At such low prices, domestic demand for energy in Iran has grown very rapidly. With the price reform, you will dampen domestic demand, which means more efficient energy use domestically, more energy available for profitable exports, and higher revenues for the country. From a domestic perspective, if prices are higher, the energy sector in Iran will become more profitable and hence be able to invest,

extract, and produce more. Furthermore, if the Iranian people are able to restrain their consumption, this will have a positive side effect on the global oil market. This will also push the domestic automobile industry to modernize itself. The country produces about 1.5 million cars per year, targeting the domestic market of 74 million people. Since gasoline is almost free, carmakers have little incentive to make their product energy efficient. But when gasoline price rises to the international level, Iranian car manufacturers will have to change the way they operate and increase the energy efficiency of their vehicles. Once this happens, Iranian-made cars will be more competitive on the export market.

2. Transition from conventional vehicles to Plug-in Hybrid Electric Vehicles (PHEV)

For the first time it was German inventor, Nikolaus Otto, who made it possible to use combustions engines in cars for the first time by the invention of the first four-stroke internal combustion engine in 1862. These types of engines are continuously being used in so-called conventional vehicles. The low-efficiency of ICE (Internal Combustion Engines) and high emission production are the most negative points about these types of vehicles. In the figure 1, the recent development in car industry is been shown.

Figure1. Schematic on development in car industry

As it can be seen from the figure (1), the first important breakthrough in car industry after the implementation of ICE in vehicles is the transfer from conventional vehicles to hybrid electric vehicles. These types of vehicles are first commenced in 1997 in Japan by the introduction of Toyota Prius. The main specification of this type of vehicle is the operation of the ICE on its efficient interval by means of a regenerative braking system. The latest generation of the vehicle is introduced in the market recently. They are mostly called PHEVs (Plug-in Hybrid Electric Vehicles) with additional capability to be charged from the grid.

3. Plug-in Hybrid Electric Vehicles (PHEV)

A PHEV is basically has the same structure as a Hybrid Electric Vehicles (HEV) but the grid charging capability is additional feature which consequently result in the necessity of higher battery capacity.

Grid connection capability in PHEVs will make it possible to coordinate energy resources for domestic consumption and also will lead to lower emission production from private cars in the business and residential areas.

The large percentage of the total emissions production is from the low-duty cars which are private and company cars. Reducing emission production is a big challenge for both developed and developing countries. On the other hand, the other major challenge in today's world in the high consumption of fossil fuels with increasing price and diminishing number of resources. Low-duty cars are one of the major sources of fossil fuel consumption. Therefore,

high fuel consumption and emission production are the major incentives to make changes in the low-duty car sector. Moreover, the new ways of electricity generation can be considered as an incentive for introduction of PHEVs.
Global green house gas emissions from the different sectors are show graphically in Figure 2. These gases are included Carbon Dioxide (72% in total), Methane (72% in total) and Nitrous oxide (26% in total) [8].

Table 1. Charging Times for Different PHEV-20s Vehicle Classes under Various Circuit Voltage and Amperage Levels

Vehicle Type	Pack Size (kWh)	Rated Pack Size (kWh)	Charging Circuit	Charging Size (kW)	Charger Rate (kWh/hr)	Time to Charge Empty Pack (hours)
Compact Car	5.1	4.1	120 V 15 Amp 120 V 20Amp 240 V 40 Amp	1.4 1.9 7.7	1 1.3 5.7	4 3 0.7
Mid-Sized Sedan	5.9	4.1	120 V 15 Amp 120 V 20Amp 240 V 40 Amp	1.4 1.9 7.7	1 1.3 5.7	4.7 3.5 0.9
Mid-Sized SUV	7.9	6.3	120 V 15 Amp 120 V 20Amp 240 V 40 Amp	1.4 1.9 7.7	1 1.3 5.7	6.3 4.7 1.1
Full-sized SUV	9.3	7.4	120 V 15 Amp 120 V 20Amp 240 V 40 Amp	1.4 1.9 7.7	1 1.3 5.7	7.4 5.6 1.3

As shown in the figure 2, 14 percent of the emissions are produced by transportation sector which is close to the industrial sector. This means that by removing the emissions from the transportation sector, the total emissions can be reduced approximately as much as industrial sector. The introduction of PHEVs can be even more interesting when the emissions from power station are low and the electricity is generated from clean resources.

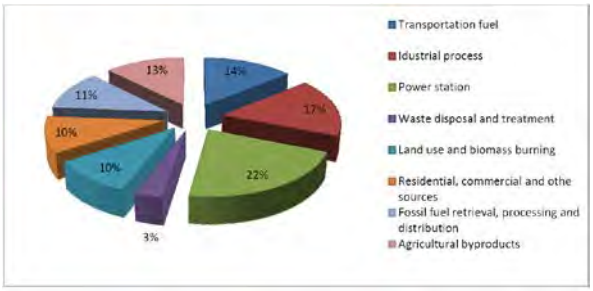

Figure2. Global Green house gasses emissions [8].

Conversion of the cars from the ones with fossil fuel consumption to the ones with electricity consumption is not just interesting from the car sector but also it is interesting from the grid point of view. The high intermittency of the electricity from renewable resources can be synchronized with the intermittency of consumption of electric cars. However, new generation is needed in order to charge the electric cars. The technical parameters of different plug-in vehicles are summarized in Table 1.

4. Plug-in Hybrid Vehicle Charging Scenarios

Electric Power Research Institute (EPRI) has performed studies regarding the energy requirements for potential PHEV vehicle designs. This information, which is summarized in Table 1, provided a basis for the charging scenarios. Figure 3 shows the power demanded for different PHEV-20 vehicle classes using a standard household electrical circuit of 120 volts and 15 amperes.

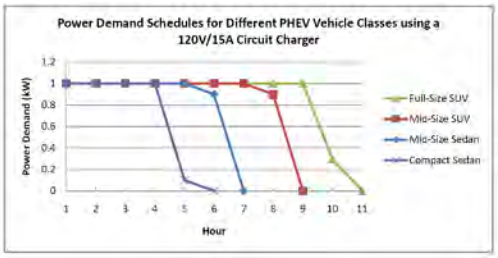

Figure 3. Power Demand Schedules for Different PHEV Vehicle Classes using a 120V/15A Circuit Charger.

The power demand schedules in Figure 3 show a consistent draw of power for the first few hours and then a partial power demand during the last hour of charging. For example, the Compact Sedan PHEV-20 requires 4.1 kWh of energy to fully recharge the battery from a 20% SOC. 1.0 kW of power is needed over the first 4 hours, and 0.1 kW during the 5th hour. This compact sedan therefore would require 4.1 hours to recharge at a rate of 1.0 kW per hour. Since most household outlets already contain 120 volt/15 amp outlets, it was assumed that most PHEVs that reach the market will charge through these circuits. Mid-sized sedan plug-in hybrids with all-electric ranges of 20 miles were used as the standard in the baseline scenarios. Variations to the electric range were used later in this paper. Using the information on charging rates and battery capacity, PHEV power demand curves were generated based around three types of charging scenarios.

The three scenarios representing how vehicle owners might charge their vehicles in the course of a day are summarized below:

Simultaneous Charging: All PHEV owners charge their vehicles at a specified time. This scenario is an adequate upper limit since recharging all the vehicles at one time maximizes the power demanded by plug-in hybrids

.

Continuous Charging: A random percent of PHEVs are connected to the grid throughout the day, requiring a continuous demand of power. A random value between 1% and 50% were established for each hour, representing the percent of PHEVs that are connected to the grid.

Normal Distribution Charging: PHEV charging follows a normal distribution around a specific hour of the day (or mean hour). This represents a scenario between the two limits.

For the simultaneous and normal distribution charging scenarios, an evening charge time of 6 pm is used for the baseline. In the simultaneous charging scenario all PHEVs plug in at 6 pm. For the normal distribution recharge, most of the PHEVs begin charging between the hours of 4 pm and 8 pm (mean hour of 6 pm and standard deviation of 2 hours). Combining the charging scenarios above with the time of day charge and charging circuit size provided the baseline scenarios for this study. Each of these is scenarios are summarized in Table 2.

Table 2. Description of Baseline Scenarios

Scenario	
Scenario 1	All mid-sized sedan PHEV-20s begin charging at 6 pm using 120V/15A charging circuits.
Scenario 2	A random percent between 1% and 50% of mid-sized sedan PHEV-20s charge throughout the day, using 120V/15A charging circuits.
Scenario 3	Mid-sized sedan PHEV-20s charge as a normal distribution about mean hour 6 pm, with a standard deviation of 2 hours, using 120V/15A charging circuits.

Different penetrations of plug-in hybrids were used with each of the charge scenarios above. The PHEVs penetrations represented 5%, 10%, 15%, and 20% of the number of registered vehicles in Tehran.

5. Baseline Charging Scenarios

Using knowledge from previous EPRI studies on lithium-ion battery technology and power demand (table 1), baseline scenarios were created and applied to electricity load demand from the Tehran Regional Electric Company (T.R.E.C). The results from the different baseline scenarios are presented with peak load day. As a reference, the average load in August 2010 is also shown. Figure 4 provides a visual representation of how different penetrations of PHEV-20s recharging at typical household electrical outlets might affect electricity load in Tehran.

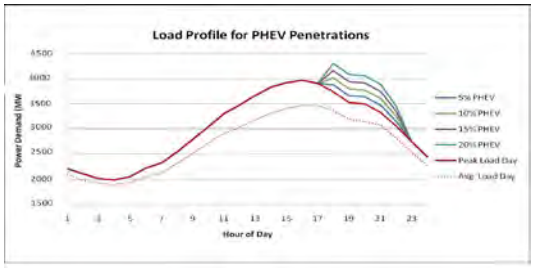

Figure 4. Load profile for PHEV-20 with varying penetrations charging under Scenario 1.

As shown by the peak load day and average August load curves, electricity load is the lowest (below 2500MW) between midnight and 8 am. Electricity generation begins to ramp up starting at 4 am up until 4 pm where it peaks. Electricity load decreases at a faster rate than its initial ramp-up and between the hours of 7 pm and 9 pm, load levels are sustained for a brief period. Peak hours roughly occur between 2 pm and 6 pm. The scenario above represents vehicle owners that all recharge at the same time in the evening (6pm) resulting in a sudden spike in demand.

Figure 5 represents a continuous charging scenario, where up to 50% of PHEV owners could begin to recharge their vehicles at any one particular time. While its probable that PHEV owners will follow a more structured recharge pattern, this scenario helps demonstrate how free access to recharging can spread the demand throughout the day, with slight fluctuations.

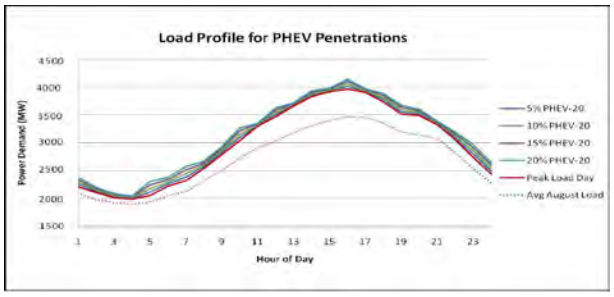

Figure 5. Load profile for PHEV-20 with varying penetrations charging under Scenario 2.

The amount of PHEV-20s that are allowed to charge at any given time is constrained to 50% in the above figure. Open access to the power grid for PHEV owners in this scenario distributes the additional power demand throughout the day, creating a completely new load profile curve.

A more realistic scenario is represented in Figure 6, where recharging occurs as a normal distribution around a specific time period. In this case, it is assumed that most PHEV-20 owners will begin recharging once home from work, around 6 pm.

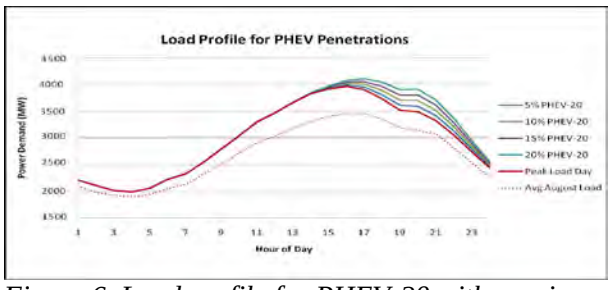

Figure 6. Load profile for PHEV-20 with varying penetrations charging under Scenario 3.

Under Scenario 3, the initial wave of PHEV owners begin charging at 3 pm, and at 6 pm, almost 20% of the owners begin charging. Since the PHEV-20s that connected to the grid between 3 and 5 pm still have not finished fully charging, this lengthens the amount of load necessary to meet demand. The maximum additional electricity demand in this scenario occurs around 8 pm and the last set of PHEV-owners charge at 10 pm, requiring additional power into the late nighttime hours.

The additional power demand at any given hour for the simultaneous scenario represents the load that is sustained for the duration of the charge, in this case, over four hours. Whereas the

simultaneous demand occurs over a short period, the continuous charging maintains a consistent load on the grid throughout the day with much smaller power required. The range for the normal distribution scenarios display the lowest power demand when the fewest PHEV-20s are charging, and the largest demand which occurs at 8 pm, when most vehicles are connected to the grid.

6. Time of Day Charging Variations

The first variation from the baseline scenario is altering the time of day that charging of plug-in hybrid vehicles begin. Shifting the charging to the morning creates the potential for additional load during peak hours. Figure 7 below shows the load profile for the peak day, applying a morning (mean hour of 9 am) charge to the load curve.

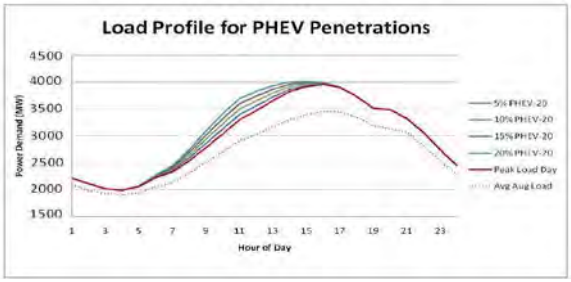

Figure 7. Load profile for PHEV-20 with aarying penetrations charging under a morning (9 am) normal distribution scenario.

As the morning charging scenario demonstrates additional that could occur when PHEV owners plug-in their vehicles after the morning commute leg, the following scenario shows how a nighttime charging scenario might impact Tehran's grid, as shown in Figure 8.

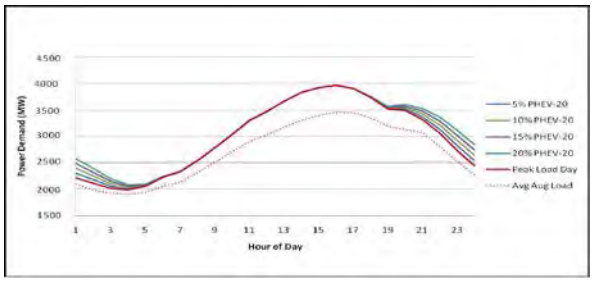

Figure 8. Load Profile for PHEV-20 with Varying Market Penetrations Charging under a Nighttime (10 pm) Normal Distribution Scenario.

Charging the PHEV-20s around a mean hour of 10 pm creates additional demand during the hours when load is diminishing, and reaches into hours when load is the lowest (3 and 4 am). Although the additional demand by PHEVs will ultimately require more electricity generation, charging during the nighttime hours, as shown above, helps to flatten the load curve. Utilizing electricity generation resources into hours when load is low and some electricity is unused, improves efficiency. Although more electricity supply is necessary to meet the demand from PHEVs in all cases, charging at night reduces the need for generating resources to be turned off and back on again.

7. Discussion

Under the simultaneous charging sharp increases can incur and although this is unlikely, it is important to understand this as a potential worst case scenario. The second recharge scenario, where less than 50% of PHEV owners are actively charging their vehicles, the overall load

profile experiences a shift to meet the elevated demand. Although vehicle owners may have the capability to recharge their vehicles multiple times per day, due to the smaller battery power capacity of PHEV-20, vehicle owners may not frequently recharge. For longer electric range PHEVs, such as a PHEV-60, or larger vehicle designs, such as Sport Utility Vehicles (SUVs) which require more energy, the battery may require multiple recharges throughout the day, if the goal is to fully utilize electric drive capability. The final recharge scenario, where recharging follows a normal distribution around 6pm, demonstrates a more realistic behavior pattern. While no sharp increases in demand are expected, it is anticipated that a gradual ramp up in load demand occur during the late afternoon hours and that these resources would be utilized into the evening hours.

8. Conclusion

The results of the study have provided insight into the how Tehran's electricity grid may be impacted from the introduction of plug-in hybrid vehicles. Hours of the day when recharging is expected to occur in large numbers, such as when commuters arrive home from work, can have significant impacts on demand. In the absence of dramatic infrastructure changes with respect to charging stations for PHEVs, most owners will recharge using standard 120V/15A electrical outlets. The charging of PHEV-20 under a 120V/15A circuit would not inconvenience most vehicle owners. The time of day for recharging plug-in hybrid vehicles is an important factor to be considered when planning for this new technology. Late evening hour recharges create additional demand when electricity generation begins to ramp down, only requiring existing generating units to be utilized for a longer duration. If the addition of recharge stations in parking lots where incorporated into the scenario, it would be possible for a portion of vehicle owners to recharge when generation is beginning to ramp up, as shown in the morning charging scenarios.

Abstract: In Europe, passenger cars use over 65% of total transport fuel energy and produce around 12% of total EU carbon emissions. Under such circumstances advanced technologies and modifications in multiple powertrain technologies in passenger cars hold an important key to reduce emissions and energy demand into future. This study compiles a set of efficiency improvement technologies and makes use of a 'Bottom-up simulation' to assess the effects of introduction these technologies on total energy demand and CO_2 emission from passenger cars up to 2030 in the EU-27. The integration of improvement technologies in vehicle will serve the purpose of increasing fuel efficiency, enhancing performance and provide further technical and environmental benefits, but it will also result in incremental costs over the vehicle baseline prices. This research also assesses changes in specific driving costs, cost of CO_2 avoidance and the payback period of incremental costs on the vehicle's economic performance. The technical improvement potentials' options considered in this study show that a 5% to 22% increase in fuel economy of car is possible. And based on assumed diffusion of technologies across total gasoline and diesel vehicles, this study infers a potential of 19% to 34% savings in energy demand and CO_2 emission by 2030.

1. Introduction

Across Europe cars have given the public greatest mobility that is adjustable to different usages, driving locations and preferences, and this trend will continue to grow into future. Over the last few years, increasing environmental concerns, rising oil prices and continuous urge for technological developments have stimulated industries and nations across the world to move towards better efficiency and sustainable practices in the transport sector. To tackle the problems associated with constantly increasing transport fossil fuel demand and greenhouse gas (GHG) emission, it has become very important to consider the alternative fuels and alternative cars for meeting environmental benefits.

In the last few years, the European car manufacturers have invested significant amount of money in the technology R&D, and have introduced more than 50 advanced technologies into the cars for the purpose of efficiency gain and emission reduction. In addition to the varied upcoming vehicle technologies like battery electric vehicles and hydrogen fuel cell vehicles, nowadays a large number of vehicle and powertrain improvement technologies are aimed at increasing the fuel economy and efficiency of the existing conventional vehicles through technical improvements. The core analysis of this paper is based on such 'technical improvement potentials'. This paper is an extension of an ongoing research under the project ALTERMOTIVE, contracted under Intelligent Energy Europe.

Currently, a huge diversity of fuels and advanced powertrain technologies are available in Europe. Table 1 states various alternative automotive mobility technologies (AAMTs) mapped under different developmental stages along the technology curve (Research, Demonstration and/or Commercial state). In Table 1 it can be seen that in addition to the conventional diesel and gasoline cars, few other AAMTs like Natural Gas Vehicles and Flexi

Fuel Cars already exist in the European market on commercial level. These technologies also show continuous process of developments for achieving higher vehicle efficiency and better customer satisfaction. The technologies included under Demonstration phase are not at commercial scale yet, but depending on the speed of progress and overcoming market and cost barriers these may come to commercial phase in next few years. The technologies exhibiting the R&D phase will continue to progress to overcome technical challenges and incompatibilities, and will come to commercial phase no sooner than 2020-2025.

2. Methodology

The method implemented for this study starts with the review of various technical improvement potentials in the European passenger cars along with their potentials in enhancing the vehicle efficiency. In next step, this study selects two sets of innovative improvement technologies called as 'Technology Option 1 & 2' and assesses the impacts of their integration on vehicle's energy demand, CO_2 emission, and economic performance. The main assessments applied in this study with the bottom-up simulation and economic estimations are:

1. Assessing the improvements in the vehicular energy consumption and consecutive CO_2 emission as a result of integration of Technology Options – Techno-Environmental assessment.
2. Assessing the changes in economic performance of the car as a result of incremental costs and technical improvements – Economic assessment.
3. Assessing the potentials of technologies in overall energy demand and emission reduction at assumed diffusion rates across EU-27 car fleet – Techno-Environmental assessment.

2.1. Techno-Environmental assessment:

The techno-environmental assessment carried through the bottom-up simulation is done to assess the energy demand and CO_2 emission by the total European passenger cars (including all types' such as gasoline, diesel, hybrid, bioethanol etc.) for a fixed annual driving distance. For setting up an energy demand baseline, energy demand projections and car fleet size

forecasts in EU-27 until 2030 were derived from Fiorello, et al., (2009). Then the bottom-up simulation tool was built up by using different vehicular data and other input values (like fuel economy, average annual traveling etc.) to assess the overall energy demand and CO_2 emission up to 2030. The general formula for the assessment is:

$$ED_t = \sum\left(F_{i,t} \times D_{i,t} \times FE_{i,t}\right) \quad [\text{PJ}] \quad \text{Eq. 1}$$

Where, ED_t is the total energy demand (including different fuels *Fu*) in the year *t*, *i* is the model year, *F* is the number of vehicles of a model year *i* running in year *t* on fuel *Fu*. *D* is the annual distance travelled by a car of model year *i* in year *t* using fuel *Fu. FE* is the average fuel economy (MJ/100km) of the car for a model year *i*, using fuel *Fu* running in year *t.*

Changes in fuel economy: It was considered that when the technical improvements occur into the car by implementation of *'Technology Options'*, the fuel economy increases by a certain %. The equation used to assess changes in the fuel economy is:

$$FE_e = FE_b \times (1 - \%E_{TO}) \quad [\text{MJ/100km}] \quad \text{Eq. 2}$$

Where, FE_e is the enhanced fuel economy, FE_b is the baseline fuel economy of the vehicle and $\%E_{TO}$ is the percent (%) by which the *'Technology Option'* enhances the vehicle efficiency.

2.2. Economic assessment:

The fuel efficiency of the vehicle can be enhanced by implementation of advanced innovative technologies, but the introduction of new technologies in vehicle will cause extra upfront investments and additional costs to the manufacturers and these costs will add extra price over the vehicle price (McKinsey, 2009). Thus, it is technically feasible to reduce the fuel consumption of new vehicles, but additional costs will be incurred. In this study, following assessments were done.

Incremental Cost of technology options: The concept of Retail Price Equivalent Multiplier (RPE factor) that represents the average additional price consumers would need to pay for an advanced technology was used to assess the incremental costs of technologies.

$$IC_{TO} = C_M \times RPE\ factor \quad \text{Eq. 3}$$

Where IC_{TO} is the incremental cost of Technology Option, C_M is the manufacturer cost of technologies (derived from AEA, 2009) and *RPE factor* is the retail price equivalent multiplier (derived from Vyas, et al., 2000; NRC, 2010).

Specific Driving Costs: the cost of driving per kilometer of vehicle. This cost in the analysis was interpreted as an aggregate construct of vehicle investment costs linked to 8% annual O&M costs, fixed annual driving distance and the vehicle lifetime of 10 years.

$$\boldsymbol{SC_d = \frac{I_a + O\&M}{D_{annual}}} \quad [€/\text{km}] \quad \text{Eq. 4}$$

Where, SC_d is the specific driving cost, I_a is the annual investment cost, *O&M* is the operation and maintenance cost and D_{annual} is the annual distance travelled by the car.

Average payback Period: It is the time period in which the incremental costs can be compensated by the monetary savings that occur as a result of decreased fuel demand by technical improvement.

$$PB_{avg} = \frac{C_i}{YS_{€/a}} \quad \text{[Years]} \quad \text{Eq. 5}$$

Where, PB_{avg} is the average payback period, C_i is the incremental cost and $YS_{€/a}$ is the annual monetary saving (€/a) per year through reduced fuel expenditure.

Cost of CO_2 avoidance or CO_2 abatement costs: It is assumed that for a technically improved vehicle the driver has to bear extra investment costs over the vehicle price. So, how much does it cost (in €) to the driver for saving each tonne of CO_2 is called the cost of CO_2 avoidance. It is calculated by the following formula.

$$CO_2\ abatement\ cost = \frac{C_i}{Tonne\ CO_{2\ saved}} \quad \text{[€/tonnne]} \quad \text{Eq. 6}$$

Where, C_i is the incremental cost and Tonne CO_{2saved} is the CO_2 saved within vehicle life time.

2.3. Sources, Data and Assumptions:

2.3.1. iTREN Reference Scenario (Deliverable-4, 2009): Fiorello, et al., (2009)

This report was chosen for fleet characteristics and energy demand projections as it delivers the quantified data in Europe until 2030 and more importantly the assessment carried in the study does not consider any technical improvements of the cars after 2008. Table 2 states the data and values extracted from Fiorello, et al., (2009).

Table 2 : Baseline values and assumptions (EU-27 passenger car fleet)

	Unit	2005	2010	2020	2030
Total no.of cars-EU-27	1,000 vehicles	211,062	228,120	265,628	294,220
Total Energy Demand	PJ	8,435	9,251	9,630	10,301
CO_2 emissions*	Million tonnes/year	624	684	712	761

Diesel Price	€/litre	0.92	1.25	1.16	1.24

*Source: (Fiorello, et al., 2009), *Calculated by Authors*

2.3.2. Concawe (WTW, Version-2b, 2006 and TTW, Version-3, 2008)

Average characteristics and data for the European passenger cars like vehicle price, engine power, fuel economy, fuel specific emission factor of the fuel etc. were derived from the Concawe reports mentioned above. Table 3 states the data derived for gasoline and diesel cars.

Table 3: Data and values derived from Concawe reports

	Unit	Gasoline	Diesel
Vehicle Price	€	19,000	20,000
Capacity Fuel/Engine Power	kW	77	74
Av. Travelling distance*	Km/yr	18,000	20,000
GHG emission	gm CO_2 eq.per km	165	140
Specific driving costs*	€/100 km	24.18	22.90

Source: (Concawe, 2008)*; *Authors' assumption/calculations*

2.4. Efficiency Improvement Technologies

There are many efficiency improvement technologies that can be introduced in today's vehicles without changing the vehicle's basic type, general size, or performance. Virtually all of the technologies are capable of increasing vehicle efficiency and reducing fuel demand, but they all are not equally ready for the commercial production. The technologies grouped as Technology option 1 and 2 in Table 4 were chosen based on their readiness as they are applicable into the conventional diesel and gasoline passenger cars within 2010-2012 timeframe.

Table 4: Technology Options considered for the study

	Technology Option 1	*Technology Option 2*
Technology Combination	1. Reduced engine friction losses 2. Improved aerodynamics 3. Low rolling resistance tyres	1. Improved aerodynamics 2. Vehicle Weight reduction 3. Optimized transmission 4. Mild downsizing with Turbo Charging 5. Start-stop-system 6. Use of advanced devices (tyre pressure monitoring system, gear shift indicator etc.)
Expected efficiency increase	Around 5%	Around 22%
Source - eff. Increase	(EPA, 2008)	(McKinsey, 2009)
Tech. cost assumption*	10% over car baseline price	30% over car baseline price
Status in Europe	Integrated into new cars by most manufacturers	High consideration for application

**Source: (TNO, 2006), (AEA, 2009)*

2.5. Technology Diffusion Assumption

The term technology diffusion in this study refers to the widespread integration of Technology Options into the new European gasoline and diesel cars up to 2030. For the simulation, the diffusion was considered only within gasoline and diesel cars because both the Technology Options are compatible into these cars without rendering any change to the size or performance of the car. Moreover, gasoline and diesel cars represent the biggest share in the total EU-27 car fleet and this trend of majority will continue to increase at least until 2030.

To build the stock of new cars in EU-27 until 2030, a review of historical vehicle registration data and socio-economic developments was done. Then the review was complemented with the expected GDP growth to establish the expected trend of new car registrations in EU-27.

The two scenarios considered for this study are:

Scenario 1: Technical Potential - Assessment of the maximum energy demand and CO_2 emission reduction potential offered by the technologies under the assumption that Technology Option 2 diffuses extensively across the fleet.

Scenario 2: Autonomous Potential - Assessment of the reduction potential form the technologies under the assumption that the Technology Option 2 diffuses to a limited extent within the new fleet, however followed by autonomous technological progress the Technology Option 1 diffuses widely across the fleet.

Table 5: Technology Diffusion Assumption

		2010	2015	2020	2025	2030
Scenario 1 (Tech.Pot)	Diffusion of Tech. Op 2 into new cars	10%	30%	50%	75%	100%
	Diffusion of Tech. Op 2 into old cars	10%	20%	25%	30%	25%
Scenario 2 (Auto.Pot)	Diffusion of Tech. Op 2 into new cars	10%	15%	20%	30%	35%
	Diffusion of Tech. Op 2 into old cars	10%	15%	18%	20%	20%

3. Results

The results presented in Table 6 are derived by considering the integration of Technology Options into the vehicle. The assessment methods for the techno-environmental and economic assessment take into account all the salient aspects like baseline vehicle price, additional investment costs Technology Options, engine size and fuel capacity, yearly driving distance, diesel and gasoline fuel price projections until 2030 from (Fiorello, et al., 2009).

Table 6: Results of techno-environmental and economic assessments at the vehicular level

Assessed value	Unit	Baseline value (G)	Gasoline Car		Baseline value (D)	Diesel Car	
			Tech. Op.1	Tech. Op.2		Tech. Op.1	Tech. Op.2
Average cost of *'Technology Option'*	€	-	350	2,800	-	350	2,450

The energy demand and emission potential results presented in Table 7 show as what could be achieved when technologies are implemented into the assumed percentage of the EU-27 new gasoline and diesel cars. The scenarios developed within this study show that 19% to 34% reduction in total energy demand and subsequent CO_2 emission can be achieved by 2030.

Table 7: Results of total energy demand and emission saving potential

Results	2010	2015	2020	2025	2030
Baseline – Energy Demand (PJ)	9,253	9,439	9,630	9,959	10,300

Source: Own calculations

It is important to note that diffusion assumptions explained here are based on authors' views supported by technology readiness and expected technical developments. In reality there may be several interactions and measures (like EU policies, market behavior, cost of technologies, consumers' preference etc.) that will affect the relative effectiveness of technologies and their deployment within industry (Skinner, Essen, Smokers, & Hill, 2010). To summarize the results, Figure 1 shows the overall potentials in energy demand and CO_2 emission savings assessed within this study. The figure is converted in % savings for the ease of understanding and combining the energy demand and emission changes until 2030.

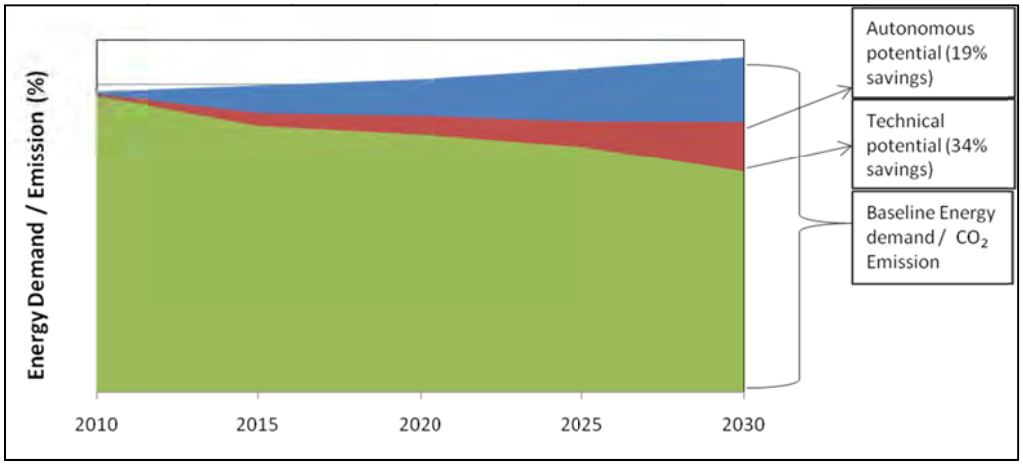

Figure 1: Total energy and CO_2 emission saving potentials
Source: Own calculations and elaboration

4. Discussion and Conclusions

The results and analysis detailed in this paper show the potentials of energy demand and CO_2 emission reduction; however, there are certain limitations in the analysis. The technologies considered in the study are based on the theoretical values and potentials for vehicle efficiency increase, but the results may vary significantly during vehicle segment applications (e.g. small, medium or large cars) and under different on-road driving conditions. Secondly, the technologies included in this study are not the only options that European car manufacturers are considering. There are many other technologies and measures that have varied degree of technology readiness and implementation within cars for the purpose of efficiency increase.

An important aspect regarding the aforementioned results is the compliance of the emission values with the EU regulations on average gCO_2/km emission. The European Commission has established the emission limiting targets by averaging emissions (g/km) of all car models weighted by the sales volumes of the manufacturers. Therefore, when the baseline emission values are compared to the EC targets then this does not imply that all the cars drive at the same mileage and emit same amount of CO_2. All car models across the Europe possess varying mileage range, therefore different vehicle models, car segments and the fuel used in them contribute differently to the average on-road CO_2 emission.

Technical improvement technologies can result in substantial improvements in new car fuel economy and subsequent GHG emission. While virtually all of the technologies are capable of enhancing vehicle efficiency, they are not equally ready for production and integration into the vehicle. Technologies included in Technology Option 1 have been widely introduced into the market until now. And, the technologies included in Technology Option 2 posses high

degree of technology readiness and high consideration by the manufacturers for integration within the current production lines.

Results stated in this study (in Table 6) have shown the increasing pattern of fuel economy in gasoline and diesel cars. Technology Options 1 & 2 have the potential to enhance vehicle efficiency by 5% and 22% respectively, which can save between 0.14 and 0.64 tonneCO_2/year per car for a fixed driving cycle. Results of economic assessment show the decreasing pattern of fuel expenditure in terms of €/100km or €/Year. The assessment shows that both the Technology Options may increase vehicle cost by 10% and 30%, but as a result of increased fuel economy and reduced fuel expenditure, the additional investment can be reimbursed within the certain time period considered as the 'Payback period'. The Technology Options are projected to result in a net cost benefit to the owner over a 10 year vehicle lifetime because the cumulative fuel expenditure savings offset the higher incremental costs. The results of technology diffusion based on bottom-up simulation show that there is a potential of between 19% and 34% reduction in the energy demand and CO_2 emission in the EU-27 up to 2030.

Abstract: This study presents experimental performance of an R134a automotive heat pump (AHP) system driven by a diesel engine and capable of utilizing the heat absorbed from the ambient air, engine coolant and exhaust gas. The experimental setup was developed from the components of the air conditioning system of a compact-size car, and tested by changing the engine speed, engine load and air temperatures entering the condenser and evaporator. The steady-state and transient performance characteristics of the AHP system for each heat source were evaluated by applying energy analysis to the system based on experimental data. Then, the performance parameters of the AHP system for three different heat sources were compared with each other and with those of the baseline heating system. The results show that the AHP system using engine coolant provides higher heating capacities and air temperatures at the register outlet in the first five minutes of the tests. However, the baseline heating system usually performs better than the AHP system when the steady-state is achieved. The AHP system caused an increase in the engine brake specific fuel consumption within the range of 4–54% depending on the engine load.

Keywords: *Automotive heat pump, R134a, Refrigeration, Air conditioning, Automobile*

1. Introduction

Passenger vehicles equipped with a water-cooled internal combustion engine usually utilize the engine waste heat in order to perform comfort heating of the passenger compartment under cold weather conditions. However, this coolant-based heating system cannot provide an appropriate thermal comfort in the passenger compartment until the coolant temperature rises to a certain value. This problem is more critical for the vehicles employing high-efficiency diesel engines due to the lack of sufficient waste heat within an acceptable duration of operation after the engine is started up. With the intention of obtaining thermal comfort rapidly, some vehicles utilize heaters using fuel or electricity. However, these systems have disadvantages such as high initial and operating cost, low efficiency and leading to air pollution as well as global warming. On the other hand, the problem of insufficient heating can be solved by adding some low cost components to the present air conditioning system of the vehicle to operate it as a heat pump. The automotive heat pump (AHP) system can heat the passenger compartment individually, or it can support the present heating system of the vehicle. In the literature, there are several investigations on the performance of AHP systems. Among these studies, Domitrovic et al. [1] simulated the steady-state cooling and heating operations of an automotive air conditioning (AAC) and heat pump system using R12 and R134a, and determined the change of the cooling and heating capacities, coefficient of performance (*COP*) and power consumption with ambient temperature at a fixed compressor speed. Hosoz and Direk [2] evaluated the performance of an air-to-air R134a AHP system, and compared its performance with the performance of the air conditioning system. Rongstam and Mingrino [3] evaluated the performance of an R134a AHP system using engine coolant as a heat source, and compared it with the performance of a coolant-based heating system at an ambient temperature of –10ºC. Scherer et al. [4] reported an on-vehicle performance comparison of R152a and R134a AHP systems using engine coolant as a heat source.

Antonijevic and Heckt [5] developed and evaluated the performance an R134a AHP system, which was employed as a supplementary heating system. They carried out the tests at very low ambient temperatures and compared the performance of the AHP system with that of other supplemental heating systems.

In this study, an experimental AHP system capable of providing a conditioned air stream by utilizing the heat absorbed from the ambient air, engine coolant or exhaust gas was developed. In the experimental system, after passing through the indoor unit, the conditioned air stream was sent to the vehicle passenger compartment through a flexible air duct. In the experiments, the engine speed, engine load and air temperatures entering the condenser (indoor unit) and evaporator (outdoor unit) were controlled and concisely adjusted. The investigated performance parameters were the air temperature at the compartment front register outlet, mean air temperature in the passenger compartment, heating capacity, coefficient of performance and the increase in the brake specific fuel consumption (*BSFC*) of the engine caused by the operation of the AHP system.

2. Methodology

The experimental AHP system was usually made from the original components of an AAC system of a compact size car. As schematically shown in Fig. 1, it employs a seven-cylinder fixed-capacity swash-plate compressor, a parallel-flow micro-channel outdoor coil, a laminated type indoor coil, two thermostatic expansion valves, a reversing valve to operate the system in reverse direction in heat pump operations, a brazed plate heat exchanger between the engine coolant and the refrigerant to serve as an evaporator and another plate heat exchanger to extract heat from the exhaust gas.

All lines in the refrigeration circuit of the system were made from copper tubing, and insulated by elastomeric material. The indoor and outdoor coils were inserted into separate air ducts of 1.0 m length. In order to provide the required air streams in the air ducts, a centrifugal fan and an axial fan were placed at the entrances of the indoor and outdoor air ducts, respectively. These ducts also contain electric heaters located upstream of the indoor and outdoor coils. The indoor and outdoor coil electric heaters can be controlled between 0–2 kW and 0–6 kW, respectively, to provide the required air temperatures at the inlets of the related coils. The refrigeration circuit was charged with 1600g of R134a. In order to gather data for the performance evaluation of the experimental AHP system, some mechanical measurements were conducted on it. The employed instruments and their locations are depicted in Fig. 1, and the characteristics of the instrumentation are reported in Table 1.

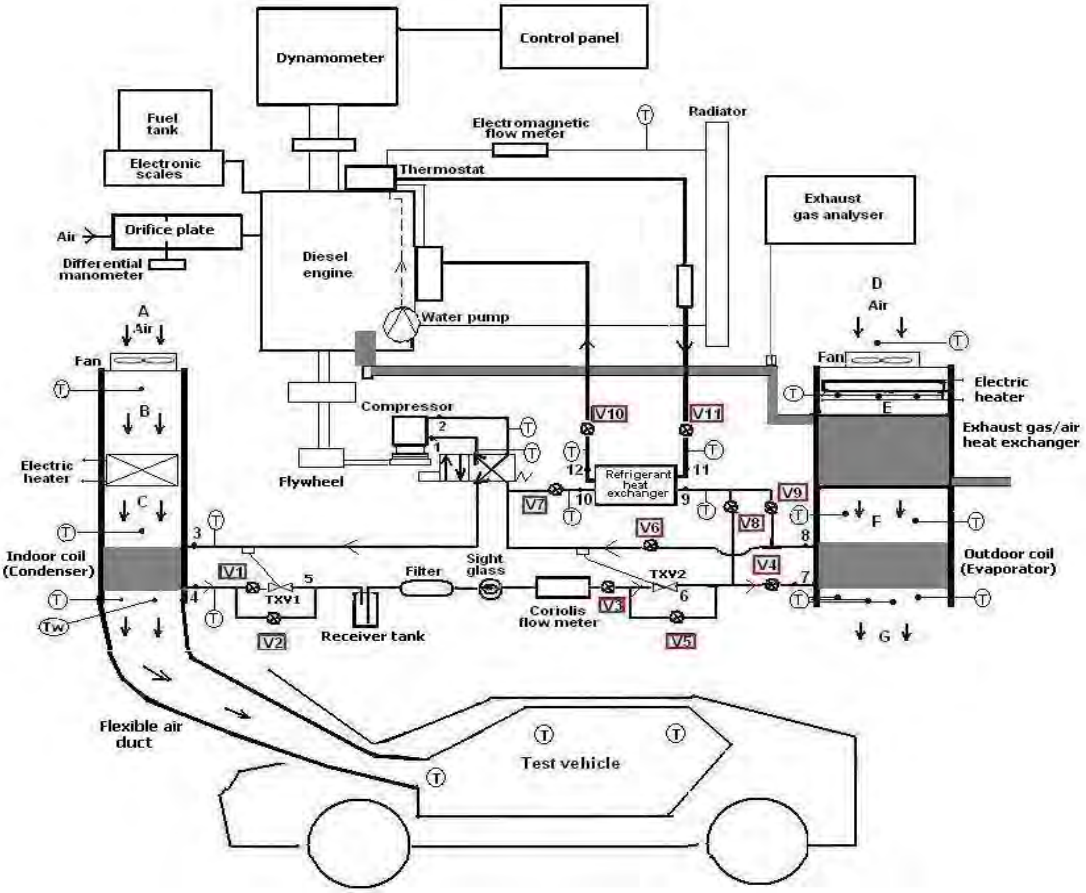

Fig. 1. Schematic illustration of the experimental AHP system and test vehicle (The arrows show the flow paths in the heat pump operations using ambient air and exhaust gas as a heat source).

Table 1. Characteristics of the instrumentation.

Measured variable	Instrument	Range	Uncertainty
Temperature	Type K thermocouple	–50–500 ºC	± % 0.3
Pressure	Pressure transmitter	0–25 bar	± % 0.2
Air speed	Anemometer	0.1–15 m s^{-1}	± % 3
Refrigerant mass flow rate	Coriolis flow meter	0–350 kg h^{-1}	± % 0.1
Compressor speed	Digital tachometer	10–100000 rpm	± % 2
Torque	Hydraulic dynamometer	5–750 Nm	± % 2

The refrigerant mass flow rate was measured by a Coriolis mass flow meter. The temperatures of the refrigerant and air at the inlet and outlet of each component were measured by K-type thermocouples. The refrigerant pressures at the inlet and outlet of the compressor were measured by both Bourdon gauges and pressure transmitters.

The AHP system was driven by a Fiat Doblo JTD diesel engine with a cylinder volume of 1900 cc and a maximum power of 77 kW at 4000 rpm. The engine torque and speed were measured by means of a hydraulic dynamometer with a maximum measuring power of 100 kW, a maximum torque of 750 Nm and a maximum speed of 6000 rpm. The fuel consumption was measured using an electronic scale and a chronometer. Most of the measurement data were acquired through a data acquisition system and recorded on a computer.

The conditioned air stream discharged from the condenser duct was supplied to the passenger compartment of the test automobile Renault Safrane. The connection between the evaporator

duct and the compartment was performed using an insulated flexible air duct. In order to measure the compartment temperatures, a thermocouple was located at the outlet of the front register, another one was suspended in the air close to the front left seat at the driver neck level, and the last one was suspended in the air close to the rear right seat at the passenger neck level.

Fig. 1 also illustrates the refrigerant flow paths in the experimental heat pump system for the cases of using ambient air or exhaust gas as a heat source. In order to perform the heat pump operation, the reversing valve is energized. Then, the reversing valve directs the high temperature superheated vapour refrigerant discharged from the compressor to the indoor coil. Afterwards, the refrigerant condensed in the indoor coil enters the outdoor unit (evaporator) through the thermostatic expansion valve (TXV2). The refrigerant evaporates by absorbing heat from the ambient air stream, which can be preheated by the exhaust gas/air heat exchanger in the heat pump operations using the exhaust gas as a heat source. Finally, the evaporated refrigerant is drawn by the compressor through the reversing valve.

In order to operate the experimental system as a heat pump using engine coolant as a heat source, the refrigerant is directed to the refrigerant/coolant heat exchanger after passing through the TXV2. In this case, the refrigerant absorbs heat from the engine coolant and has a high superheat at the exchanger outlet. In order to test the baseline heating system, the heater core is located downstream of the indoor coil and connected to the proper terminals of the engine thermostat. Further information on the experimental AHP system and its instrumentation can be found in references [6, 7].

The performance parameters of the experimental AHP system can be evaluated by applying the first law of thermodynamics to the system. Using this law for the indoor coil (condenser), the heating capacity of the experimental AHP system can be evaluated from

$$\dot{Q}_{cond} = \dot{m}_r (h_{cond,in} - h_{cond,out}) \quad (1)$$

where $\dot{m}_r$ is the refrigerant mass flow rate and h is the enthalpy of the refrigerant.

Assuming that the compressor is adiabatic, the compressor power absorbed by the refrigerant can be obtained from

$$\dot{W}_{comp} = \dot{m}_r (h_{comp,out} - h_{comp,in}) \quad (2)$$

The energetic performance of the AHP system is found by evaluating its *COP*, defined as the ratio between the heating capacity and compressor power, i.e.

$$COP = \frac{\dot{Q}_{cond}}{\dot{W}_{comp}} \quad (3)$$

The power output from the engine, which is called the engine brake power, can be determined from the product of the engine torque and engine speed, i.e.

$$\dot{W}_{brake} = T \frac{\pi n}{30} \quad (4)$$

The brake specific fuel consumption of the engine can be evaluated from

$$BSFC = 3600 \frac{\dot{m}_F}{\dot{W}_{brake}} \quad (5)$$

where $\dot{m}_F$ is the fuel consumption rate of the engine.

3. Results

In order to perform the tests, the diesel engine was operated at five different speeds, namely 850, 1200, 1550, 1900 and 2250 rpm. Because the diameters of the crankshaft and compressor pulleys are the same, the engine speed is equal to the compressor speed. The tests at 850 rpm were performed at the dynamometer loads of both 5 Nm (idling operation) and 60 Nm, while tests at other speeds were performed only at the dynamometer load of 60 Nm. In all tests, the air flow rate at the front register outlet was adjusted to its maximum (0.403 m^3s^{-1}). In the tests using ambient air and exhaust gas as a heat source, the air flow rate passing through the outdoor coil was also adjusted to its maximum (0.52 m^3s^{-1}). Before performing the tests, the air temperatures at the inlets of the indoor coil ($T_{ind\ coil,\ ain}$) and outdoor coil ($T_{outd\ coil,\ ain}$) both were fixed to 5 °C. Meanwhile, the relative humidity of the air stream entering the outdoor coil was between 50 and 70%. After these adjustments, the diesel engine was started up and the engine speed along with dynamometer load was rapidly adjusted to the required values. Using data acquired in the test operations, the steady-state performance of the AHP system was evaluated from the Eqs. (1–5), while the air temperature at the outlet of the front register and the mean air temperature in the compartment were considered as the parameters showing the transient behaviour of the system.

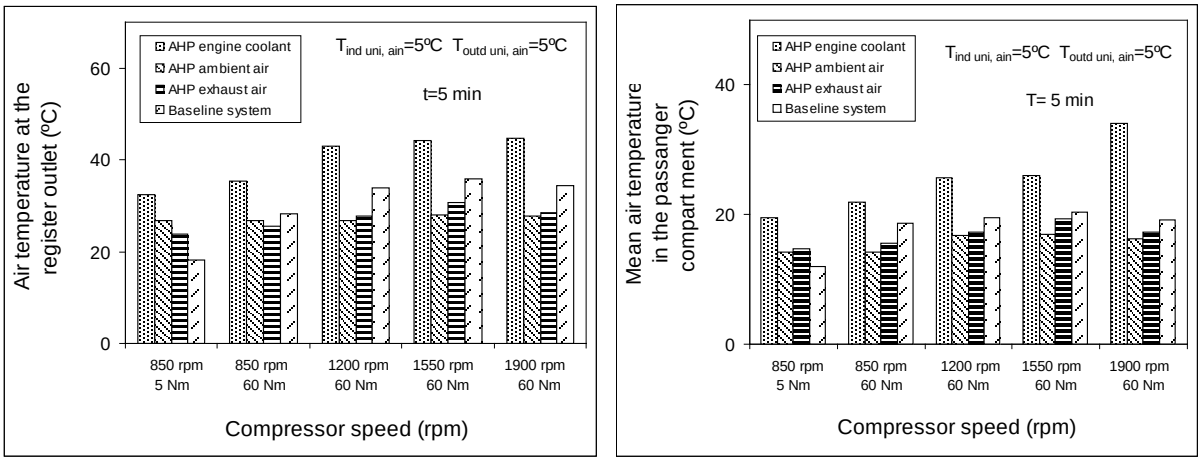

Fig. 2. The change of the air temperature at the compartment front register outlet (a); the change of the mean air temperature in the compartment (b) (both temperatures were recorded at the end of five-minute operation period).

Fig. 2 (a) shows the comparison of the fifth minute air temperatures measured at the front register outlet of the vehicle for the AHP systems and baseline heating system for different compressor speeds and dynamometer loads. It can be seen that the AHP system using engine coolant has higher air temperatures at the front register outlet compared with the AHP systems using ambient air and exhaust gas as well as with the baseline heating system. As the engine coolant temperatures increases, the evaporating temperature also increases, thus yielding higher condensing temperatures and conditioned air temperatures. It is seen that in

the heat pump operations, the air temperature at the front register outlet rises immediately after the compressor is started up. At 850 rpm speed and 5 N m load conditions, the AHP system using engine coolant provides a fifth minute air temperature at the front register outlet of 32°C, while the AHP system using ambient air and exhaust gas yields 26 and 23°C, respectively, and the baseline heating system provides only 18 °C, which is unacceptably low.

The air temperature at the front register outlet rises for all AHP systems when the engine speed and load are increased. In the AHP systems using engine coolant and exhaust gas, this increase is due to the elevated coolant and exhaust gas temperatures, respectively. As the engine speed increases, the refrigerant mass flow rate also increases, thus providing higher heat rejection in the condenser and higher air temperatures at the front register outlet for all AHP systems. Although the AHP system using engine coolant yields higher fifth minute conditioned air temperatures than the baseline heating system, the AHP systems using ambient air and exhaust gas cannot usually provide so high temperatures. Fig. 2 (b) demonstrates the changes of the fifth minute mean air temperatures in the passenger compartment as a function of compressor speed. When the engine speed and load are increased, the mean air temperature in the passenger compartment rises for all AHP systems and the baseline system. For the operations with the engine coolant, this increase is due to the elevated coolant temperature.

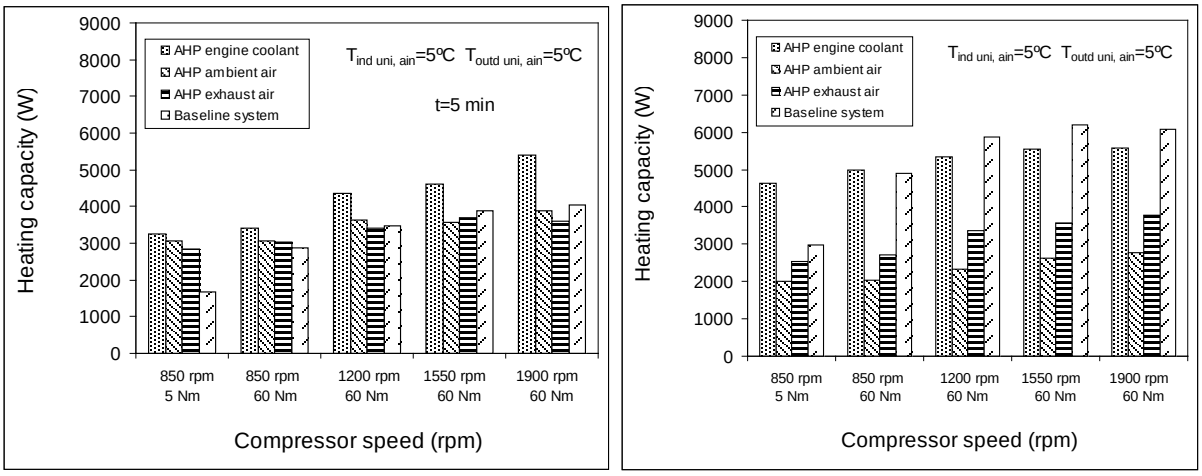

Fig. 3. The change of the heating capacity at the end of five-minute operation period (a); the steady-state heating capacity (b).

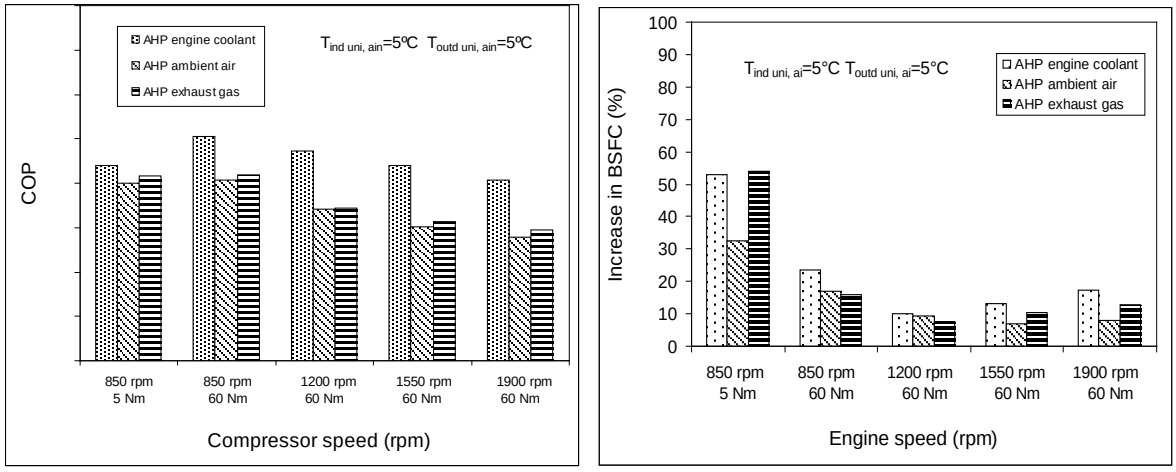
Fig. 3 (a) indicates the variations in the fifth minute heating capacity as a function of compressor speed. The heating capacity at the end of the five-minute operation period increases with the compressor speed at a constant engine load. At 60 Nm load conditions, the coolant based AHP system has the highest fifth minute heating capacity at all engine speeds, which is usually followed by other heat pump systems and baseline heating system. Fig. 3 (b) demonstrates that the steady-state heating capacities are usually higher than the fifth-minute ones. In the AHP system with the engine coolant, the refrigerant absorbs a greater amount of heat from the coolant heat exchanger, thereby providing considerably higher heating capacities compared with the AHP system with ambient air or exhaust gas. In the tests performed at 850 rpm and 5 Nm, the coolant based AHP system has the highest steady-state heating capacity, which is followed by the baseline heating system, AHP system using exhaust gas and AHP using ambient air in descending order. However, as the compressor speed is increased, the heating capacity of the baseline heating system gets higher.

Fig. 4(a) indicates the variations in the coefficient of performance of the experimental AHP system as a function of compressor speed based on steady-state data. It is seen that the *COP* for heating decreases by increasing the compressor speed since the compressor power increases faster than the heating capacity does with increasing compressor speed. The AHP system using engine coolant provides the highest *COP* compared with the AHP systems using ambient air and exhaust gas. Fig. 4 (b) shows the impact of the operation of AHP systems on the brake specific fuel consumption at different compressor speeds and engine loads. The *BSFC* increase caused by the AHP operations is very low when the engine speed and load are at high values because most of the power provided by the engine is applied to the dynamometer at these conditions. On the other hand, most of the power provided by the engine is used by the compressor of the AHP system when the engine is operated at low speeds and loads. Therefore, the increase in the *BSFC* due to the operation of the AHP system ranges between 4% and 54% depending on the engine speed and load.



(a) *(b)*

Fig. 4. The change of the COP (a); the increase in the brake specific fuel consumption caused by the operation of the AHP system (b).

4. Discussion and conclusions

Both transient and steady-state performance parameters of an experimental automotive heat pump system charged with R134a and using ambient air, exhaust gas and engine coolant as a heat source have been evaluated. The AHP system was coupled to the passenger compartment of a test vehicle by means of a flexible air duct in order to supply the conditioned air stream to the compartment. The performance of the AHP system for each source was revealed by performing tests at various compressor speeds and engine loads. The performance parameters of the AHP system for each heat source were compared with those of the system using other heat sources and with those of the baseline heating system. Based on experimental data, the heating capacity, coefficient of performance, air temperature at the front register outlet, mean air temperature in the compartment of the test vehicle and the increase in the *BSFC* caused by the operation of the AHP system were presented as a function compressor speed. The following conclusions can be drawn from this investigation:

- When the engine is operated at idling conditions (n=850 rpm and T=5 Nm), the AHP system using engine coolant provides the highest steady-state conditioned air temperatures and heating capacities compared with the AHP system using ambient air and exhaust gas and with the baseline heating system.

- On increasing the engine torque and speed, the baseline heating system provides higher heating capacities after the steady-state has been achieved.
- The AHP system using any heat source yields higher conditioned air temperatures and heating capacities than the baseline heating system at the end of five-minute operation period when the engine is operated at the idling conditions.
- Only, the AHP system using engine coolant as a heat source provided a better fifth-minute heating capacity than the baseline heating system at speeds over 850 rpm when the engine load is 60 Nm.
- The AHP system using the engine coolant yields the highest *COP*s, while the AHP system with ambient air results in the lowest ones.
- The AHP system causes an increase in the *BSFC* of the engine within the range of 4–54% depending on the engine speed and load.

Compared with the baseline heating system, when the engine speed and load are at low values, the use of all considered AHP systems at transient phase are advantageous in terms of heating capacity and conditioned air temperature. Because the AHP system using the engine coolant provides higher heating capacities than other alternatives, this system can heat the passenger compartment individually, or it can support the present heating system of the vehicle in expense of increased *BSFC*.

Abstract: New Zealand is a small isolated country in the South Pacific with a population of 4.3 million people that has a strong commitment to reducing greenhouse gas emissions stemming both from its drive for global branding of principal export commodities and a desire to invest in new green technologies. New Zealand's renewable electricity generation reserve using biomass and wind alone is as much as 11 times the 2009 annual electricity demand. In this study the practical limits of fossil fuel reductions in the electricity and road transport sectors of the New Zealand economy are investigated using the multi-region partial equilibrium economic model UniSyD to examine a low carbon scenario in which oil reaches a maximum of US$200/bbl in 2030 in conjunction with a carbon tax of US$200 per tonne of carbon dioxide equivalent. In this scenario biofuel and electric drive vehicles are found to constitute 8% and 36% of the light vehicle fleet in 2050 respectively, with the balance of 56% still being fossil fuel vehicles. Government regulation is likely needed to reduce the proportion of fossil fuel vehicles to below 30% of the total fleet.

Keywords: *Alternative fuel vehicle, battery electric, hydrogen fuel cell, emissions*

1. Introduction

New Zealand is a small isolated country in the South Pacific with a population of 4.3 million people that has a strong commitment to reducing greenhouse gas emissions stemming both from its drive for global branding of principal export commodities and a desire to invest in new green technologies. As part of the commitment to reduce greenhouse gases New Zealand is one of the 187 countries to sign the Kyoto Protocol [1], one of 126 countries that agreed to the Copenhagen Accord [2], and in 2010, joined 28 other countries that have an emissions trading scheme [3].

In 2009 New Zealand produced 72.5% of its electricity from renewable energy [4] with the government aiming to increase this to 90% by 2025 [5]. Based on data from [6] and [7] New Zealand's potential renewable electricity generation reserve using biomass and wind alone is as much as 11 times the 2009 annual electricity demand with this being reduced to a factor of four if a wholesale electricity price limit of 8.4 USc/kWh is imposed. This provides opportunity to consider excluding fossil fuels from the electricity generation and transport sectors except where necessary to provide stability to the national electricity grid.

Studies on the economic impacts of alternative vehicle technologies on the New Zealand economy ([8], [9], [10]) have shown that a hydrogen fuelled fleet offers significant savings over a long range (320 km) battery electric vehicle (BEV) fleet. To achieve up to 80% reductions in greenhouse gas emissions from the transport sector a transition to all-electric vehicles will be necessary. This transition will include the adoption of a range of vehicle technologies [11].

Replacing fossil fuels in the electricity generation mix in New Zealand was shown to be possible for the period 2005-2007 [12]. The key factor in optimizing supply was the effective use of hydro in conjunction with wind. Wind energy spillage, peak load shifting and back-up fossil based peaking plant, were also important elements.

In this study the practical limits of fossil fuel reductions in the electricity and road transport sectors of the New Zealand economy to 2050 are investigated using the multi-region partial equilibrium economic model UniSyD4.4. The term "practical limit" in the context of this study means the utilization of all the available renewable energy resources of New Zealand that are economically viable within the scenario parameters. These resources include hydro, geothermal, wind, biomass (lignocellulose, rape seed) and solar.

2. Methodology

To explore the practical limits of fossil fuel reductions in the electricity and road transport sectors two scenarios were constructed. Each scenario excluded plug-in hybrid vehicles (PHEV) on the basis that these are an intermediate technology between conventional internal combustion engine vehicles (ICEV) and full electric drive vehicles. The scenarios are:

(i) Fossil Future (FF) in which no electric vehicles except hybrids (HEV) compete with the ICEV fleet before 2050. The carbon tax is US\$15/t-CO_{2eq} and the oil price rises at 2% per annum in real terms to a maximum of US\$120/bbl by 2030.
(ii) Renewables Future (RF) in which BEVs with a 320 km range and HFCVs compete for market share in the vehicle fleet along with HEVs. The carbon tax is US\$200/t-CO_{2eq} and the oil price rises at 4.7% per annum in real terms to a maximum of US\$200/bbl by 2030. No coal fired fossil fueled electricity generation is permitted.

The scenarios were simulated using the multi-regional partial equilibrium model UniSyD4.4 [8]. This is a system dynamics based model with a high degree of technological specificity in the electricity generation and transport sectors of the New Zealand economy. Each energy sector considers existing technologies and those that are contending to come on-stream to 2050 such as co-generation of hydrogen and electricity from coal or natural gas with sequestration as an option [8]. The model contains about 1150 variables and equilibrates supply and demand in fortnightly time steps in four primary markets in 13 geographic regions of New Zealand. These four markets comprise electricity generation, hydrogen generation, lignocellulose from purpose grown forests and the vehicle fleet. The model incorporates dynamic interactions based on the elasticity of prices with demand. The primary energy resource base for the model consists of hydro, geothermal, wind, biomass (lignocellulose, rape seed), natural gas, coal and solar.

The electricity market regions generate, import and export electricity based on the price of regional production and grid transmission costs. Options for electricity generation or energy saving on a domestic scale include micro-cogeneration of electricity and heat using either hydrogen or natural gas along with rooftop photovoltaics and solar thermal water heating. Temporal fluctuations in wind are neglected.

In the hydrogen market there are four centralised plant types of biomass gasification, coal gasification, large steam methane reforming and coal co-generation of hydrogen and electricity with sequestration of emissions using a solid oxide fuel cell topping cycle. There are five sizes for each plant to match supply with change in demand. Plants in the electricity and hydrogen markets are built by extrapolating demand growth from the previous three years up to four years in the future.

In the lignocellulose market, supply from forests is directly related to the forest residuals and purpose grown forest supply curve based on data from [6]. The biomass cost is determined on a marginal pricing system set in competition between the use of biomass for hydrogen,

bioethanol production and electricity generation. The decision to build a new biomass based plant is determined by the same mechanism as the hydrogen market.

The vehicle market model uses a standard logit choice, also known as a conditional logit model [13] to determine the market share of any particular vehicle technology. The market share is a function of elasticities of fuel cost, purchase price as shown in Fig. 1, maximum range and consumer driving distance.

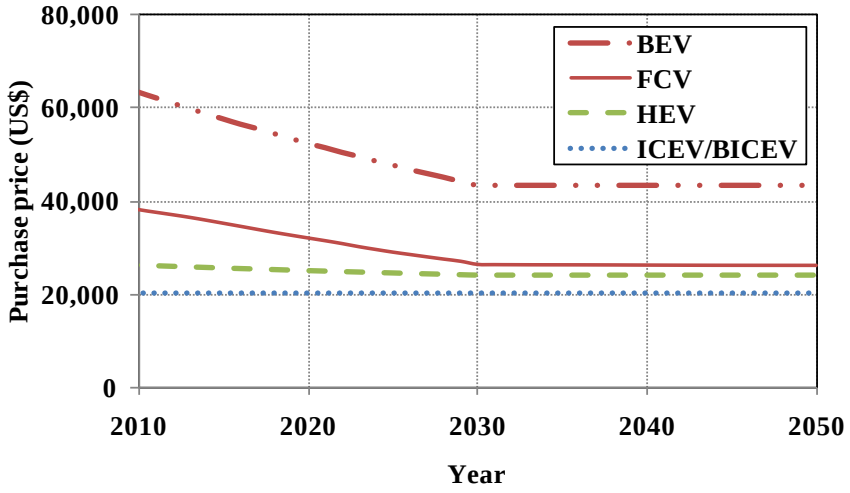

Fig. 1: Purchase price of alternative vehicles.

The standard logit choice model used in this study gives the market share of item i (S_i), as a function of the price (p_i), the price elasticity (β_i), and the intrinsic preference parameter (γ_i). The market share, S, is given by [13]:

$$S_i = \frac{e^{(\beta_i p_i - \gamma_i)}}{\sum_j e^{(\beta_j p_j - \gamma_j)}} \quad (1)$$

A significant feature of Fig.1 is that the long term purchase price of BEVs with a 320 km range is likely to be 80% higher than the mean of the other options. In the vehicle market ICEVs, HEVs, FCVs, and BEVs compete for market share. As imported vehicles represented 48.6% of the light fleet in 2009 [14] the imported and New Zealand new light vehicle fleets are modeled separately.

3. Results

The model results for the Fossil Future and Renewables Future scenarios are shown in Figs. 2 and 3 respectively. Under the FF scenario Fig. 2a shows electricity generation from wind increases rapidly after 2025 with the mandated phasing out of fossil fuels. Wind penetration in 2050 is 35% of total generation by 2050 with hydro 38%, geothermal 18% and 9% other renewable generation such as biogasification. In Fig. 2b the electricity price averages about 7.0 USc/kWh after 2030 with the price spike in 2022 reflecting a short term electricity shortage due to the phasing out of coal production that is independent of carbon tax policy. In Fig. 2c, bioethanol production from forest resources provides fuel for 12% of the vehicle fleet by 2050 (Fig. 2e and 2f) with the balance of 88% being fossil fueled. In Fig. 2d GHG emissions decrease by 7% between 2010 and 2050 with a 34% reduction during the period 2020 to 2030 with the reduction in fossil fueled electricity generation. Improving fuel

economy in the vehicle fleet limits increases in GHG emissions for the period 2030 to 2050 to 17%.

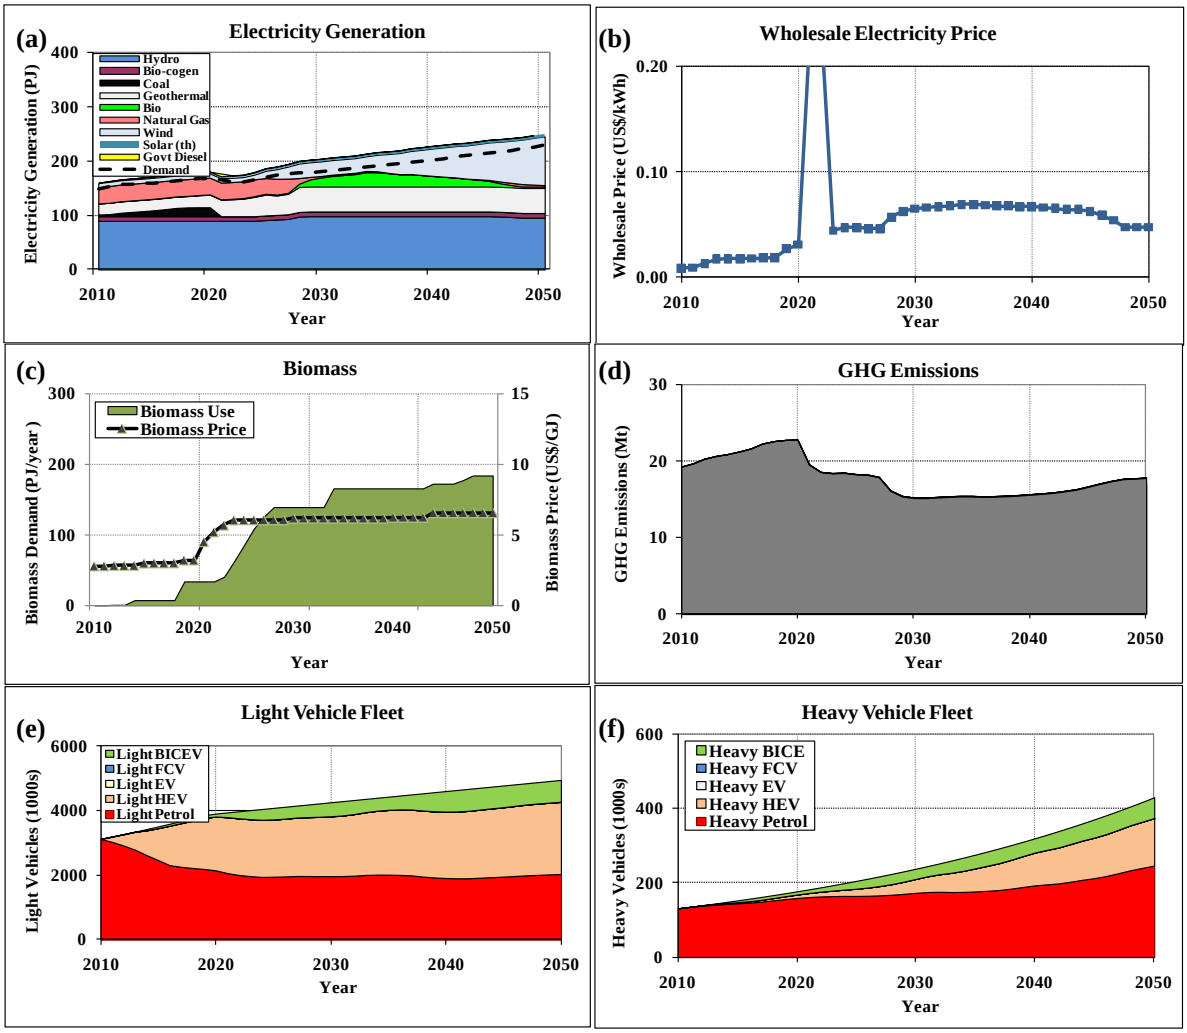

Fig. 2: For the Fossil Futures scenario: (a) Electricity generation profiles. (b) Hydrogen production profiles. (c) Wholesale electricity price. (d) Wholesale hydrogen price. (e) Biomass demand and price. (f) GHG emissions. (g) Light vehicle fleet. (f) Heavy vehicle fleet (g) Fuel economy. (h) Fuel cost per k of travel.

Under the RF scenario in Fig. 3a the high carbon tax eliminates coal fired generation and natural gas generation ceases by 2018. By 2050 the generation profile consists of 41% wind, 36% hydro, 14% geothermal and 9% other renewable generation such as biogasification. Total renewable generation is 97%. In Fig. 3b the electricity price rises to a high of 13 USc/kWh in 2013 with the sudden rise in carbon tax from US$15/t-C to US$200/t-C. Prices average about 7.2 USc/kWh after 2030. In Fig. 3c hydrogen production commences with forecourt electrolysis in 2015 with large scale hydrogen production from biogasification commencing in 2020. Fig. 3d shows that the hydrogen production price is close to US$5.00/kg after 2020. In Fig. 3e biomass use rises sharply from 2016 to 2020 as a primary fuel for hydrogen production by biogasification. In Fig. 3d, GHG emissions decrease by 58% between 2010 and 2050. In Fig. 3g light BICEVs, HFCVs, and EVs constitute 8%, 28% and 8% respectively of the light vehicle fleet in 2050, with the balance of 56% being ICEVs and HEVs. In Fig. 3h, heavy BICEVs and HFCVs constitute 14% and 44% respectively of the heavy vehicle fleet in 2050, with the balance of 42% being ICEVs and HEVs.

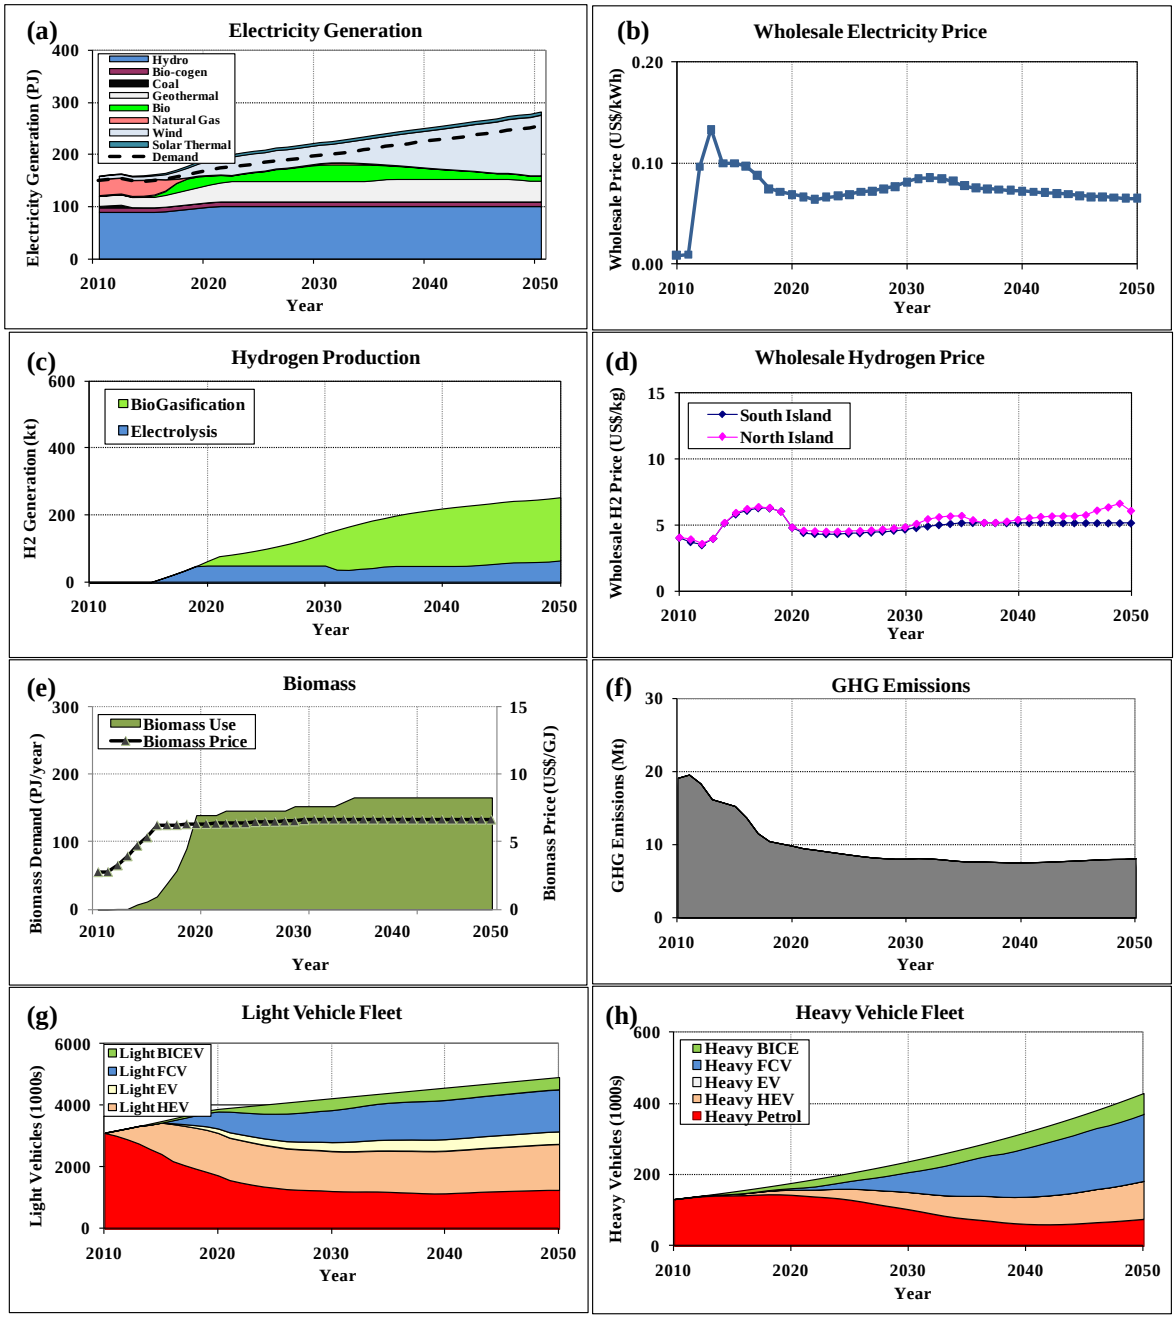

Fig. 3: For the Renewables Future scenario: (a) Electricity generation profiles. (b) Wholesale electricity price. (c) Hydrogen production profiles. (d) Wholesale hydrogen price. (e) Biomass demand and price. (f) GHG emissions. (g) Light vehicle fleet. (f) Heavy vehicle fleet (g) Fuel economy. (h) Fuel cost per k of travel.

4. Discussion

Two primary consequences emerge from a comparison of the Fossil Future and Renewables Future scenarios. Firstly in 2050 in both scenarios all generation excluding backup peak load generation is renewable. The only effect of the high carbon tax in the RF scenario is to reduce geothermal generation by about 4% and replace this with wind. All GHG emissions are from the vehicle fleets. GHG emissions in the RF scenario are 54% less than in the FF

scenario by 2050 which equates to a 54% reduction by weight in fossil vehicle fuel. Secondly the proportion of light ICEVs under the RF scenario of 56% is 32% less than that under the FF scenario of 88%. The fact that the combined penetration of ICEV and HEV in the RF scenario remains high at 56% is a result of the improving fuel economy of ICEVs and HEVs that enhances the competitiveness of these technologies and delays their replacement by all electric BEV and HFCV technologies. Reducing the penetration of ICEV and HEV to less than 30% of the total fleet may require government regulation to encourage adoption of electric vehicles. The primary focus of any regulation should be to reduce the purchase price of electric vehicles with subsidies while recovering the subsidy as a fuel tax. The motive behind this is that purchasers value an incremental reduction in purchase price at twice that of a reduction in running costs [15].

The average electricity price under RF remains stable at about 7.2 USc/kWh despite the increased electricity demand for hydrogen production by electrolysis and subsequent recharging of electric vehicles. This increase in electricity price is buffered by the large wind resource available at less than 8.4 USc/kWh referred to earlier in this study.

Wind penetration in the RF scenario is 41% by 2050 which poses significant issues for the stability of New Zealand's electricity grid. In Denmark the Danish Transmission System Operator is planning for up to 50% wind penetration in the transmission system [16]. However New Zealand cannot import electricity from neighboring countries.

Mason et al. [12] examined wind penetration in the New Zealand electricity system of up to 35% during 2005-2007 when demand totaled 54% of expected demand in 2050. The study concluded that penetration rates of 19% could be achieved by utilizing the existing hydro system to balance periods of low wind generation with almost no reduction in electrical energy from hydro generation.

Wind penetration of 18% has been estimated [17] to incur integration costs of 0.6 USc/kWh as shown in Table 1.

Table 1. Wind integration cost (adapted from [17]).

Year	2010	2020	2030
Installed wind power capacity (MW)	634	2066	3412
Wind energy (PJ)	8.3	24.1	39.1
Wind energy as % of total generation	5	12.5	18
Additional wind integration cost (USc/kWh)	0.14	0.14	0.61

Recent wind integration studies [17, 18] suggest enough standby generation must be available to meet a 'no wind' scenario. Analysis of a 19-year daily synthetic wind speed dataset [19] showed that no wind generation is likely to occur for two days every three years under a geographically diverse wind portfolio. In order to cater for the 'no wind' scenario requirement at 41% wind penetration in 2050, New Zealand will require active demand side management, smart flexible gas contracts and peaking based hydro management coupled with fast start standby thermal generation. This could include remote shut-down of selected hot water heating installations, and short term diversion of electricity and gas supplies from selected large industrial electricity users such as aluminum [20] and methanol [21] production plants. Diversion from large industrial plants has the potential to provide additional backup electricity generation of up to 50% and 66% respectively of predicted wind generation in 2050 under the RF and FF scenarios. Further measures may involve a mixture of pumped hydro storage using off peak electricity, or changing the operating limits of hydro lakes for very short periods.

To ensure grid stability a number of load balancing generation and load shifting options will be needed. Load balancing options would principally include hydro with support from fossil fuelled peaking plants. Load shifting options could include remote shut-down of selected hot water heating installations, pumped hydro storage using off peak electricity, and smart metering that allows real time electricity billing to encourage fast consumer response to electricity price.

This study used an upper bound carbon tax of US$200/t-C to examine renewable energy penetration limits. Marginally lower penetration rates of renewable energy may be possible with a carbon tax of US$100/t-C although a detailed study of this option is outside the scope of this paper.

5. Conclusions

New Zealand's has the potential to achieve over 90% electricity generation from renewables by 2050 but maintaining or exceeding this target to 2050 will require complex integration of peak load backup generation to balance the variability of wind generation. This target is largely independent of the carbon tax due to the large and economically viable wind resource. In the vehicle fleet, in the absence of plug-in hybrid vehicles and without government regulation, 44% of the light vehicle fleet is expected to be electric drive by 2050. The penetration rates of electric vehicles will be enhanced with purchase price subsidies capitalised from fuel taxes.

Abstract: This paper describes a novel concept regarding the method for research and development of future vehicles. It is shown that the traditional rate of progress cannot keep up with the increasingly pressing issues of global warming and social sustainability. A new, holistic approach which takes into account the form, operation and social aspects of the future society is suggested. This approach tries to remove the boundaries between different sections of science and also accelerate the rate and speed of adoption of new technologies into the final, mass-produced vehicle. Such an approach can pave the way for the creation of a vehicle that reaches our goal of zero accidents and zero emissions.

Keywords: *Sustainable Transport, Social Sustainability, Future Mobility and Technology*

1. Introduction

The issue of global warming and its relation to human-induced emissions is well known. In 2009, both the European Union and G8 leaders agreed that CO_2 emissions must be cut by 80% by 2050 in order to stabilise the concentration of greenhouse gas (GHG) emissions in the atmosphere at a level of 450 ppm of CO_2 equivalent and keep global warming below the level of 2ºC. Transport accounts for about one-fifth of global energy use and one-quarter of energy-related CO_2 emissions [1]. To achieve the necessary deep cuts in greenhouse gas emission by 2050, transport must play a significant role and achieve 95% decarbonisation. Car ownership worldwide is projected to triple to over two billion by 2050 and, without strong global action, a respective growth of energy use and CO_2 emissions will occur [1]. Fig. 1 shows estimation for EU total greenhouse gas emissions. It can be seen that, following the baseline scenario which already includes large efficiency improvements, especially in industry, the emissions are expected to remain constant. The amount of additional effort that must be put in each sector in order to achieve the necessary emission cuts is clearly visible [2].

Fig. 1. EU total GHG emissions forecast for 2050 and comparison to target.

Similarly, annual global road-traffic fatalities sum to more than 1 million and injuries to more than 50 millions [3]. Awareness, technological advances and stricter legislation have lead to

the reduction of injuries and fatalities in developed countries as can be seen in Fig. 2; however the increasing level of car adoption, especially in developing countries, means that the global number of fatalities and injuries is likely to increase [3]. The cost of road accidents, in both social and financial terms is not negligible. For example, the cost of fatalities in EU-27 during 2006 corresponded to approximately 2% of the total GDP [4].

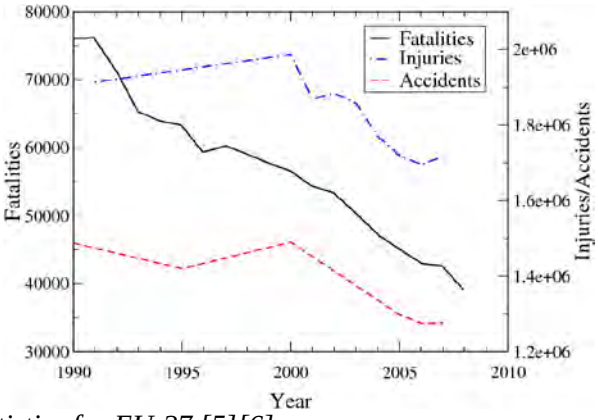

Fig. 2. Road accident statistics for EU-27 [5][6].

Current automotive technology improves at incremental steps, as conventional, long-existing concepts are optimised towards their theoretical limits. Compared to previous decades, current cars provide higher levels of safety and have a similar or lower environmental footprint at the same time. Stricter legislation and industrial competition have supported this trend by leading to the introduction of new or improved technologies in the course of the years. However, growing concerns of the climate change mean that this rate of progress is not viable, as shown in Fig. 1.

The introduction of the mass-produced automobile represented a revolution in affordable, highly flexible mobility and convenience. This flexibility makes its use appropriate especially in cases where large investments in mass transportation are not viable. Its usage has led to significant changes in society and has contributed to economic growth, supporting the growth of small and medium-size businesses over the years. Currently, transport is one of the backbones of European economy, accounting for about 7% of GDP and more than 5% of total employment in the EU. How can we continue to enjoy the benefits of car mobility in a sustainable way, without the associated risks of traffic accidents and accelerated climate change? In the following sections we try to share selected elements of our vision for research carried out in Toyota Motor Europe for creating the future image of automotive transportation, as well as the necessary technologies to make this sustainable. More specifically, in Section 2 we describe our research methodology. In Section 3 we outline our perceived image of the future car and present key technologies that will render it possible. Finally, in Section 4 we summarise our findings.

2. Research strategy

The automobile has evolved over several decades into a practical and reliable product by following a solid approach of thinking and engineering. This traditional approach is starting to become a limitation to the rate of further technology improvement, unable to keep up with the requirement for drastic changes shown in Section 1. The automotive industry is faced with a lot of challenges to deliver innovative products to its customers, and some will likely require a big innovation jump. Currently developed and emerging technologies need to be implemented in new vehicles rapidly, at a rate and on a scale that is unprecedented in the last 40 years of

transport evolution. New technologies that deal with weight reduction, performance optimisation and efficient usage of energy resources need to be developed for reversing the trends of the past decades and achieving our targets in GHG emission cuts, without a negative impact on existing levels of quality and comfort. This will require answers to paradoxical questions such as how can we produce a vehicle which is extremely lightweight and completely safe at the same time? How can we manufacture a vehicle which provides complete freedom and pleasure to the driver and passengers, without any environmental impact? Such questions are indeed paradoxical when following the traditional way of thinking. A fresh, "out of the box" approach is therefore needed to provide answers and solutions which are realistic and feasible in a short timeframe compatible with our extremely challenging targets.

2.1. Limitations of current methodology

Before describing a new research strategy, we first reflect on the more than 100 year long automotive history in order to understand the logic and the potential of the current direction for improving the environmental performance of cars. Fig. 3(a) shows the history of average fuel consumption in Europe and the US for the period 1975-2002. In comparison, fuel consumption of the first mass-produced vehicle, Ford Model T, in 1908, was around 11-18 lt per 100 km [7]. It can be seen that after period of a relatively strong improvement in average fuel economy during the 70s, homologated consumption has roughly stabilised in the US and drops only slowly in EU. This can be explained by Fig. 3(b), which shows the relative evolution of vehicle mass, power and engine size in EU for the same period. It is clear that during the same period, vehicles have become heavier, more powerful and relatively faster. Increases in engine size and vehicle mass can partly be attributed to dieselisation (as diesel vehicles have a lower power/mass ratio), but even so it is evident that the trend for bigger, faster and theoretically safer cars has off-set the gains in efficiency.

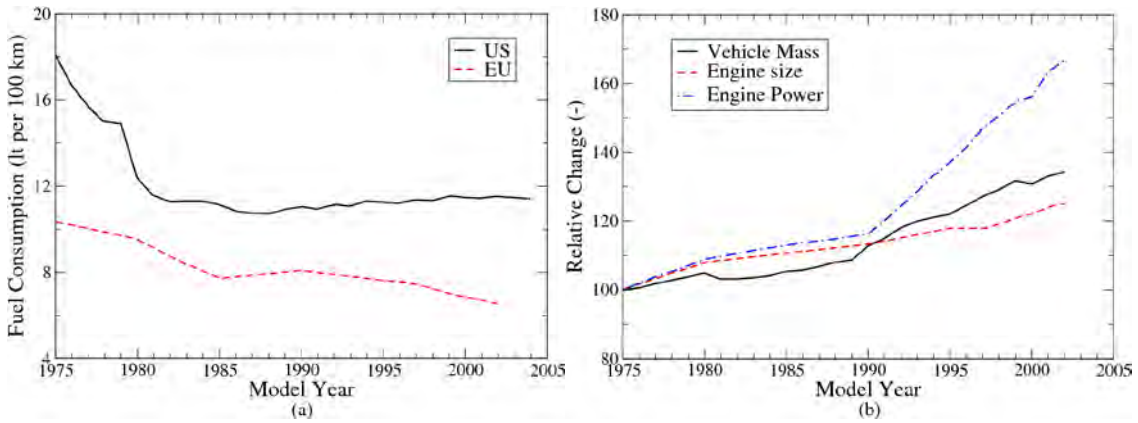

Fig. 3. Evolution of (a) US and EU motor vehicle economy from 1975 to 2003 and (b) average weight, power and engine size of new cars sold in EU from 1975 to 2002[8]

As a second example, Table 1 shows the evolution of a typical vehicle over the last decades. As specifications can vary a lot over different countries and model generations, some typical values are shown, corresponding to a compact sedan vehicle, with comparable acceleration performance. The trend of increasing weight and dimensions is obvious, with a current vehicle being more than 0.5 meters longer, and almost double the weight, compared to 40 years ago. It is also interesting to note that the average fuel consumption has had small fluctuations over the years, with significant reductions being achieved in the last decade, bringing us back to the levels of 1960's. These numbers also verify the findings of the average vehicle evolution trends, with the levels of safety and comfort improving considerably over

the last decades at the expense of potential improvements in performance and fuel consumption.

Table 1. Evolution of Toyota Corolla Sedan typical specifications. Figures obtained from internal TME material.

Year	Length (mm)	Weight (kg)	Engine size (lt)	Power (kW)	Acceleration (s)	Cd (-)	CdA (m^2)	Fuel consumption (lt/100km)
1966	3848	700	1.2	50	13.7		0.6	6.4
1970	3945	801	1.4	63	11.6		0.61	6.82
1974	3995	930	1.6	61	12.6	0.43	0.776	7.92
1979	4048	821	1.5	55	11.5	0.43	0.798	7.51
1983	4135	920	1.6	62	11.6	0.37	0.696	7.22
1987	4191	955	1.6	70	11	0.33	0.62	7.22
1991	4270	1000	1.6	81	10.4		0.631	
1997	4295	1035	1.6	81	10.7	0.33	0.644	7.81
2000	4365	1125	1.6	81	10.3			
2006	4540	1310	1.6	97	10	0.3	0.73	6.4

The design and production of a car is a very challenging exercise, with many contradictory demands. Such demands, limited by existing practices and infrastructure investments, lead invariably to compromises in the final product, and do not allow the full potential of technology to be exploited. The shortcomings of this approach can also be noticed in the current development of new generation, alternative drive-train vehicles, which are essentially developed on the platform of traditional ICE cars with a direct replacement of engine and the addition of energy storage or conversion devices in space which could opportunistically be used for the comfort of the passengers or as optimised shape for drag reduction. Similarly, the current strategy of tackling the possible dangers that inherently quiet electric vehicles may pose to pedestrians by adding artificial noise is another example of lack of "new thinking" in what could be a chance for a significant reduction in urban noise pollution.

2.2. New approach

It becomes clear from subsection 2.1 that in order to induce the required paradigm shift, a new way of thinking and performing research is necessary. Since several years, we try to seek inspiration in all kinds of science around us. Such inclusive thinking incorporates cutting edge research in engineering. We can find interesting concepts in the work of several research groups. A recent example is the development of a battery which can also be used as a structural material [9], therefore removing significant duplication of the weight. Research from NASA has led to a self-sustainable marine vehicle [10], while Lotus Engineering has recently shown that a significant weight reduction can be achieved using relatively standard technologies and with a minimum impact in cost [11]. However, our truly multidisciplinary research approach extends beyond the conventional limits of engineering to concepts not directly related to vehicles, such as biology and social sciences, and can provide new seeds of technology which are not limited by topic and therefore also not in scope. In nature we observe many truly amazing technology-like functions, and we have long been looking here for inspiration to solve some of our fundamental engineering challenges related to both vehicle safety and sustainable energy efficiency. Another pillar of our approach is that we take into account the future society structure and operation and thus our real target becomes to increase the efficiency of the whole system, rather than a single component, as done traditionally. In such a holistic approach, we consider the automobile not as an individual unit,

but as a living part of a bigger organism. This way, many of the existing obstacles can be overcome and a higher rate of development can be achieved.

In addition, we consider practical aspects such as the cost of new technology, investments in infrastructure, local energy resources availability, as well as human aspirations and market diversity. Sustainable mobility, apart from dealing with environmental and energy issues, must also satisfy the individual customer needs, meaning that it must maintain or improve upon the current acceptable levels of performance, safety, comfort and practicality. It must also respond and adapt to changes in lifestyle, such as urbanisation and network connectivity, converting such changes into opportunities for further improvements. Finally, it must maintain and extend the personal freedom of the driver and the passengers, keeping the aforementioned benefits of private transportation, in a socially and environmentally responsible manner.

Such a quest for a potentially sustainable automotive transportation technology, as described in Section 1, is slowly starting to gain traction globally. A recent example is the LA Auto Show Design Challenge which has been providing a platform for presenting new ideas over the past seven years. A different theme, relevant to different aspects of future car usage, is employed each year, and some interesting ideas can already be seen [12].

3. Image of the sustainable vehicle

Following the approach described in Section 2, we estimate that the amount of energy needed for car transportation by 2050 is possible to be one order of magnitude lower than current levels and the emitted greenhouse gases close, if not equal, to zero. By removing inefficiencies in all the subsystems and introducing new technology concepts, we are aiming at creating a vehicle which can propel itself without any fossil fuel derived energy support while maintaining the current levels of vehicle performance and occupants comfort.

3.1. Evolving society

The large-scale availability of affordable liquid fuels has essentially sparked a modern industrial revolution over the 20th century and shaped the transportation sector. Today transport is at a transition point, as it is starting to become a victim of its own success. The genesis of our image for the future car should therefore be viewed in the context of its existence inside the future society. A society which we believe will be characterised by the lack in cheap resources, growing levels of population and urbanisation. This future society will be more extrovert and will strive to remove inefficiencies following a global optimisation approach. In such an environment, information will constantly be transferred and exchanged, allowing each subsystem to automatically adapt its operation in order to support a smooth global operation. New information technologies, providing immense wealth of information, are already starting to move in this direction [13].

Apart from the information exchange, which is necessary for a smooth coexistence of the different structures in a society, another important concept which needs to be materialised is that of energy exchange. By this, we mean the constant adaptation of energy resources used, in order to achieve the most efficient energy production, as well as the constant energy re-usage process, during which energy is converted into different forms without loss. The successful combination of energy and information exchange processes will ensure the achievement of such a smart and self-regulating entity.

3.2. Shaping the future car

In such exchanging society, different means of transportation have their own role to play. We believe that the desire for the pleasure, freedom and practicality of personal mobility will not be eclipsed, and therefore the personal car will continue to have an important role. By actively taking advantage of opportunities presented in the future society, automotive transportation can adapt and be optimised in order to achieve successful merging and co-existence in the daily life of its citizens.

A self-sustainable vehicle has, first of all, to remove the past inefficiencies. Fig. 4 shows the energy losses in two usual driving scenarios, according to [14]. It can be seen that the energy which finally results in the actual mobility of a conventional car corresponds to less than 20% of the available energy from the fuel. A lot of new technologies aim at reducing or removing such energy losses, although, arguably, the most significant of these losses is inherent to the historical operation of the thermal engine and is the hardest to tackle. Another source of inefficiency is the mass of the vehicle itself and the associated inertial effects. As shown in Section 2, the improvements in engine technology have been offset by the weight increase over the last decades, with the fuel economy not being able to improve as drastically as it could. It is highly paradoxical that a vehicle of more than 1000kgs is needed for the transportation of an 80kg person. It is clear that different technology is required in the design of future vehicles.

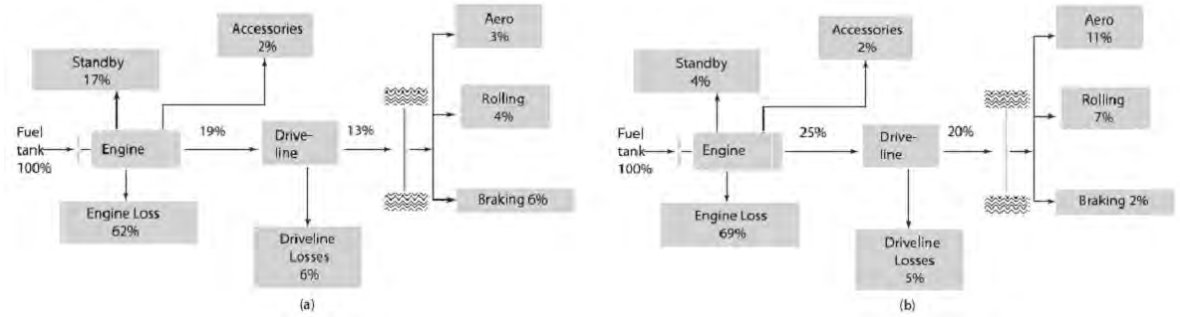

Fig. 4. Energy dissipation in (a) urban and (b) highway driving [14]

Completely in line with our image of the future society, the future vehicle takes advantage of all the available information and energy forms in order to maximise its potential and optimise its operation. Like the combined intelligence of a school of fish that travel together in a way that offers them safety and ensures the minimum drag during their movement in the water, our future vehicle can communicate with its surroundings and adapt its operation in a way that removes the danger of accidents, while respecting the individuality and the preferences of the driver. Moreover, this communication and adaptation allows the usage and re-usage of the available energy in the best possible way without losses, but with continuous transformation from one form to another.

A significant gain can be achieved by reducing the mass of the vehicle considerably. We envisage a five-fold reduction in this sector. A combination of ideas will be necessary for this target to be achieved. First of all, the novel intelligent safety systems will ensure that it is possible to avoid any dangerous situation at all times, and therefore reduce the reliance on increasingly stronger individual vehicle structures, which can be parallelised more to the sturdiness of an elephant, rather than the elegance and nimbleness of a bird. Then, a new generation of materials, inspired by nature and based on simple, cheap building blocks which gain their strength by their internal microstructure will allow the creation of vehicles which

are more in line with their natural surroundings. The human organism consists of materials which do not necessarily have significant individual strength or potential. However, due to their relative organisation and control under powerful sensory and cognitive skills, they can be protected by catastrophic damage and are capable of achieving comparatively amazing results. Finally, the integration of multiple functions in fewer structures or components can remove unnecessary weight.

Such optimizations can significantly reduce the amount of energy which is necessary for mobility. This has initially a positive impact on the rate of existing resource depletion. More importantly, though, it can enable an era of desired self-sustainability, where the naturally occurring energy streams can be harvested and exchanged efficiently, thus minimising the link to fossil fuel consumption.

Fig. 5. Example of image enhancement by novel night vision algorithm: (a) Original frame. (b) Tone mapped version. (c) After noise reduction. (d) After noise reduction with sharpening.[15]

Fragments of such ambitious thinking can already be seen in cutting edge research. An example of research is a novel night vision system, inspired by the eyes of nocturnal insects [15]. The algorithm developed in this project was born from understanding how an insect can hunt for food which is beautifully coloured flowers at night, navigating with its normal eyes. A sample result is shown in Fig. 5. Whereas traditional technologies might saturate in terms of performance, results obtained from such a holistic research framework can have the potential to leap-frog beyond current frontiers.

3.3. Contribution of the engineer

We are faced with the tough challenge of adapting this totally new knowledge back into existing systems and applications of our industry, to fully measure and evaluate its true potential, but it is a challenge which we are working hard to overcome. To do so, first we try to play a binding role by bringing different kinds of science together and removing the borders between them. Secondly, we try to identify the potential and feasibility of each technology, and quickly pursue its development and application into the final product through interaction with development, production engineers, marketing etc. For successful guidance in such an approach, we set a clear future target, like the one we are presenting in the current paper. We believe, based on our experience from ongoing projects, that this concept will allow a revolutionary design and integration of subsystems, paving the way to radically new implementations.

4. Summary

We have a dream of zero accidents and zero emissions for our future car. The pressing sustainability issues mean that our dream is relevant more than ever. In this paper, we propose the development of technologies which support the process of exchanging energy and information as a way to reach this target. By such challenging of traditional thinking we aim

to spark innovation for game-changing technologies, leading to a truly sustainable mobility solution, from both an environmental and social point of view.

Abstract: The main disadvantage of Electric Vehicle is the lack of capability of storing sufficient energy to run the vehicle for a long time. The energy storage capacity of battery used in electric vehicle is very low compare to conventional fuels used in modern automobiles. The operation, performance and efficiency of motor driven electric vehicles are much better than engine driven vehicles, at the same time electric vehicles are very much environment friendly. Still electric vehicles are falling behind in the automobile industries due to the problem of storage of energy. This paper is based on the concept of charging the batteries of an electric vehicle when it is in motion or propelling. This may be done by using the energy of wind which is caused by the relative motion between the vehicle and the wind surrounding it. Wind turbines can be mounted on the body structure of the vehicle to generate electricity in such a way that it must not create any additional drag force (rather than the existing drag force due to frontal area and skin friction) upon the vehicle. An elaborate aerodynamic analysis of the structure of the vehicle along with the flow pattern and wind turbine is presented in the paper. Some techniques and methods are proposed to minimize the drag imposed by the introduction of the turbines as much as possible. Optimum values of different design parameters and rated velocity of the vehicle are of prime concern. With this concept it may be possible to increase the mileage of an electric vehicle up to 20%-25% and it will also save the charging time of the battery to a great extent. Flow pattern over the vehicle is simulated using software called ANSYS CFX.

1. Introduction

When a vehicle moves it experience wind resistance which are classified in two different forms- frictional drag and form drag. Frictional drag arises due to viscosity of air and form drag arises due to variation of air pressure in the front and rear side of the vehicle [1]. As the vehicle moves forward, it lefts the air stream behind. A turbulence or disturbance is created on the wind when a vehicle moves through it. If stationary wind turbines are placed near the road then energy can be extracted from the wind stream generated due to the movement of the vehicle. Such a study had been carried out in University of Arizona by a group of students. If it is possible to capture those wind streams within the vehicle itself then it can be used to recover some of energy that has been used to overcome the form drag (aerodynamic drag) of the vehicle. If this wind energy is used to extract some power in such a way that it does not create any component of force or thrust opposite to the direction of the propulsion of the vehicle, then this gained energy can be used to produce electricity to charge up the battery of the electric vehicle itself. At the same time drag can be expected to be reduced by passing this air to the rear side (Low pressure side) of the vehicle. Air stream sliding over the body of the vehicle cannot enter into the rear side due to vortex shedding [1]. If air streams are allowed to flow in this region by any means then the form drag will be reduced by some amount and at the same time it may be possible to generate electricity using the kinetic energy of wind. Several studies had been carried out in this field but none of them are proved to be scientific. During the Second World War, wind turbines are used in submarines to charge up the batteries when they remained static and float in the water. At present it is also common to use turbines in ships, caravans and vehicles when they are parked. But to extract power from a

moving vehicle is quite difficult as the turbine will act as a load for the vehicle. Most of the design showed that the turbines are placed over the vehicle roof without considering the fact that it will impose an additional load for the vehicle and on the other hand no measures had been taken to reduce it. A design by Rory Handel and Maxx Bricklin showed that it has four tactically placed air intakes which will channel the air flow over the car's body towards the turbine. No such detailed design was available.

In this paper the topic is dealt by considering all the scientific facts and laws of energy conversion. A new approach is proposed and simulation of the design is carried out to analyze the behavior of the model. Some theoretical formulas have been used for the purpose of calculations.

2. Basic Theory

It is assumed that the vehicle is moving in a calm and steady wind stream with zero wind velocity. If the vehicle is moving at a constant speed of 15 m/s (54 km/h), then we can think a wind stream with15 m/s is flowing around the vehicle. Normally this wind will cause a drag force which is opposite to the direction of the propulsion of the vehicle. At constant speed (zero acceleration) the energy requirements to move the vehicle forward are –To overcome the frictional force (rolling resistance of road) and to overcome wind resistance [1]. At this Condition, if the air stream flowing around the vehicle (which was not interacting with the vehicle previously) is allowed to enter inside and let it flow down to the rear side; then it may be possible to use these air streams to generate power. The vehicle has already interacted with this wind and it deflects the stream of wind at the two sides of it by stagnation at the front. This is the energy that had been lost from the vehicle to overcome the aerodynamic resistant. Now if these stream generated by the interaction of the wind and vehicle is captured within the vehicle in such a way that it would not impose an additional drag at the direction of propulsion of the vehicle, some of the energy can be recovered and fed back to the battery by means of conventional energy conversion processes. Placing a wind turbine can serve the purpose. At the same time it will help to increase the pressure at the back side (according to Bernoulii's equation pressure will be increased if velocity is decreased and velocity will be reduced at the back side of the turbine after energy extraction) which will reduce the drag force that existed before with the conventional design of the vehicle. So, vortex shedding will be reduced at the rear side. For this it is necessary to modify the design of a vehicle which gives provision of air flow through the vehicle. On the other hand positioning of the turbines will also be important because they must be placed in such a way that they do not impose or create any additional drag on the vehicle. Symmetrical positioning of the turbine can do the trick as the thrust acting on the turbines will cancel each other.

3. Design and Modeling

We can consider a vehicle which is redesigned to allow airflow and wind turbine can be set up to extract energy. Wind turbines are set in parallel with the flow of air. This set up will not create any additional thrust at the direction of propulsion. Two basic equations will be needed to explain the air flow and power extraction.
The air flow through the vehicle is given by, [2]

$$Q = C_v A v \qquad (1)$$

Where, Q = flow rate in cubic meter per second.
C_v = opening effectiveness

[Value for C_v is 0.5 - 0.6 for perpendicular flow and 0.25 – 0.35 for skewed flow] [2]
A = Area in square meter
v = air velocity in m/s
This equation (1) will determine the amount of air flow through the vehicle inlet area.
Output power from a wind turbine is given by [4],

$$P_T = 0.5\, C_P\, \rho\, Q\, v^2 \qquad (2)$$

Where,

P_T = Power output from the turbine in watt.
C_p = Power co-efficient
(Assuming, C_p = 0.4 for the design) [4]
ρ = air density; 1.225 kg/m^3.
Q = air flow in m^3/s.
v = air velocity in m/s.

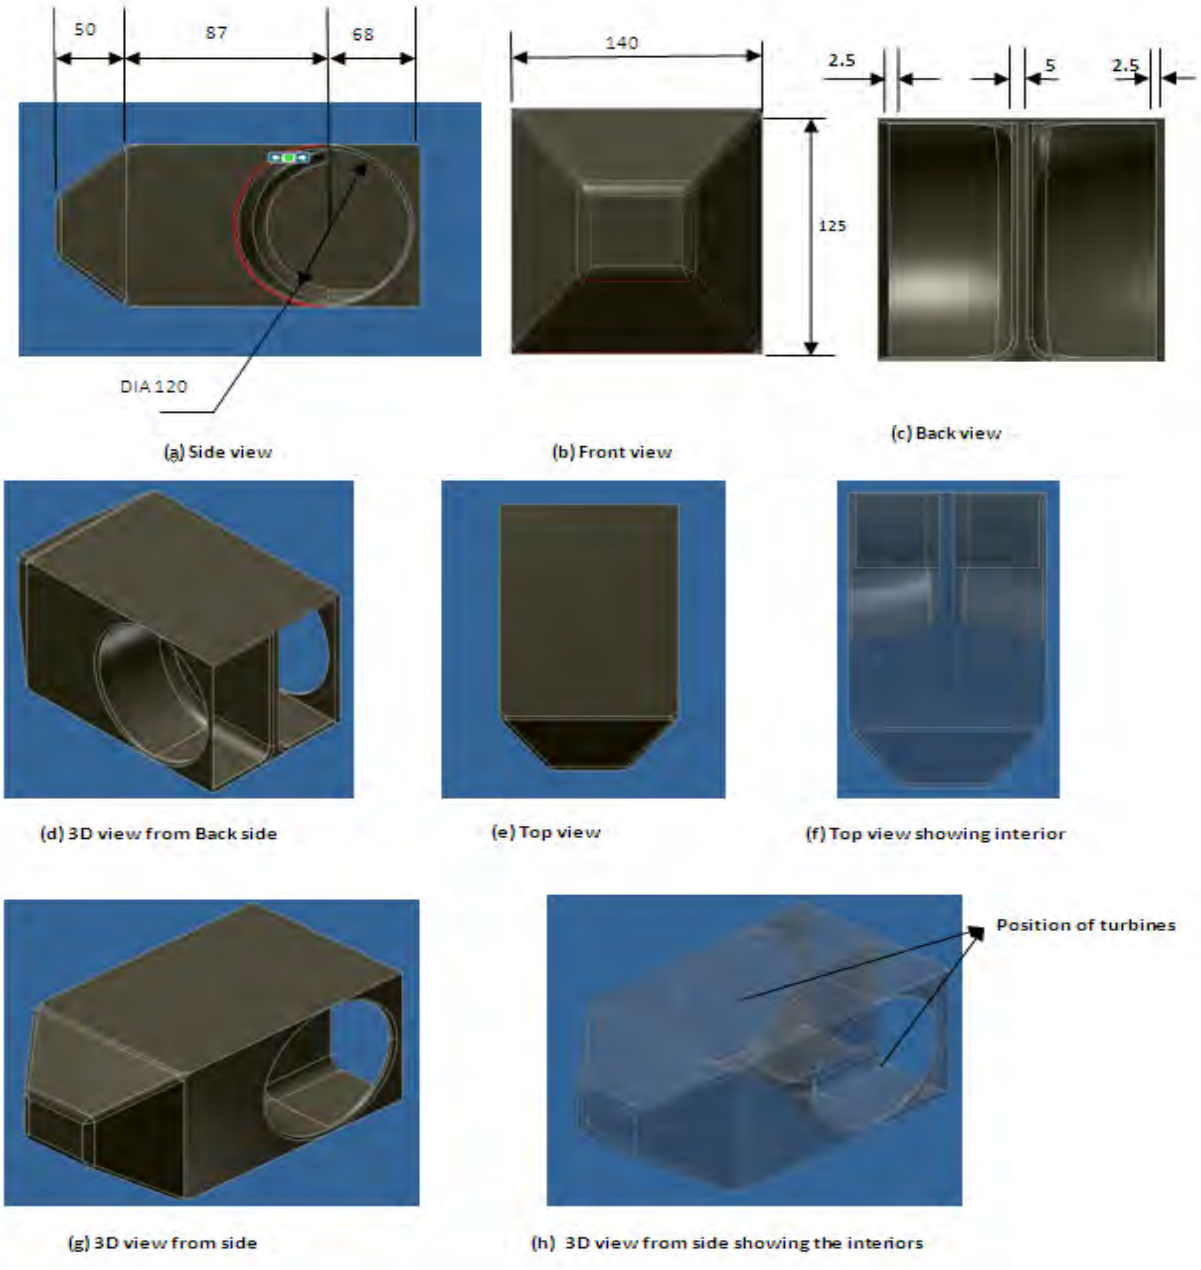

Fig. 1. 3D and isometric views of the model. The diameter of the turbine is 120 cm which is placed at the rear side of the vehicle. The length of the vehicle is 255 cm. All dimensions in the diagram are in centimeters.

In conventional vehicle air cannot go to rear side of the vehicle due to presence of boundary layers and vortex shedding. If a high-pressure and a low-pressure region can be connected via a neutral zone, then air can flow in between these pressure regions. Our design will allow the air to flow in this manner. The detail designs with dimensions are shown in the fig.1.

The vehicle is run by a 1.5 KW DC motor which has five 12V, 120 A-h D.C battery to supply power to the motor. The vehicle has to move at a velocity of 54 km/h i.e.15 m/s. The design of the vehicle is shown here with all dimensions. In this design the wind turbines are set in such a way so that the axial thrusts on the turbines are 180° apart to each other which results in the cancellation of two thrusts. In this way this symmetrical positioning of the turbines will create no additional drag component over the vehicle. Placing the turbines on the top will increase the frontal area as well as the drag acting on the vehicle. So that approach is not scientific. Rather some solar panels can be placed on the top to aid the recharging of the vehicle, both in motion and parked position. In addition if the vehicle is parked in a place where the wind velocity is above cut in speed then it is possible to charge the vehicle and thus it could aid the total charging system and hence charging time can be reduced.

4. Wind turbine

The wind turbine chosen for power generation has the features stated bellow [5] –

- Two blades (for low solidity).
- Horizontal axis.
- Lift type.
- High lift to drag ratio with efficiency ranging from 0.4 to 0.45. They need a relatively high tip speed ratio ($\lambda = \omega R / v_w$). For our design we have chosen $\lambda = 6$. For this value of λ it can be assumed that the value of C_p will be 0.4 to 0.45.

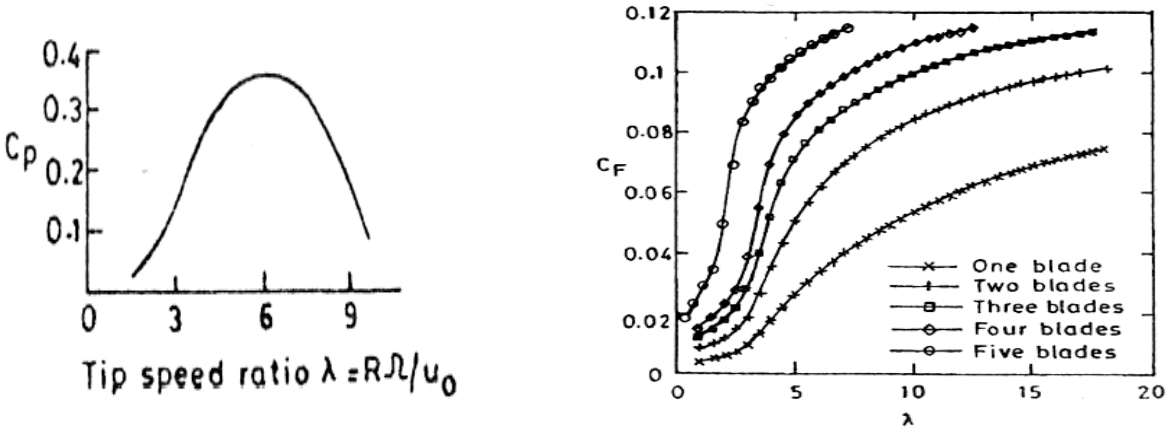

Fig. 2: Power Coefficient and Axial Thrust Coefficient for HAWT [6].

From $C_p - \lambda$ and $C_F - \lambda$ curve we can see $C_p = 0.4$ and $C_F = 0.055$ [6]

Where,

C_F = axial thrust co-efficient.

So, $C_p/C_F \approx 7$

This implies that as at perfect dynamic matching generated power will be greater than the power spend due to thrust. In other words the generated power by a turbine will be greater

than the thrust acting on the blade as an aerofoil section has high lift to drag ratio. On the other hand, turbines are placed in parallel to the flow rather than perpendicular to the flow.

5. Generator

We want to use an A.C. generator with 3-Φ windings with increased no. of poles. The poles will be permanent magnets and the no. of poles will be 8.

$\lambda = 6 = \omega R / v_w$; $\omega = 6\ v_w/R = \frac{6 \times 15}{0.6} = 150$ rad/s; R.P.M, $N = \frac{60 \times \omega}{2\pi} = 1433.12$;

This eliminates the need of a gear box in the system.
We shall use a three phase A.C. to D.C. converter to charge the batteries. Cúk converter is used to give a constant 60V at the output. The current of the converter will vary with the variation of the speed of the vehicle or the r.p.m of the turbine keeping the terminal voltage fixed.

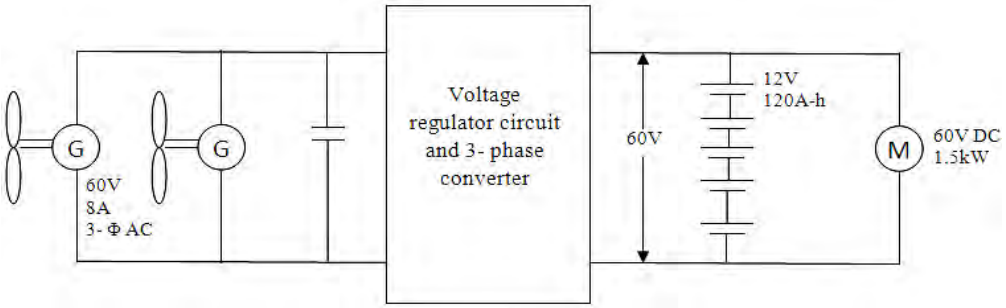

Fig. 2. Charging and control circuit of the battery. 3Φ windings are used to reduce the ripples. A motor control circuit can be used to control the motor and it will also introduce the provision of Regenerative Braking. Simple Power diodes can be used for designing the converter circuit. The cut-in velocity (minimum wind velocity to generate power) of the turbines is 5m/s.

6. Calculation

Using equation (1) we can calculate the amount of air flow,
$Q = C_v\ A\ v \quad = 0.25 \times 0.8 \times 1.131 \times 15 \times 2 = 6.8\ m^3/s$

Here, $A = \pi r^2 = 3.1416 \times 0.6^2 = 1.131\ m^2$

$v = 54$ kmph $= 15$m/s

Here multiplier of C_v is 0.8 as ratio of the inlet and outlet area is 1.38. C_v is chosen as 0.25 as it is a skewed flow [3].

So, Power, $P_w \quad = \frac{1}{2} \rho\ Q\ v^2 = \frac{1}{2} \times 1.2 \times 6.8 \times 15 \quad = 918$ W

Assuming, $C_p \quad = 0.4$ Then we have,

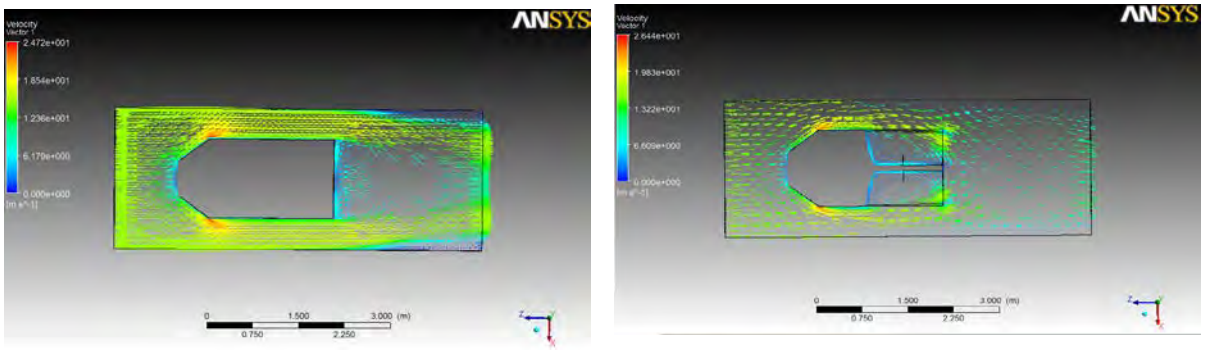
$P_T \quad = 918 \times 0.4 = 367.2\ W \approx 360\ W$

So, each turbine will produce a power of 180 W. This much power will be fed back to the battery when it is moving at a constant velocity of 15m/s.

So increase in mileages = (1500-1140)/1500 x 100% = 24%. This is due to the feeding back of some of the energy captured by the turbine which is spend to overcome the aerodynamic drag. That means the turbines are capturing some fractions of the energy which has already been spend by the vehicle to overcome the aerodynamic drag.

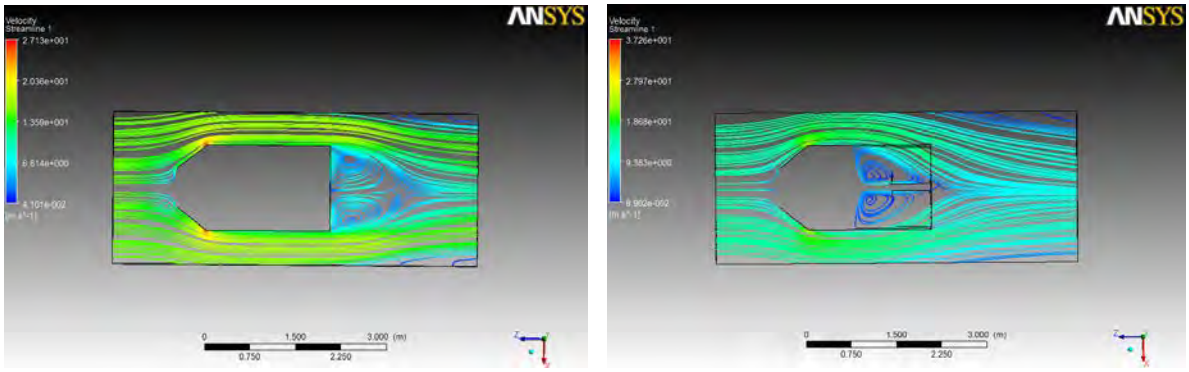
7. Simulation Result

The Flow pattern over the model is simulated using ANSYS CFX. Two models had been chosen for simulation. One is the conventional design and another one is modified design which includes turbines on the vehicle. Using the simulation result the pressure difference and force acting in the direction of flow (i.e. the thrust acting against the direction of propulsion) is calculated. The simulation results are shown and analyzed in the following figures.



(a) Conventional vehicle model without ducts for turbine **(b) Modified vehicle model with ducts for turbine**

Fig. 3. Flow pattern around the vehicle using the velocity vectors. Wind is entering inside the vehicle and going out. Energy will be extracted from this flow.



(a) Conventional vehicle model without ducts for turbine **(b) Modified vehicle model with ducts for turbine**

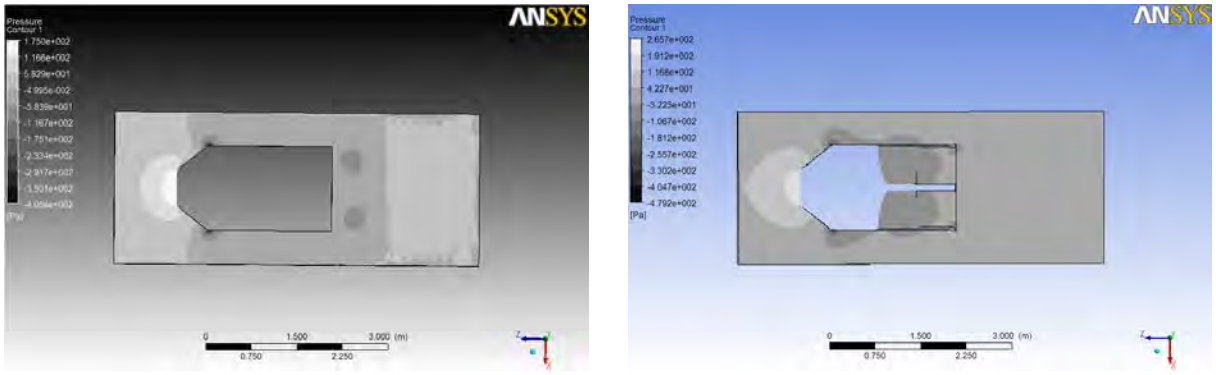
Fig. 4. Streamline of flow over the two different models of the vehicle. It may be noted that the vortexes on the modified design is reduced. On the other hand an additional propulsive thrust can be obtained as the streamlines are leaving the vehicle.

Analyzing figure 3 and 4, it can be seen that the wake region and vortexes are reduced for the modified design which implies that the force (form drag) that existed before is reduced. So it can be concluded that the prediction of flow through the duct and hence reduction of drag should be possible with this modified design. On the other hand, turbines can be placed in these ducts for extraction of some of the kinetic energy contained in the flow. The inlet and outlet pressure along with forces of these two models found from simulation are tabulated in Table 1.

Table 1. Simulation results for pressure and forces

Comparison Parameters	Conventional Design		Modified Design with ducts for turbine	
	Inlet	Outlet	Inlet	Outlet
Pressure(Pa)	2.29185	-1.24196	2.28742	0.240414
Force(Drag)(N)	45.9144	6.5354	15.5202	11.605

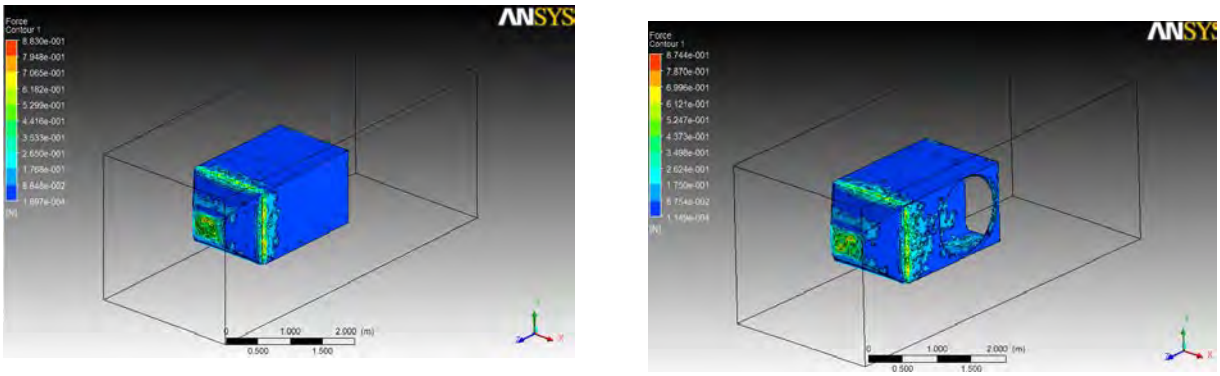
Table.1 shows the plane force and pressure over the two designs have been tabulated. The variation of force and pressure are identical for the both designs, but there are variations in the magnitudes of the parameters. The outlet pressure is increased for the modified design which indicates a reduction in form drag.



.

(a) Conventional vehicle model without ducts for turbine **(b) Modified vehicle model with ducts for turbine**

Fig. 5. Pressure contour around the two models.These figures indicate that the variation of pressure and generation of force due to this pressure variation would be identical but opposite in direction. This symmetry in the design should cancel out the additional thrust crated on the vehicle.



(a) Conventional vehicle model without ducts for turbine

(b) Modified vehicle model with ducts for turbine

Fig. 6. Force contour showing force exerted by the air on the two vehicles which are almost same.

Further analyzing the diagrams we can see (from Fig.3) that the thrust will not be on the axis of the turbine. That means an additional drag force will arise due to placement of the turbines. We predicted that the thrust will be 180 degree apart and hence cancel out each other. But

from velocity vectors we found that the thrusts are not fully at opposite rather they are in a skewed direction. The horizontal components will cancel each other but the vertical components will impose a resultant force. Hence a resultant thrust will be generated against the direction of propulsion on the turbine.

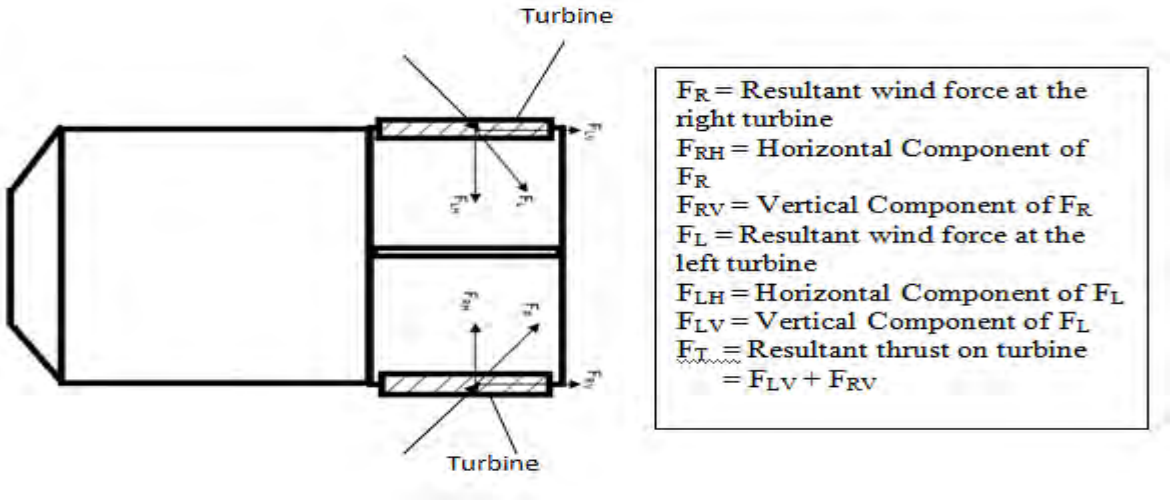


Fig. 8 : Resultant thrust generated on the turbines due to air flow through the ducts.

8. Conclusion

The prime concern with this model is that whether this design will create any additional resistive force components opposite to the direction of the propulsion. It has been found by the simulation that a drag will be induced due to addition of turbine. Overall simulation result along with graphs from Fig.3 will suggest that the overall effect will be same which means the modified design will experience almost same amount of drag compare to the conventional one. But the addition of turbines may give the provision of capturing some energy which will offer some benefits for the vehicle as discussed earlier. A physical structure of the design should be used to carry out wind tunnel tests which are yet to be done. At first the system may resembles with perpetual motion. But a careful observation may indicate that the system is trying to recover some of the energy spend to overcome the aerodynamic drag. The concept of placing symmetrical turbines is presented for the very first time by us. We believe it requires more research and elaborate analysis which we expect to continue in future.

Abstract: Whether biofuels production from starchy biomass can actually be environmentally is still an open question. A modelling approach for strategic systems design combining lifecycle analysis (LCA) and supply chain optimisation (SCO) analysis can significantly contribute to clarify the question. Here we discuss the possibility of managing and optimising the biomass cultivation stage and its integration through the entire production network in order to tune the environmental performance of bioethanol production. The design task is addressed through a quantitative modelling tool, which aims at steering crop management towards the best fertiliser usage and distillers dried grains with solubles (DDGS) end-use in order to ensure optimal whole system performance in terms of both profit and greenhouse gas (GHG) emissions.

Results shows how a crop management strategy devised from a whole systems perspective can significantly contribute to reduce biofuels carbon footprints. In particular, it is observed that through whole systems optimisation, the GHG emissions of so-called first-generation biofuels can approach those associated with second generation ones.

Keywords: *Bioethanol, Whole system optimisation, Supply chain, GHG emissions*

1. Introduction

Over the past years biofuels for transport have been acknowledged as one of the key issues within the world energy agenda. Among the alternatives, bioethanol through first generation productions was first hailed as the most appropriate solution aiming at a partial substitution of oil-based fuels. Although the initial verve, founded on the potential economic benefits as well as on the energy supply security ensured by a broad range of suitable feedstock (i.e sugar cane and starchy biomass), the first generation pathway has recently known oppositions by both the public opinion and part of the academic community. The core of the question revolves around ever increasing doubts on whether bioethanol could effectively ensure the expected potential in terms of global warming mitigation, particularly when the energy vector derives from the conversion of starchy biomass [1,2].

This did contribute to heat up an already existing debate on the actual carbon footprints of these productions. Most of the studies addressing the question [1-6] state that ethanol derived from starchy biomass can actually contribute to a partial oil displacement [3,4,6], although the effective environmental impact tightly relates to the technological and geographical context in which the system performs, and to specific details in the operation of the overall supply chain. For example, GHG emissions from corn-based ethanol production can be estimated between 3% and 86% [5] lower than the emissions from gasoline production, depending on how the ethanol is produced. This large variability is mainly related to biomass production conditions: climate, properties of soil, cropping management and cultivation practice in general [3] can generally contribute to about 45% of the overall GHG emissions [7]. The raw nerve is represented by mineral fertilisers (mainly nitrogen-based ones) as their extensive application in biomass cultivation stage is the primary source of GHG such as nitrous oxide (N_2O) [8]. On the other hand, nitrogen dosage would also entail *direct effects* on biomass production

parameters and, as a consequence, *indirect effects* on the subsequent stages of the network itself. Technically, increasing the nitrogen input per unit of cultivated land causes: *i*. a direct increase in the corn yield, and, indirectly, in the ethanol yield; *ii*. a direct increase in the yield of grain protein to the detriment of starch content of corn grains, and, indirectly, improving the by-products (i.e. DDGS) yield to the detriment of the ethanol yield; *iii*. a direct increase in costs related to fertilisers, but indirectly to reducing operating overheads as an indirect consequence of the potential increase in both ethanol and DDGS yield; *iv*. an indirect increase of the total global warming impact due to greater GHG emissions coming from both fertiliser production and N_2O release from soil.

Another important aspect of the lifecycle emissions relates to the end-use of valuable sub-products (e.g. heat and power or DDGS), and the assumptions about the products that they displace (e.g. coal-derived energy and soya meal) [7]. This is influenced by nitrogen application, too: the potential increase in by-products yield coming from the over-dosage of mineral fertiliser can cause an indirect increase in emission credits coming from products displacement.

All these issues evidence a conflicting situation which cannot be cleared up by means of a mere heuristic evaluation of the pros and cons of fertiliser application. Thus, it raises the obvious need for a fully integrated analysis embodying all those issues (i.e. global warming mitigation together with economic and financial feasibility) that may help defining a more comprehensive and quantitative view of the interactions along the entire biofuels production system so as to assist both crop and fuel producers and, most importantly, policy makers in their strategic decisions. To the best of our knowledge, no analysis has so far been presenting the adoption of modelling tools to *optimise* the overall bioethanol supply chain by taking into account the entire set of production stages in the supply chain including biomass cultivation.

Some of our prior works have addressed the development of optimisation tools linking LCA and SCO models (i.e. Multi-objective Mixed-Integer Linear Programming - MoMILP), and specifically devised for the optimisation of both the environmental and economic performance of biofuels production [7]. Here we discuss the possibility of managing and optimising the biomass cultivation stage, too, and its integration within a quantitative MoMILP model which aims at tuning the environmental performance of bioethanol production so as to identify strategies for deep, system-wide reductions of GHG emissions.

Eventually, the emerging biomass-based ethanol production in Italy is assessed as a real world case study to demonstrate the actual approach capabilities in steering the crop management toward the best overall nitrogen fertiliser usage and DDGS end-use technical choice ensuring best whole-system performance in terms of both profit and GHG emissions.

2. Methods and modelling assumptions

The modelling framework here described is conceived as an optimisation problem in which the production chain is required to comply with both profit maximisation and impact minimisation criteria. Key components of the optimisation problem include biomass production response to nitrogen dosage (yields, costs, etc); biofuel production facilities capital and operating costs as a function of biomass characteristics; transport logistics costs and emissions; environmental burdens of biomass and biofuel production as a function of nitrogen dosage as well as of the DDGS end-use options; and energy market features (energy purchase prices and green credits).

The objective is to determine the optimal system configuration in terms of financial profitability (NPV) and GHG emissions. Therefore, key variables to be optimised include nitrogen dosage over the biomass crop field, DDGS end-use solution, system financial performance over a 10 years horizon and system impact on global warming.

The problem is referred to a fixed land surface (30,000 ha) fully cultivated to supply the biomass needs of a unique production plant of flexible capacity, anyway ranging within a consistent interval, namely 80–120 kt/y.

2.1. Mathematical formulation

The mathematical formulation of the proposed framework is based on the modelling approaches adopted in the design of multi-echelon SCs [9,10], by also introducing multi-period features to address the financial analysis (which is performed over a 10-years time horizon).

2.1.1. Objective functions

The first objective considered is the NPV (Obj_{NPV} [€]) of the business to be established. This imposes the maximisation of profit-related indexes, and hence the Obj_{NPV} value is required to be written in its negative form:

$$Obj_{NPV} = -NPV = FCC - DNI \quad (1.a)$$

where *FCC* [€] are the facility capital costs and *DNI* [€] represents the discounted net incomes.

The second objective is to minimise the total daily GHG impact (Obj_{TDI} [kg CO_2-eq/d]) resulting from the SC operation. Thus, the definition of Obj_{TDI} needs to consider each life cycle stage contribution, as expressed by the following equation:

$$Obj_{TDI} = \sum_s I_s \quad (1.b)$$

where I_s [kg CO_2-eq/d] are the stage-related environmental impacts resulting from the operation of the single stage *s*.

2.1.2. Economics

The *FCC* term accounts for the capital investment required to establish a new fuel conversion facility. However, this model allows for the choice between two different technological options according to the two mentioned options proposed for DDGS use: k =1, which involves the standard conversion technology in which DDGS is processed as a simple by-product to be sold to the animal fodder market; or k = 2 which envisages the construction of a CHP station fuelled by DDGS to produce heat and electricity.

According to this, *FCC* can be calculated by alternatively assigning the capital investment value (CI_k [€]) corresponding to the technological features adopted, as expressed by:

$$FCC = \sum_{n,k} CI_k \cdot W_{n,k} \quad (2)$$

where $W_{n,k}$ is the binary decision variable controlling whether to establish a production facility of type k when a nitrogen dosage n is applied: a value of 1 allows for the construction of the plant type k, otherwise 0 is assigned.

The discounted net incomes *DNI* is defined as the sum over the 10 year operating period of the annual profit before taxes (*PBT* [€/y]) plus the annual depreciation charge related to the capital investment (*D* [€/y]) minus the taxation charge for each year *t* (*TAX* [€/y]), as expressed by the following equation:

$$DNI = \sum_t (PBT - TAX + D) \cdot \varepsilon_t \quad (3)$$

All the terms on the right hand side of Eq. (3) have been discounted through the application of a discount factor (ε_t) defined as [11].

The profit before taxes *PBT* represents the gross annual profit and has been defined as the difference between the total annual revenues *TAR* [€/y] and the total operating costs *OC* [€/y] for year *t* minus the depreciation charge *D*. Accordingly:

$$PBT = TAR - OC - D \quad (4)$$

TAR represents the annual incomes which depend on both ethanol and DDGS sales:

$$TAR = MPe \cdot \sum_{n,k} Pe_{n,k} + \sum_{n,k} Pd_{n,k} \cdot MPd_{n,k} \cdot \omega_k \quad (5)$$

where *MPe* is the bioethanol market price (set equal to 709 €/t according to [12]); $Pe_{n,k}$ [t/y] and $Pd_{n,k}$ represent, respectively, the ethanol and DDGS production rate related to plant technology *k* when a nitrogen dosage *n* is applied to crop biomass; $MPd_{n,k}$ is the DDGS market value and depends on the DDGS end-use solution *k*. When DDGS is used as soy-meal substitute in the animal fodder market ($k = 1$), $MPd_{n,1}$ is the market price that also depends on the nitrogen dosage *n*. On the other hand, if power generation is chosen as the end-use option ($k = 2$), $MPd_{n,2}$ identifies the average market price per unit of electric energy sold to the grid. This does not depend on the nitrogen dosage *n* in any case. This modelling solution also requires the application of a conversion factor, $\omega_{n,k}$, to quantify the amount of by-product produced per unit of DDGS. Thus, when power generation is chosen as end-use solution ($k = 2$), $\omega_{n,2}$ [$kWh_e/t_{10\%m}$] identifies the amount of energy that can be sold to the grid per unit of DDGS produced. On the other hand, when DDGS is used as a soy-meal substitute in the animal feed market ($k = 1$), the amount of by-product to be sold should be equal to the overall DDGS production. In order to comply with Eq. (5), $\omega_{n,1}$ [t/t] has been set equal to 1.

OC is given by the sum of the annual operating costs over the entire supply chain. This has to account for the contribution of all the supply stages (*s*), i.e. biomass production (BP), ethanol and DDGS production (EP) and transports (for biomass, BT, and ethanol, ET), minus the by-products allocation credits (BC). Accordingly:

$$OC = \sum_{n,k} \begin{bmatrix} (Pb_{n,k} \cdot UPCb_n)_{BP} + (Pe_{n,k} \cdot UPCe_n)_{EP} + (UTCb \cdot Pb_{n,k})_{BT} \\ + (UTCe \cdot Pe_{n,k})_{ET} - (Pe_{n,k} \cdot UCRd_{n,k})_B \end{bmatrix} \quad (6)$$

where $Pb_{n,k}$ represents the biomass production rate supplying a conversion plant of type *k* when a nitrogen dosage *n* is applied to crop fields, $UPCb_n$ [$€/t_{DM}$] and $UPCe_n$ [€/t] are respectively the unit production costs for biomass and ethanol, *UTCb* [$€/t_{DM}$] and *UTCe* [€/t] define the unit transport costs for biomass and ethanol respectively, and $UCRd_{n,k}$ is the cost reduction per unit of DDGS used as a valuable alternative *k* and produced when a nitrogen dosage *n* is applied.

The last factor defining *PBT* in Eq. (4) is the depreciation charge *D* evaluated by simply dividing the total capital investment (*FCC*) by 10 (thus assuming a constant depreciation strategy).

2.1.3. Environmental impact

The definition of stage-related environmental impacts I_s [kg CO_2-eq/d] resulting from the operation of the single stage *s* is calculated as follows:

$$I_s = \sum_{n,k} f_{s,n,k} \cdot F_{n,k} \quad \forall\, s \tag{7}$$

where $f_{s,n,k}$ is the a g lobal emission factor representing the carbon dioxide emissions equivalent at stage *s* for technology *k* and nitrogen dosage *n* per unit of reference flow; whereas $F_{n,k}$ uniquely defines the reference flows for each individual life cycle stage and expresses them explicitly as a function of the design variable controlling the optimisation problem. In this problem $Pb_{n,k}$ represents the reference flow for biomass production and biomass transport, $Pe_{n,k}$ for ethanol production and ethanol transport, whereas $Pd_{n,k}$ refers to the emissions credits.

2.1.4. Logical constraints and mass balances

All the variables defined in the above are linked to the specific SC features through the definition of a set of constraints that must be satisfied in each of the SC stages.
A set of relations is formulated to constrain the goods production rate together with the binary variables. In particular, $Pb_{n,k}$ is the dominant production variable and is defined as follows:

$$Pb_{n,k} = LA \cdot GY_n \cdot W_{n,k} \quad \forall\, n,k \tag{8}$$

where *LA* [ha] is the land availability (30,000 ha, as declared in the previous section) and GY_n [t_{DM}/ha] the grain yield per hectare when a nitrogen dosage *n* is applied.

Once the biomass production is quantified, the ethanol and DDGS production rates can be derived by simply applying a specific conversion factor. Accordingly:

$$Pe_{n,k} = Pb_{n,k} \cdot \gamma_n \text{ and } Pd_{n,k} = Pb_{n,k} \cdot \delta_n \quad \forall\, n,k \tag{9}$$

where γ_n [$t_{biofuel}/t_{biomass}$] and δ_n [$t_{10\%m}/t_{biomass}$] are respectively the alcohol and DDGS yields when biomass is cropped by applying a nitrogen dosage *n*.

2.2. Response curves

The definition of the variables response to nitrogen dosage is based on the comprehensive work by Smith et al. [13], which, however, refers to wheat. Since no complete sets of data could be retrieved on corn, it was decided to tune up the wheat data set to corn cultivations on the few data available. Correlations for wheat reported in [13] have been used to define both the graphical and the mathematical dependence of corn grain yield (*GY*), grain protein content (*PY*), DDGS yield (*DDGSY*) and alcohol yield (*EY*) on nitrogen dosage (*ND*). The entire set of model parameters and their inherent dependence on ni trogen application have to be estimated on the basis of these response curves. Because we wish to maintain model linearity, we use a piecewise linear dependence of key variables on ni trogen dosage. The nitrogen dosage variable is discretised into a number (=12) of intervals *n* (25 kg_N/ha of extension). Note that in general climatic and land characteristics may have an impact on the actual crop

response to nitrogen dosage and this should be taken into account when applying the methodology.

The technological related parameters, i.e. GY_n, δ_n, γ_n and μ_n, have been directly obtained by the corresponding response functions. In particular, μ_n is the soy-meal replacement factor representing the amount of soy-meal that can be replaced by DDGS. Thus, in this work we do not assume an allocation by energy on DDGS, but a substitution as fodder at iso-nitrogenous and iso-energetic conditions. According to [14], this has involved the application of a substitution ratio of about 0.68 $kg_{soy\text{-}meal}/kg_{DDGS}$ (defined assuming a DDGS protein content of about 76% compared to soy-meal). Then, the DDGS protein content (and, hence, the substitution ratio response to nitrogen) has been scaled according to the nitrogen dosage applied.

On the other hand, both economic and environmental parameters has been defined adapting the approaches of [7,15] by varying the nitrogen-dependent inputs according to the trend in the response curves.

3. Results and discussion

The modelling framework as presented was used to determine the optimal system configuration according to the two conflicting objectives discussed in the above. Design variables (the nitrogen dosage over the biomass crop field and the DDGS end-use option) were optimised by means of the CPLEX solver in the GAMS® modelling tool [16]. The model considers two technological options for DDGS end-use: *i)* soy-meal substitute to be sold in the animal fodder market, or *ii)* fuel fed to a combined heat and power (CHP) station.
A first instance has been assessed by assuming standard market conditions for the electricity selling price ($MPd_{n,2}$ = 91.34 €/MWh_e). The sub-optimal set of solutions (◆) coming from the trade-off between the environmental (total impact, TI, expressed in kt CO_2-eq) and the financial (Net Present Value, NPV, expressed in M€) criteria is reported in Fig. 1.

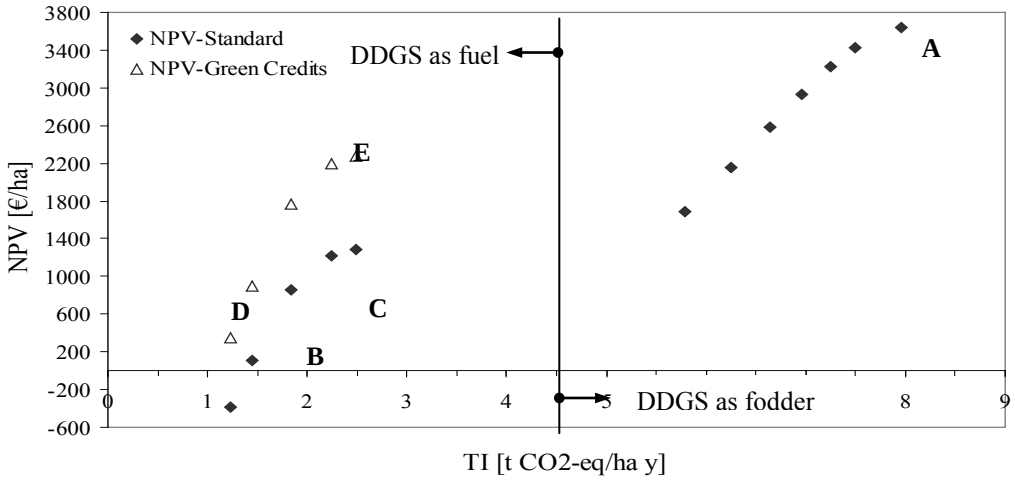

Fig. 1. Pareto set of solutions: NPV vs. Total Impact (TI)

Point A on the diagram represents the best optimum in terms of economic performance that can be obtained by applying a nitrogen dosage of 237.5 kg_N/ha and using DDGS as animal fodder substitute. However, this is not a feasible solution if we consider the EU targets (which impose a minimum of 50% of emission savings with respect to conventional fuels by 2017): point A, indeed, corresponds to a GHG emissions reduction of about 21% that totally amount to 238.9 kt CO_2-eq (about 67.6 kg CO_2-eq/GJ_{EtOH}). The mentioned target is never met if we

keep using the DDGS as animal feed substitute. Thus, it is worth to investigate on the other alternative, namely the use of DDGS to fuel a CHP station. In this case, we assist to a sensible GHG emissions reduction by still remaining within the economic feasibility region. It is possible to obtain payback times lower than 6 years from point B up to point C. The environmental optima (that also assures feasible economic conditions) involves a nitrogen dosage of 87.5 kg_N/ha (point B) so allowing for a GHG emissions reduction of about 80% (17.1 kg CO_2-eq/GJ_{EtOH}) with respect to gasoline and realising an NPV of about 25.7 M€ (the payback time is still reasonable and amounting to about 6 years). On the other hand, the financial optima (still assuring feasible environmental performance) involves a greater nitrogen dosage (162.5 kg_N/ha, point C) so resulting in higher GHG emissions, although still more than acceptable (21.2 kg CO_2-eq/GJ_{EtOH}, corresponding to 75% of emissions savings with respect to gasoline), and realises an NPV of about 38.5 M€ (the payback time is now 5.5 years).

The situation might be even more profitable if the bioethanol business would be supported by governmental subsidies, as it is actually envisaged according to the latest Italian regulation on renewable energy: accordingly the electric energy produced from renewable energy sources can be sold at a price of 180 €/MWh_e. The positive effect of these subsidies is evident from the set of sub-optimal solutions (△) reported in Fig. 1. Considering the solution involving DDGS as animal feed substitute, the situation does not change because green credits do not affect the financial features of this option. On the other hand, the financial performance is actually enhanced if DDGS is used to fuel a CHP station: the points between D and E represent feasible options in terms of both economic and environmental criteria. For instance, by applying a nitrogen dosage of 37.5 kg_N/ha (point D) the environmental optima entails a GHG emissions reduction amounting to about 82% (15.8 kg CO2-eq/GJ_{EtOH}) with an economic profit of about 27 M€ over a 10 years horizon (the payback time is about 6 years, still). However, if the profit maximisation is preferred, it is possible to apply up to 162.5 kg_N/ha (point E) so as to keep within the environmental feasibility region (the GHG emissions reduction would be 75% with respect to gasoline) and realising excellent financial performance: as shown in Figure 7.6, the NPV now amounts to 68.4 M€ so allowing for the lowest payback time (4 years).

4. Conclusions

It is clear that the analysis of biofuels production is a complex task, particularly when environmental issues are taken into account. Broader information, analysis tools, interactions between different types of expertise are necessary to obtain a full comprehension of such a multifaceted problem. If the final goal is fuel instead of food, the overall chain might have to be operated in a different way and the boundary between "first-generation" and "second-generation" biofuels may start blurring. This is why decision makers should be provided with tools capable of evaluating how the system may react to different options and how its design may change if optimised towards specific goals. On the one side, it is important to identify the existing optimal points; on the other hand, we need to assess how flexible the system is in terms of profitability, GHG emissions and environmental and social impacts.

In this contribution we showed how whole-system optimisation tools can be exploited to address these issues. We considered the nitrogen balance optimisation and the technology selection in a first generation bioethanol supply chain according to economic and environmental goals. Results demonstrate that the only way to meet the EU standards (50% of GHG emission savings by 2017) on corn bioethanol in Italy is to adopt a technological solution envisaging the construction of a CHP station to be fuelled with DDGS. This requires

moderate nitrogen dosage as a mineral fertiliser (about 160 kg_N/ha) so as to reach GHG emission savings of about 75% with respect to gasoline production. It is also worth mentioning that a more thoughtful use of mineral fertiliser would also reduce other environmental impacts associated with fixed nitrogen application to agricultural soils (i.e. eutrophication and acidification of the ecosystem). However, this would require support through the deployment of governmental subsidies so as to ensure all the competitiveness and economic efficiency requirements imposed by the global market.

Over the years, the discussion has broadened by incorporating the analysis of the entire supply chain and more recently even the indirect effects of land use change. In fact, future work will need to deal the analysis and modelling of the effects that the land conversion from crop-for-food to crop-for-fuel would generate.

Abstract: Many countries are using and considering the increased use of biodiesel blended fuels to slow their growth of fossil fuel use for transportation purposes. Before the use of biodiesel fuels increase, it is critical that we understand the effect of using biodiesel blends on vehicle emissions, so that we better understand what air quality impacts to expect. Many previous reviews of biodiesel effects on emissions have combined all of the emissions data available to construct a single value for the effects on pollutant emissions. This includes combining emissions data from both light-duty and heavy-duty diesel vehicles and engines, combining vehicle data from chassis dynamometer and on-road emissions testing. In this review, we will analyze the effects on vehicle emissions of switching from petroleum diesel fuel to biodiesel blended fuels for light-duty and heavy-duty vehicles, separately. We will not include engine emissions data in this analysis. For the heavy-duty vehicles, we will also separate results for on-road emissions testing from chassis dynamometer testing. The emissions of regulated pollutants will be evaluated, including hydrocarbons (HC), nitrogen oxides (NOx), carbon monoxide (CO) and particulate matter (PM), as well as carbon dioxide (CO_2) emissions and fuel economy. In these analyses, we have found some statistically significant differences in the effects of biodiesel use on the emissions between heavy-duty vehicles based on dynamometer and on-road emissions testing, and light-duty vehicle dynamometer data. For vehicle emissions from heavy-duty vehicle tested using a dynamometer and on-road emissions techniques, the emissions of CO, CO_2 and PM were found not to be significantly different for B20, but the HC, NOx and fuel economy results were significantly different. The results of the heavy-duty and light-duty dynamometer emissions were found to not differ significantly for any pollutant, other than PM emissions when B20 blended fuels were used. When the results of the emissions studies were not significantly different, the results were combined to determine the effect of biodiesel use on vehicle emissions.

Keywords: *Renewable fuels, Biodiesel, Vehicle emissions, Regulated air pollutants, Hazardous air pollutants*

1. Introduction

Many countries are evaluating a variety of alternative fuels for use in motor vehicles in an attempt to reduce greenhouse gas emissions and to improve the energy security of the country. Biodiesel and other biofuels are substitute fuels capable of replacing fossil fuels on a large scale in the transportation sector. Although biodiesel currently accounts for a small portion of the total diesel fuel used, increasing its use requires that we understand the impact that biodiesel could have on vehicle emissions, and ultimately on air quality.

Vehicle emissions are affected by the fuel that is used. There have been several reviews of the effects of biodiesel fuel use on emissions, but many of these have used engine emissions tests in addition to or instead of vehicle emissions tests [1-4]. Emission measurement methods include engine and chassis dynamometer tests, tunnel studies, and more recently, remote sensing and portable (or on-board) emissions monitoring systems. Engine dynamometer systems are quite useful for research purposes, but because these systems test only the engine, they are missing many factors that may affect the real-world emissions of vehicles. Chassis dynamometer studies test the entire vehicle and can use realistic driving cycles which are expected to produce more representative emissions results. Chassis dynamometer testing is more complicated and expensive than engine testing, so less of that data is available. Remote sensing and on-board emissions measurements have also been used to assess the effects of using different fuels on vehicle emissions. Remote sensing uses spectroscopic measurements of a vehicle that passes through the light beam to measure the concentrations of emitted pollutants. These measurements provide only a snapshot of the emissions at a particular

location and thus cannot characterize an entire operating cycle for a vehicle. On-board emissions measurement systems offer the advantage of being able to capture real-world emissions during an entire operating cycle for the vehicle. In this review, we will focus on the analysis of vehicle emissions data that is more representative of real-world operating conditions, from chassis dynamometer and on-board emissions measurement systems.

2. Analysis Approach

In this paper, we will assess the impact of biodiesel fuel use by looking at the relative value of a property, such as pollutant emissions from a biodiesel blended fuel divided by that from conventional diesel fuel use for a particular vehicle. This reduces some of the variability in analyzing vehicle emissions data, since vehicles that emit larger or smaller quantities of a pollutant when using diesel fuel are expected to also emit larger or smaller quantities of that pollutant when using a biodiesel blended fuel. If the use of biodiesel fuels does not affect the property being studied the relative value will be 1. For example, a value of 1.12 indicates that the property has increased by 12% with biodiesel fuel use and a value of 0.89 would indicate a decrease by 11% with biodiesel fuel use. In this analysis, at least twenty measurements were required to assess statistical significance. This minimum number of measurements was used in an attempt to assure the representativeness of the data. These relative emissions and fuel economy data were tested for normality using the Lilliefors test. These data were found not to be significantly different from a normal distribution. This allows the use of conventional statistical techniques in these analyses.

3. Heavy-Duty Diesel Vehicle Emissions

Quite a bit of data exists for biodiesel blended fuels in heavy-duty (HD) diesel vehicles where the emissions were measured using chassis dynamometers and on-road using portable emissions monitoring systems (PEMS). These two different sources of emissions data will be analyzed separately.

3.1. Heavy-Duty Diesel Chassis Dynamometer Studies

The data used to assess the effect of biodiesel fuels use on HD vehicles from dynamometer studies comes from 19 different studies and includes 124 different tests. Much of the data on the emissions effects of biodiesel blended fuels from chassis dynamometer studies of HD diesel vehicles was for 20% blends of biodiesel with petroleum diesel (B20) and neat biodiesel (B100) fuels. Since a total of twenty valid measurements are required in order to assess the significance of the effect of biodiesel blended fuels on a measurement, only hydrocarbons (HC), nitrogen oxides (NOx) and carbon monoxide (CO) had sufficient data for the assessment of both B20 and B100 biodiesel, while sufficient data was also available for B20 blends to assess the significance of the effects on carbon dioxide (CO_2), particulate matter (PM) and fuel economy. For these HD vehicles, the use of biodiesel led to a decrease for hydrocarbon emissions of 5.7 ± 4.4% (95% confidence interval) for B20 and 23.0 ± 9.2% for B100, a decrease for CO emissions of 4.1 ± 6.4% (not significant) for B20 and 24.0 ± 7.2% for B100, and an increase in NOx emissions of 3.5 ± 2.3% for B20 and 9.0 ± 2.8% for B100. The use of B20 blended fuels also led to a decrease for CO_2 emissions of 0.4 ± 1.0% (not significant), for PM emissions of 13.3 ± 5.1%, and for fuel economy of 2.6 ± 1.2%. There was an insufficient quantity of emissions test data for other biodiesel blends to characterize the variability in the emissions data, and to allow one to reliably assess the significance of the effects on the emissions of HD vehicles tested using chassis dynamometers.

3.2. Heavy-Duty Diesel On-Road Vehicle Emissions Studies

The data used to assess the effect of biodiesel fuels use on HD vehicles from on-road studies comes from 14 different studies and includes 94 different tests. Almost all of the data for these on-road vehicle emissions tests of HD diesel vehicles are for B20 blends. For these HD vehicles, the use of B20 blends led to a decrease for hydrocarbon emissions of 21.7 ± 4.4% (95% confidence interval), a decrease for CO emissions of 6.6 ± 5.4%, and a decrease in NOx emissions of 3.3 ± 3.4% (not significant). The use of B20 blended fuels also led to an increase for CO_2 emissions of 3.0 ± 3.6% (not significant), a decrease for PM emissions of 15.2 ± 6.0%, and an increase for fuel economy of 6.3 ± 8.1% (not significant). One of the major complications of the on-road PEMS testing for evaluating different fuels is the much poorer matching of the operating conditions of the vehicles with these different fuels. This generally leads to increased variability in the results.

3.3. Differences between Chassis Dynamometer and On-Road Heavy-Duty Vehicle Emissions Data

The chassis dynamometer and on-road vehicle emissions data for HD vehicles were tested to determine if the results were significantly different for these two testing procedures. It was found that there was no significant difference in the results of the emissions test methods for the CO, CO_2 and PM data using B20 blends. However, the results were significantly different for the HC, NOx and fuel economy data between the two data sets. For the HC data, B20 blends led to a significant decrease in HC emissions in both cases, but only about 5.7% for the dynamometer studies and 21.7% for the on-road studies. The decrease from the on-road studies with B20 were similar to the effects of B100 seen with the dynamometer data. For the NOx data, B20 blends led to a significant increase in NOx emissions of about 3.5% for the dynamometer studies, while there was a 3.3% decrease (not significant) in NOx emissions in the on-road studies. The data continues to support an increase in NOx emissions with biodiesel blends in HD diesel vehicles. In the case of the fuel economy data, B20 blends led to significantly lower fuel economy of about 2.6% from the dynamometer studies, but led to a 5.7% increase (not significant) in fuel economy for the on-road studies. The data continues to support a decrease in fuel economy with B20 biodiesel blends in HD vehicles.

Since there was no significant difference in the results of the dynamometer and on-road emissions studies using B20 blends for the HD vehicle emissions of CO, CO_2 and PM, these data sets were combined and the significance of the effects on this larger pooled data set were assessed. For the CO emissions data with B20, a 4.1% decrease (not significant) was found from the dynamometer studies and a significant 6.6% decrease was found from the on-road studies. With the combined data set, a significant decrease of 5.3 ± 4.1% was found for CO using B20 blends. For the CO_2 emissions data with B20, a 0.4% decrease (not significant) was found from the dynamometer studies and a 3.0% increase (not significant) was found from the on-road studies. With the combined data set, a 1.6 ± 2.2% increase (not significant) was found for CO_2 using B20 blends. These data support the conclusion that the use of B20 biodiesel fuels has no significant effects on the emissions of CO_2. For the PM emissions data with B20, a significant 13.8% decrease was found from the dynamometer studies and a significant 15.2% decrease was found from the on-road studies. With the combined data set, a significant decrease of 14.5 ± 3.9% was found for PM using B20 blends.

4. Light-Duty Diesel Vehicle Emissions using Chassis Dynamometers

The data used to assess the effect of biodiesel fuels use on light-duty (LD) vehicles from dynamometer studies comes from 47 different studies and includes 259 different tests. LD

diesel vehicle emissions have been measured almost exclusively by use of chassis dynamometers. PEMS have not been used extensively in the study of LD diesel vehicle emissions. The available data consists of a number of studies conducted in North America, Europe, Asia and Australia. The studies conducted in North America tend to be dominated by studies of larger vehicles, including pickup trucks, while those elsewhere in the world include a larger fraction of cars, passenger and delivery vans. This data set also includes biodiesel fuels that are made from different biooil feedstock (soy, rapeseed, canola, palm, coconut, used cooking oils, animal fats, etc.). The emissions test data for light-duty vehicles contains many more tests with varying biodiesel percentages, not largely B20 and B100.

Fig. 1 shows the relative emissions of HC, NO_x, CO, CO_2, PM and fuel economy effects of using various biodiesel blended fuels based on chassis dynamometer testing of LD vehicles from a number of different studies. From this figure it is clear that there is a relatively large quantity of data available with different biodiesel percentages, and that there is considerable variability in the individual measurements of the relative emissions effects of biodiesel blended fuels. Similar figures are seen when one looks at the HD diesel emissions data. For the regulated pollutant emissions, there are more that 20 sets of test results available for the B5, B10, B20, B30, B50 and B100 biodiesel blends. This allows the evaluation of statistical significance of the effects of these blends on vehicle emissions.

For the LD diesel vehicle emissions we observed the following effects of the biodiesel blended fuels. For the HC emissions the effects of the biodiesel blends is an increase of 1.6 ± 4.5% (95% confidence interval) for B5, an increase of 4.2 ± 5.2% for B10, a decrease of 4.1 ± 5.5% for B20, a decrease of 0.3 ± 5.4% for B30, a decrease of 0.9 ± 10.3% for B50, and a decrease of 5.8 ± 14.8% for B100. None of the observed effects on hydrocarbon emissions are statistically significant. For NOx emissions the effects of the biodiesel blends was an increase of 1.1 ± 2.7% for B5, of 5.1 ± 2.3% for B10, of 5.8 ± 2.2% for B20, of 7.2 ± 2.7% for B30, of 7.3 ± 3.5% for B50, and of 6.5 ± 3.5% for B100. The biodiesel blend effect on NOx emissions is consistently a statistically significant increase for all of these blend levels, except B5. The effect of the biodiesel blends on CO emissions show a decrease of 0.7 ± 2.9% for B5, an increase of 2.7 ± 5.9% for B10, a decrease of 5.5 ± 3.5% for B20, an increase of 4.8 ± 6.0% for B30, an increase of 4.7 ± 10.8% for B50, and an increase of 12.9 ± 14.3% for B100. For the CO emissions, none of the biodiesel blends above had a statistically significant effect, except the decrease observed for the B20 blend. For the CO_2 emissions the effects of the biodiesel blends was a decrease of 2.0 ± 2.3% for B5, a decrease of 1.1 ± 0.9% for B10, a decrease of 0.4 ± 1.2% for B20, an increase of 1.1 ±1.4% for B30, an increase of 1.2 ± 1.3% for B50, and an increase of 0.8 ± 1.4% for B100. This data shows a small statistically significant decrease in CO_2 emissions only for the B10 blend. None of the other results are statistically significant. The effect of the biodiesel blends on PM emissions show a decrease of 1.0 ± 5.0% for B5, a decrease of 14.8 ± 3.5% for B10, a decrease of 5.8 ± 4.9% for B20, a decrease of 16.0 ± 3.6% for B30, a decrease of 9.1 ± 8.6% for B50, and a decrease of 7.0 ± 14.8% for B100. The decrease observed for the B10, B20, B30 and B50 blends are statistically significant, and they are relatively large effects in the range of 6-16% decrease, but none of the other biodiesel blend levels resulted in a statistically significant effect. For the fuel economy results, only the B5, B10, B20, B30 and B50 blends had a sufficient quantity of data (more than 20 values) to assess the significance of the effects. The fuel economy was found to decrease (or fuel consumption increased) by 0.4 ± 1.2% for B5, by 0.3 ± 1.0% for B10, by 1.0 ± 1.8% for B20, by 1.3 ± 2.0% for B30, and by 1.9 ± 2.5% for B50. None of the fuel economy effects are statistically significant.

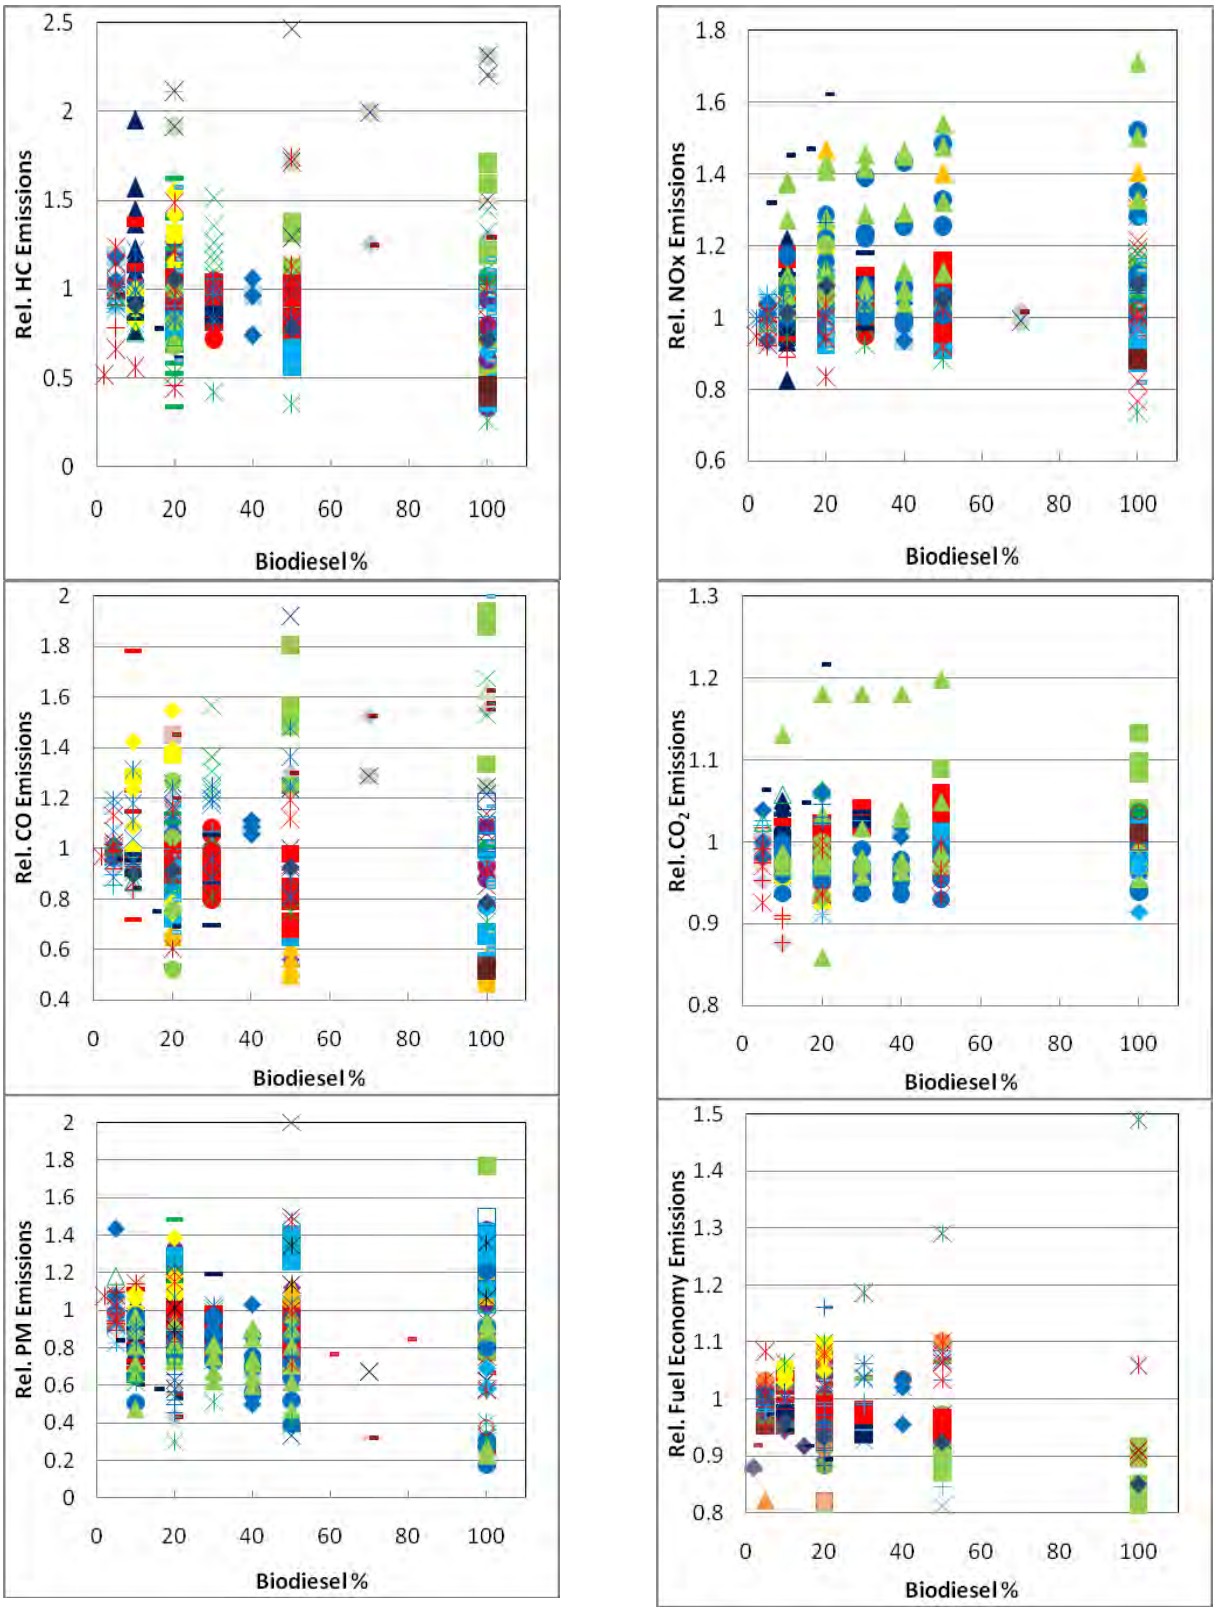

Fig. 1. Chassis dynamometer test results of relative emissions of hydrocarbons, nitrogen oxides, carbon monoxide, carbon dioxide, particulate matter, and vehicle fuel economy for biodiesel fuel relative to diesel fuel in light-duty diesel vehicles.

Sufficient data exists to allow one to begin to explore the effects of biodiesel fuel use on the emissions of formaldehyde, acetaldehyde and total polycyclic aromatic hydrocarbons (PAH) for LD vehicles. The effects of the biodiesel blends on formaldehyde emissions were increases of 28.9 ± 17.1% for B10, 27.5 ± 21.8% for B20 and 34.9 ± 8.7% for B30, while the effects on acetaldehyde emissions were increases of 40.7 ± 76.1% for B10, 69.9 ± 126% for B20 and 23.1 ± 7.2% for B30. All of the increases found for formaldehyde emissions were statistically significant, but only the acetaldehyde emissions increase for B30 was statistically significant. The results for the effects of the biodiesel blends on the emissions of total PAH were confusing, with the total PAH emissions reduced by 8.3 ± 6.4% for B10 and 8.9 ± 9.8% for B20, while for the B30 and B100 blends, the total PAH emissions increased by 21.2 ± 18.4% and 33.4 ± 53.7% respectively. Only the results for B10 and B30 were statistically significant.

5. Comparison of Heavy-Duty and Light-Duty Diesel Vehicle Emissions

The only comparisons that can be made between HD and LD diesel vehicle emissions are for B20 blends, where sufficient data exists for the HD diesel dynamometer and on-road and LD dynamometer tests, and for HC, NOx and CO emissions where sufficient data exists for HD and LD dynamometer tests with B100 fuels. For the HC emissions, we have found that the emissions from HD vehicles in the on-road emissions studies are significantly lower that the HD dynamometer test results. The HD on-road emissions results are also significantly lower than the LD dynamometer results, and the HD and LD dynamometer results are not significantly different from each other. The HD and LD dynamometer results have been combined for the B20 blend, resulting in an overall HC emissions decrease of 4.9 ± 3.5% from the combined dynamometer data. Again for NOx emissions, the HD on-road emissions results were significantly lower than the HD dynamometer results and were significantly lower than the LD dynamometer results. There was no significant difference between the HD and LD dynamometer results for NOx. The HD and LD dynamometer results have been combined for the B20 blend, resulting in an overall NOx emissions increase of 4.7 ± 1.6%. For the CO emissions, the HD on-road emissions results were not significantly different that the HD dynamometer results, and the combined HD emissions results were not significantly different than the LD dynamometer results. The HD dynamometer and on-road emissions results, and the LD dynamometer emissions results were combined for the B20 blend, resulting in an overall CO emissions decrease of 5.4 ± 2.9%. For the CO_2 emissions, the HD on-road emissions results were not significantly different that the HD dynamometer results, and the combined HD emissions results were not significantly different than the LD dynamometer results. The HD dynamometer and on-road emissions results and the LD dynamometer emissions results were combined for the B20 blend, resulting in an overall CO_2 emissions increase of 0.9 ± 1.5%. For the PM emissions, the HD on-road emissions results were not significantly different that the HD dynamometer results, but the combined HD emissions results were significantly lower than the LD dynamometer results. The HD dynamometer and on-road emissions results were combined for the B20 blend, resulting in an overall PM emissions decrease of 14.5 ± 3.9%. The fuel economy from HD vehicles in the on-road studies are significantly higher than the HD dynamometer test results. The HD on-road fuel economy results are not significantly different from the LD dynamometer results, and the HD and LD dynamometer results are not significantly different from each other. The HD and LD dynamometer results have been combined for the B20 blend, resulting in an overall fuel economy decrease of 1.8 ± 1.1%.

For the HC emissions from B100 blends, we have found that the emissions from HD and LD dynamometer data are not significantly different. The HD and LD dynamometer results have been combined for the B100 blend, resulting in an overall HC emissions decrease of 13.4 ±

9.2%. For the NOx emissions from B100 blends, the emissions from HD and LD dynamometer data are not significantly different. The HD and LD dynamometer results have been combined for the B100 blend, resulting in an overall NOx emissions increase of 7.5 ± 2.4%. For the CO emissions from the B100 blend, the heavy duty dynamometer results are significantly lower than the LD dynamometer results.

6. Conclusions

Most reviews of the effects of biodiesel blended fuels use on vehicle emissions combine all of the available data engine and vehicle, LD and HD to assess the effects. As has been found in this work this is not always a valid approach. In this work, we have only used vehicle emissions data, no engine data, and we have found some significant differences in subsets of this vehicle data.

In this work, it was found that there some of the emissions for HD diesel vehicles tested using dynamometers and on-road were significantly different. For B20 blends, the HC emissions for both test procedures led to significant decreases emissions in these emissions of 5.7% for the dynamometer studies and 21.7% for the on-road studies. In the cases of NOx emissions studies, a statistically significant increase in NOx emissions was found for B20 blends from the dynamometer data, while the on-road studies resulted in a 3.3% decrease that was not significant. For fuel economy, the dynamometer data for B20 showed a significant decrease in fuel economy of 2.6%, while the on-road data gave a 5.7% increase that was not significant. For each of these three measures for the two different sources of HD vehicle emissions data, the dynamometer data was significantly different from the on-road data. It is not be valid to combine data from the dynamometer and on-road studies of B20 blended fuels for HC and NOx emissions and fuel economy to determine the effects of using these fuels in HD vehicles. But since the B20 data for CO, CO_2 and PM emissions derived from these two different test procedures are not significantly different, it is valid to combine these data sets to assess the overall effects of B20 on these emissions from HD vehicles.

In comparing the results of studies on LD and HD vehicles for B20 blends, we have found no significant differences in HC and NOx emissions and fuel economy between the LD and HD dynamometer studies, and we have found no significant differences in emissions of CO and CO_2 between the LD dynamometer and the combined HD dynamometer and on-road test data. But the PM emissions for B20 fuels are significantly different between the LD dynamometer and the combined HD dynamometer and on-road test data. Table 1 summarizes the statistically significant results for B20 blended fuels, where the HD and LD data are combined when there is no significant difference between the subsets of the data.

Being able to partition data to allow one to explore subsets of vehicle emissions data requires large quantities of data. Many other factors need to be explored, but there is a shortage of adequate data to be representative of these other factors. There is inadequate data available to allow one to assess the effects of biodiesel fuel use on emissions of hazardous air pollutants, such as benzene, 1,3-butadiene, etc. As seen in this work, there is sufficient data to begin exploring the effects on LD vehicle emissions of formaldehyde, acetaldehyde, and polycyclic aromatic hydrocarbons. We need much more data to begin assessing the effects of biodiesel fuel use on ultrafine particulate emissions, especially, particle number and particle size distributions in emissions. Different biodiesel feedstocks are more commonly used in different areas of the world, such as soy oil in North America, rapeseed oil in Europe and palm oil in southern parts of Asia. Additional vehicle emissions data is necessary to explore the effects of different biodiesel feedstocks on vehicle emissions.

Table 1. Summary of statistically significant results for B20 and B100 biodiesel blends for combined LD and HD dynamometer (dyno) and HD on-road emissions data.

Emission	Biodiesel Blend	Tests	Biodiesel Effect	95% Confidence Interval	Number of Measurements
HC	B20	HD & LD Dyno	-4.9%	±3.5%	204
HC	B20	HD On-road	-21.7%	±4.4%	89
HC	B100	HD & LD Dyno	-13.4%	±9.2%	122
NO_x	B20	HD & LD Dyno	+4.7%	±1.6%	227
NO_x	B100	HD & LD Dyno	+7.5%	±2.4%	143
CO	B20	HD, LD Dyno & HD On-road	-5.4%	±2.9%	286
PM	B20	HD Dyno & HD On-road	-14.5%	±13.9%	137
PM	B20	LD Dyno	-5.8%	±4.9%	109
Fuel Economy	B20	HD & LD Dyno	-1.8%	±1.1%	94

Abstract: With the ambitions to further increase its share of more sustainable vehicles, Stockholm Public Transport Authority (SL) carried out a project to evaluate the performance of ethanol hybrid buses together with bus manufacturer Scania and bus operator Nobina. Ethanol hybrid buses were operating in regular suburban public transport traffic in Stockholm between May 2009 and June 2010. The purpose of this paper is to evaluate the potential of the ethanol hybrid buses in general and their energy efficiency in particular. The evaluation is based on experimental data, mainly from standardised duty cycle tests, but also general experiences during the trail, for example error reports. The buses have a series hybrid powertrain with super capacitors as energy storage. At favourable conditions the fuel reduction is approximately 20 %. The potential additional fuel savings of the start/stop software has been tested and adds at least another 10 % fuel reduction. Not all of the hybrid system's components are yet robust enough, thus they need further development to fully commercial. Hybrid city buses have great potential but are currently not technically mature and proven, nor have the overall costs over the lifetime of the vehicle reached a commercial level as yet.

Keywords: *Ethanol hybrid bus, Series hybrid, Duty cycle, Urban public transportation, Energy analysis*

1. Introduction

Six ethanol hybrid buses and one reference bus were operated during a one-year field test to evaluate the robustness and energy saving potential of their hybrid powertrain. Partners in the project were the Stockholm Public Transport Authority (SL), the bus manufacturer Scania and the bus operator Nobina and it was carried out with funding from the Swedish Energy Agency. This is a unique project because it is one of the first times renewable-fuelled hybrid buses have been tested and operated in real traffic. The buses were operating in Stockholm's south suburban areas but were also taken out of traffic to perform standardised duty cycle tests on a test circuit, tests intended to better reflect inner-city driving. The objective of the field test from Scania's perspective was to test the hybrid powertrain in real traffic early in the development process in order to find weaknesses in the hybrid system. From SL's and Nobina's point of view the project aimed to evaluate the status and the potential of hybrid buses and was a way to enhance the development of even more environmentally friendly vehicles in their fleets. Already today (2010), SL has the world largest fleet of renewable-fuelled buses with more than 400 ethanol buses and 100 biogas buses in operation out of a fleet of around 2000 buses. The target is that 50 % of all buses should run on renewable fuels at the end of 2011 and 100 % by 2025 [1]. In this paper the general operational findings are presented with focus on evaluation of robustness of the powertrain (one-year field test) and the energy efficiency potential (duty cycle tests).

2. Methodology

The objectives are to evaluate the robustness and the energy efficiency potential of ethanol hybrid buses. In order to evaluate the robustness of the hybrid powertrain, the drivers and technicians filed error reports during the one-year field test. To attain reproducible experimental data in order to evaluate the energy efficiency potential, duty cycle tests were carried out. More details about the experimental set-up, see section *5. Experiments and results.*

3. Towards sustainable urban transportation

There are many reasons for promoting more sustainable urban transportation:

- To reduce emissions harmful to public health such as NOx, particulates and noise.
- To reduce emissions of greenhouse gases, most important fossil CO_2.
- To secure energy supply for the transport sector in the long term.

Additionally, by increasing the share of public transportation the problems with traffic congestion decrease. Traffic congestion becomes worse as the population in urban areas increases and cities become more densely populated while simultaneously more transports of people and goods must be carried out in the same or even less space than before.

The CO_2 emissions are, apart from increasing the share of public transport, tackled cost-efficient by shifting from fossil to renewable fuels. This has positive impact also on the energy security issue, especially if bio fuels may be produced locally. Bio fuels may sometimes be used as low-blends in fossil fuels, and sometimes as high-blends or pure fuels. There are political targets and also legislation for introduction of bio fuels in various regions, e.g. the EU is to have 10 % renewable fuels by 2020 [2]. A local example is the Swedish Government's vision that the Swedish transport sector should be independent of fossil fuels by 2030 [3]. Most widely spread renewable fuels are ethanol and biodiesel but other fuels, such as biogas are also getting increased attention in some markets [4].

At the same time as more bio fuels are introduced in the transport sector, vehicles must be as energy or fuel efficient as possible, irrespective of the fuels used, i.e. fossil and/or renewable. Striving for fuel efficiency is an ongoing process and has been the single most important force of competition in the commercial vehicle industry for decades – fuel efficiency improvements are introduced when commercially feasible. Commercially feasible refers to the lifecycle cost of an improvement in comparison with its expected benefits. This is for fuel efficiency improvements the development and production costs, expected lifetime, replacement cost if the lifetime of a new component is short as well as additional repair and maintenance costs measured against fuel cost saving or CO_2 saving. Hybridisation is one proposed method for vehicle fuel savings. A hybrid powertrain also gives the potential to improve the vehicle by other means and to make it more attractive for the passengers, e.g. noise impact can be minimised during start and acceleration since the internal combustion engine is assisted by one or more electric motors. If the vehicle has a series hybrid powertrain, i.e. a completely electric propulsion system, the powertrain usually offers a completely step less, and thereby very comfortable, drive without any jerks at all due to gear shifts. In this powertrain, there are also possibilities to improve the vehicle design and layout because there are basically no restrictions imposed by a mechanical transmission, prop shafts, cardan angles etc [5]. Even though hybrid buses seem to have a good potential there is no production of hybrid buses in common commercial terms, only small series production as tests and demo fleets, or politically driven and heavily subsidised fleets. In North America there are a few thousands hybrid buses running in Seattle, New York City, San Francisco and Toronto among other cities, all heavily subsidised by the government or local municipalities. The extra cost for hybridisation is usually very high, in the range of 100,000 € or even more extra per vehicle [6] and the technology is not yet proven, especially the energy storage systems (e.g. battery). Even so, hybrid buses, if designed and implemented in a clever and cost-efficient way, may play an important role in a future sustainable transport system due to their potential for energy saving, especially if combined with renewable fuels.

4. The bus

The ethanol hybrid bus is a Scania OmniLink, a three axis, 13.7 meter long low-entry city/suburban bus with a rear boggie. The internal combustion engine (ICE) is a diesel engine slightly adapted (e.g. higher compression ratio) to combust ethanol according to the diesel combustion process. The renewable fuel (ED95) used for the engine consists of 95 % ethanol and 5 % additives (ignition improver, lubricating additive etc). This is the third generation of ethanol engines from Scania since start of production in the late 1980s. So far around 700 ethanol buses have been delivered, mainly to Stockholm but also to number of cities worldwide.

The hybrid buses are equipped with a series hybrid powertrain, i.e. with fully electric propulsion. A 150 kW electric motor propels the mid axle of the bus. A high power and high torque generator is mounted on the internal combustion engine. The electric motor, generator and power electronics are delivered by Voith. The energy storage system in the hybrid powertrain consists of super capacitors, not batteries. Four 125 V modules from Maxwell connected in series offer total usable storage capacity of 400 Wh.

Fig 1. The Scania OmniLink ethanol hybrid bus and a schematic illustration of the series hybrid powertrain [Photo: Stefan Wallin, SL]

A reference bus with an identical ethanol engine but equipped with a conventional six-speed hydraulic automatic gearbox with retarder from ZF was also operated during the field test. The reference bus has the same identical exterior dimensions (excluding the roof hood containing the energy storage) and interior design as the hybrid bus. The only difference is that the hybrid buses have one seat missing in front of the rear door of the bus due to a conduit for cabling and coolant pipes to the power electronics and the energy storage system mounted on the roof. The hybrid bus is approximately 1.5 tonnes heavier than the reference bus.

Type: Scania OmniLink Low-entry city bus	Description
General	
Dimensions *(L × W × H)*	13.7 m × 2.55 m × 3.54 m
Kerb weight	16 tonnes
Max weight	26 tonnes
Passenger capacity	115 (40 + 75) (minus one seat in hybrids)
Internal Combustion Engine	Diesel ethanol engine
Fuel	ED95
Maximum Power output	198 kW (270 hp)
Maximum Torque	1 250 Nm
Emission level	Euro V / EEV
Hybrid components	
Type	Series hybrid
Electric motor	Voith TFM
Maximum Power	150 kW
Maximum Torque	2 750 Nm
Generator	Voith TFM
Maximum Power	220 kW
Maximum Torque	1 250 Nm
Energy Storage Unit	Maxwell Super Capacitors
Number of modules	4
Total capacity (useable)	400 Wh
Maximum voltage per unit	125 V
Maximum voltage in total	500 V

Fig 2. Technical description of the ethanol hybrid bus

5. Experiments and results

The one-year field test generated considerable experience as regards the robustness of the hybrid powertrain. In order to evaluate the energy efficiency potential, duty cycle tests were carried out to obtain experimental data representing various traffic situations. The nature of the suburban route did not produce data relevant for an energy flow analysis for city traffic.

5.1. Evaluation of powertrain robustness from one-year field test

Based on error reports filed by the drivers and technicians during the field test, the main malfunctions were divided into three categories: 1) ICE, internal combustion engine 2) the bus in general and 3) hybrid powertrain-related errors. To further evaluate the hybrid powertrain, this section is divided into four subgroups (a – d) to evaluate the robustness of its main areas. Compilation of results from error report is shown in Figure 3.

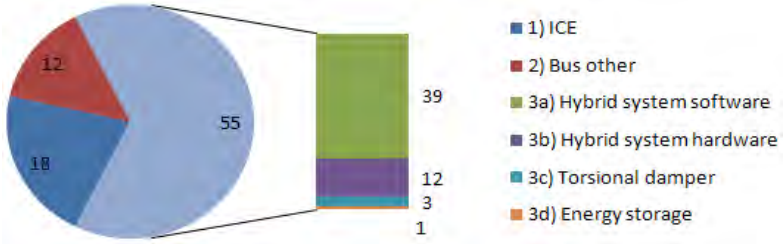

Fig 3. Error reports filed during the one-year field-test.

The robustness of the hybrid powertrain is the focus for this paper, but just to mention something about the other two categories, also the internal combustion engine underwent development during the field test period, e.g. the fuel injections system was improved. Upgrading the engine eliminated many of the errors reported during the first part of the test period. The hybrid software is still under development; during the field test it was too sensitive to interference from e.g. abnormal parameter values sent from other hybrid components as well as the 24 V system voltage level. Through maintenance charging of the 24 V start battery; the number of software reports was reduced. Malfunctions due to hardware are caused predominantly by three components: the direction sensor on the electric motor, the electric motor itself and the torsional damper between ICE and generator. Due to the hybrid management road safety system, incorrect indication of torque to the direction sensor will immediately shut down the system. Some sensors were malfunctioning and therefore replaced and other reported errors were just false alarms. The construction of the electric motor in the tested version was not durable enough for this 3-axle hybrid bus application and had a life of about 15 000 – 20 000 km in several buses causing many filed error reports. This problem arose rather late in the project and was not yet resolved when the field test ended, but is defined and considered possible to tackle with further development. The torsional damper (3c) was initially too weak and when replaced by a stronger one the problem was solved. The only problem reported concerning the energy storage was a fan failure and therefore not caused by the super capacitors. The super capacitors may, as far as this one-year field test is concerned, be regarded as suitable energy storage for the application as regards robustness.

5.2. Evaluation of energy efficiency potential by standardised duty cycle test

In order to evaluate the potential of the hybrid powertrain, standardised duty cycle tests, according to SORT – Standardised on-road tests cycles (developed by the International Association of Public Transport, UITP), were carried out. The key parameters in a traffic situation are the average speed and the number of stops per kilometre, see Table 1. Variations due to topography are neglected to make the test repeatable, hence duty cycles are assumed to be completely flat.

Table 1. Characteristics of the three SORT duty cycles, from UITP 2004 [7]

	SORT 1	SORT 2	SORT 3
Average speed [km/h]	12.6	18.6	26.3
Stops per kilometre	5.8	3.3	2.1
Time idling [%]	39.7	33.4	20.1
Cycle type	Urban	Mixed	Suburban

Figure 4 shows the three performed duty cycles' continuous velocity profile coupled with the energy content in the super capacitors expressed as the state-of-charge (SOC) where 100 % is fully charged and the lowest level is restricted to 25 % (half nominal voltage) to decrease the risk of chemical side reactions and thereby increase capacitor service life. Experiments show that the super capacitors obtain a high round-trip efficiency, generally above 90 %. Super capacitors have high power density [8] and are therefore a suitable energy storage units for heavy vehicles equipped with regenerative braking. The kinetic energy accumulated during deceleration, is converted in the electric motor into electric power charging the super capacitors. If not stored in the super capacitors, it will be used to propel the ICE via the generator or, last of all, dumped in the resistor as heat to the cooling system, see Figure 1. SORT 1 tests show dynamic energy storage management without long time periods of completely charged or empty super capacitors. As seen in Figure 4 already during the SORT 2 test the energy storage will be restricted in terms of size (400 Wh), i.e. the energy storage system is fully charged. During SORT 3 tests, the charge oscillates between its extreme values. The capacity of the energy storage system is therefore a limiting factor for a bus in driving situations similar to SORT 2 and 3 but feasible for SORT 1, urban operation.

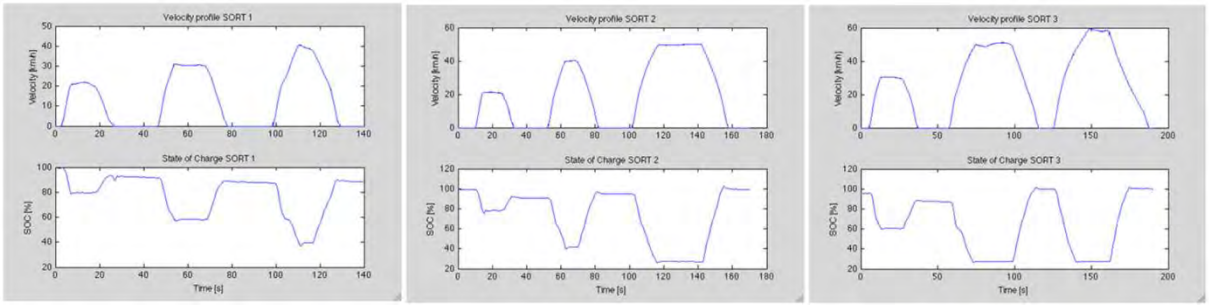

Fig 4. Velocity profile (top) and corresponding SOC profile (bottom) for SORT 1-3 test cycle

Performed SORT cycle tests with the reference bus enable quantification of the absolute fuel consumption reduction generated by the hybridisation, see Table 2.

Table 2. Fuel consumption SORT duty cycles.

	Reference Fuel consumption [litre/ 100 km]	Ethanol hybrid bus Fuel consumption [litre/ 100 km]
SORT 1	89.5	72.5
SORT 2	79.0	63.0
SORT 3	71.0	63.0

A significant fuel consumption reduction is attained for the cycles SORT 1 and SORT 2, 19 %, and 20 %, from 89.5 to 72.5 l/100 km and 79 to 63 l/100 km, respectively. The fuel consumption reduction for SORT 3 corresponds to 11 %, from 71 to 63 litre/100 km. In order to increase the level of detail, the energy spent per driving mode was explored, see Figure 5.

The four driving modes were defined as:

Idling – vehicle speed (υ) is zero, $\upsilon(i)=0$
Deceleration – when not idling and acceleration is negative $\upsilon(i) > \upsilon(i+1)$
Acceleration – when not idling and acceleration is positive $\upsilon(i) < \upsilon(i+1)$
Cruising – when not idling and acceleration is zero. $\upsilon(i) = \upsilon(i+1) \neq 0$

Fig 5. The energy and time spent per driving mode for duty cycle tests with hybrid bus according to the three SORT-cycles

Even though a large time is spent idling (about 1/3 of the time), the fuel consumption during this driving mode is moderate (between 5 and 15 %). The most fuel-consuming driving mode is acceleration where approximately 60 % (varies between 57.7 and 62.8 %) of the total fuel consumption is utilised during about 30-35 % of the time.

5.2.1. Start/stop

To further decrease the fuel consumption it is possible to install a software start/stop feature, which automatically turns of the ICE when idling. Analogous to the time spent as in Figure 5 the fuel consumption when the start/stop software operated was measured. The fuel consumption during idling drops drastically, now only consuming between 2.97 % (SORT 1) and less than 1 % (SORT 2 and 3). Decreasing the fuel demand during idling (which for the SORT cycles, corresponds to approximately 30 % of the time and in real traffic sometimes up to 60 % or more) has a significant impact on the overall fuel consumption, seen in Table 3:

Table 3. Fuel consumption during SORT duty cycles with the buses

	Reference [litre/ 100 km]	Ethanol hybrid bus [litre/ 100 km]	Ethanol hybrid bus with start/stop [litre/ 100 km]
SORT 1	89.5	-19 %	-33 %
SORT 2	79.0	-20 %	- 21 %
SORT 3	71.0	-11 %	- 13 %

5.2.2. Energy flow analysis using Sankey diagram

The energy flows through the electrified powertrain, see Figure 1, for the urban SORT cycle are illustrated in Figure 6 by a Sankey diagram. The Sankey diagram presents an average overview of the energy flows, and is not representative for a specific time during the cycle but is illustrative for the complete cycle. The energy flows in and out of key hybrid components are on-board measured data. The total power input is calculated from the instantaneous amount of fuel injected, in gram per stroke, using the lower heating value and density of ED95, 26.8 MJ/kg and 820 g/l, respectively. Losses for the ICE correspond to energy losses such as heat, mechanical and transmission losses. The energy consumption for running the auxiliary systems is also accounted for as an energy loss over the ICE. The efficiency in the generator is defined as the ratio between electrical power output and mechanical input. The generator and its inverter has experimentally proven to have an average efficiency of around 92 %.The energy storage efficiency, when SOC-balanced just as the round-trip efficiency, is calculated as the ratio between the total energy storage output and total energy storage input.

The energy storage efficiency is consistently about 90 % for all the three cycle tests. When decelerating, the electric motor operates as a generator and recovers brake energy. The share recovered brake energy almost exceeds 20 % of total power input. The efficiency of the electric motor is defined as the ratio between the average power input from the powertrain and the mechanical power output. The experimental average efficiency of the electric motor is approximate 92%. The share of power dumped upon the resistor during the SORT 1 cycle is small which indicates adequate energy storage size. The share, which is not regenerated, constitutes the term of losses due to aerodynamic drag, rolling resistance, transmission losses and wheel brakes.

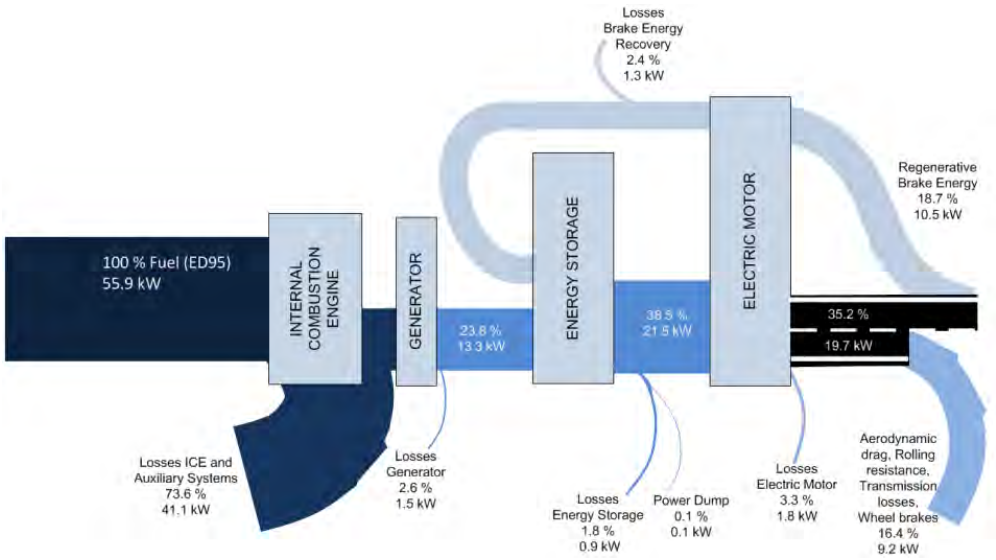

Fig 6. Sankey diagram of average, experimental power (energy) flows for the SORT 1 cycle

5.3. Field test – Urban Stockholm

The SORT 1 cycle tests indicated that the series hybrid system has high potential for significant fuel consumption savings. This lead up to a one-day field test in central Stockholm, during rush hour, to evaluate the potential of transferring the SORT results onto public transportation. Both the ethanol hybrid bus and the reference bus operated two routes: 2 and 66. To perform only a one-day test results in statistically uncertain values but still generates data that hopefully may indicate potential for urban regular transport. Due to organisational and legal reasons, since the bus operator participating in the project was not responsible for the inner-city bus routes, the city field test could not be prolonged.

Table 4. Characteristics of routes 2 and 66 in Stockholm

	Route 2	Route 66
Average velocity [km/h]	12.2	12.4
Stops per kilometre	6.15	5.0
Time idling [%]	25.4	22.36

The fuel consumption reductions are not of the same order as for the SORT tests. For route 66 the hybrid powertrain gives an insignificant (less than 1%) fuel consumption reduction. The fuel consumption may be reduced by 9.3 % for route 2. An explanation to the poor result might be related to the test method used, that the buses were operated nose-to-tail, a method that normally works well in a controlled environment such as a test track. However, in dense real traffic when, apart from consider the other bus, other vehicles and pedestrians as well as traffic regulations, the bus is subjected to weak accelerations and decelerations, which results in poor brake-recovery for the hybrid bus.

5.3.1. London Hybrid Bus Trials

The results from both the duty cycle tests and the field test are similar to the results of an extensive diesel hybrid bus trail in London, hosted by Transport for London (TfL), which also had difficulties in obtaining the significant fuel consumption reduction achieved during duty cycle test for regular public transport [6]. Based on the Millbrook proving ground's London Transport Bus (MLTB) test cycle the average fuel consumption reduction was 31 %, an average attained from series, parallel and mixed hybrid buses, both single and double-decked. During the hybrid bus trail in London, 56 hybrid buses operated 10 routes. The results were scattered between almost reaching the TfL 30 % reduction target and an actual increase in fuel consumption. For all vehicle manufactures, the results indicated a much smaller (or non-existing) fuel consumption reduction than expected. This indicates that fuel consumption reductions due to the hybridisation, when operating on public urban routes oscillate depending on the prevailing traffic situation since there are parameters in real-life traffic which can not be transferred to a test situation. A general conclusion from operation of hybrid buses in London is that the overall costs over the lifetime of a hybrid vehicle are not on a commercial level yet, i.e. the fuel savings do not equal the extra cost of the vehicles.

6. Experiences and conclusions

The series hybrid powertrain have experimentally shown potential for reducing the fuel consumption in urban traffic by up to 20 % and additionally 10 % when utilising the start/stop software. In conformity with similar experiments with hybrid buses, it is not evident that the fuel reduction potential may be realised on real life routes since the fuel reduction potential is dependent on the route characteristics. A recommendation for the next project is that the real inner-city fuel saving potential should be validated in real operation on inner-city bus routes. Some components of the hybrid system still need some development as regards robustness. The super capacitors did work consistently during the whole field test and may so far be considered to be suitable as energy storage for this hybrid vehicle application.

Abstract: Energy security and the mitigation of greenhouse gas emissions (GHG) are the driving forces behind the development of renewable fuel sources worldwide. In Sweden, a relatively rapid development in bioethanol usage in transportation has been driven by the implementation of national taxation regulations on carbon neutral transport fuels. The demand for bioethanol to fuel transportation is growing and cannot be met through current domestic production alone. Lignocellulosic ethanol derived from agricultural crop residues may be a feasible alternative source of ethanol to secure a consistent regional fuel supply in Swedish climatic conditions. This paper analyzes how the regional energy system can contribute to reducing CO_2 emissions by realizing local small scale bioethanol production and substituting petrol fuel with high blend ethanol mixtures for private road transport. The results show that about 13 000 m^3 of bioethanol can be produced from the straw available in the studied region and that this amount can meet the current regional ethanol fuel demand. Replacing the current demand for petrol fuel for passenger cars with ethanol fuel can potentially reduce CO_2 emissions from transportation by 48%.

Keywords: *Agricultural crop residues, Straw, Bioethanol, Transport fuel, Greenhouse gas emissions (GHG)*

1. Introduction

According to the EU Directive, the target share of renewable energy sources as a percentage of gross final energy consumption in Sweden in 2020 is 49% [1]. Over the period 1990-2006 the proportion of renewable energy in final energy use has increased from 33.9% to 43.3%. Renewable electricity generation and renewable energy from the industrial sector contribute most to the proportion of renewable energy in final energy use in Sweden today with 18% and 14% respectively. Renewable energy use in the transport sector accounts for less than 1% of the final energy use [2].

Road traffic dominates in domestic Swedish transportation and contributes 93% of the total energy use in the transport sector (2009) [3]. Road transportation, which consists of private transport (mainly passenger cars), public transport and trucks, uses mostly fossil fuels, petrol and diesel. Use of renewable fuels such as ethanol, FAME (fatty acid methyl ester), biogas, and renewable electricity increased to 5.4% of the total energy use in transport by the end of 2009. Ethanol fuel made up 50% of liquid biofuels used in 2009 [3]. In 2007-2008 the corresponding share of ethanol fuel was almost 60% [4]. Along with a reduction in petrol fuel use in the last few years, ethanol use has also increased because almost all petrol is now a low blend E5 ethanol mixture. At the same time use of FAME and biogas increased by 8% and 1% respectively.

In Swedish transportation, the main current use of ethanol is as a 5% additive to petrol fuel (E5) or as high blend ethanol mixtures (E85, ED95). According to data presented by [3], from 2003-2009 the share of E5 in petrol fuel in Sweden increased from 45% to 95%. Total ethanol use in the Swedish transport sector increased from about 150 000 m^3 in 2003 to 391 000 m^3 in 2009 [5]. The use of low blend ethanol fuel (E5) grew from 125 000 m^3 to 229 000 m^3, whereas the use of high blend ethanol fuels (E85, ED95) grew from 25 000 m^3 to 162 000 m^3 during the period 2003-2009 [5].

However, domestic commercial ethanol fuel production in 2009 was 221 150 m^3. Currently, bioethanol is produced by Lantmännen Agroetanol in Norrköping by fermentation of wheat grains with a capacity of 210 000 m^3, which almost meets the demand for low blend ethanol. SEKAB in Örnsköldsvik produces 16 000 m^3 ethanol from sugary liquor from sulphite pulp from Domsjö Factories, and the SEKAB pilot plant [6] produces 150 m^3 ethanol from wood residues.

Ethanol demand in Sweden is much higher than domestic ethanol production. In the Swedish climate, cultivation of lignocellulosic biomass for bioethanol production is a possible alternative but there are still hurdles to overcome for the conversion of lignocelluloses to biomass. Consequently, realizing local small scale ethanol production can help regions to become more fossil fuel independent. This can also contribute to decreasing local environmental impact caused by transportation when replacing petrol fuel with renewable fuel. GHG emissions from road traffic totalled 29.1 million tonnes CO_2 eq in 2006, 63.6 % of the total Swedish transport sector emissions [7]. It is therefore of great importance to increase the use of biofuels in road transport, to make transport less dependent on fossil fuels and reduce GHG emissions.

GHG benefits of ethanol are discussed by Börjesson, where GHG emissions are estimated for the current Swedish grain-based ethanol production system [8]. Studies on technical performance of ethanol production integration with existing combined heat and power (CHP) plants have been published in recent years [9-11]. Models analysing road traffic energy demand and GHG emissions from transportation are developed for transport systems in China, Greece and Denmark [12, 13].

This paper focuses on analysing the potential for CO_2 emissions savings by substituting petrol use in the region with ethanol fuel, and does not consider the details of ethanol production. Based on an analysis of straw supply, current and potential ethanol and petrol fuel demand, we evaluate the possibilities for a self-sufficient road transport fuel system.

The present paper addresses the following questions. What is the regional demand for bioethanol, in 2009 and in 2020? Is there sufficient cereal straw available for local ethanol fuel production in the studied region in 2009 and 2020? What proportion of CO_2 emissions can be avoided in the region by substituting petrol use with ethanol fuel?

2. Methodology

In this study, input data is predominantly obtained from Swedish Official Statistics (SOS), which is also presented by state authorities (e.g. Swedish Energy Agency, Swedish Board of Agriculture) responsible for dissemination of statistical data in their respective areas. Input data collection is performed according to the structure shown in Figure 1.

The study region comprises the Sala-Heby municipalities, with around 35 000 inhabitants and a total area of 2 443 km^2 [5]. They are typical small municipalities with a predominantly service oriented economy. There are also small scale and decreasing farming and production industries and some tourist activities. A large part of the working population commutes to larger cities outside of the study region. Sala and Heby are neighbouring municipalities that belong to different counties (Västmanland and Uppsala) and are situated about 100 km northwest of Stockholm.

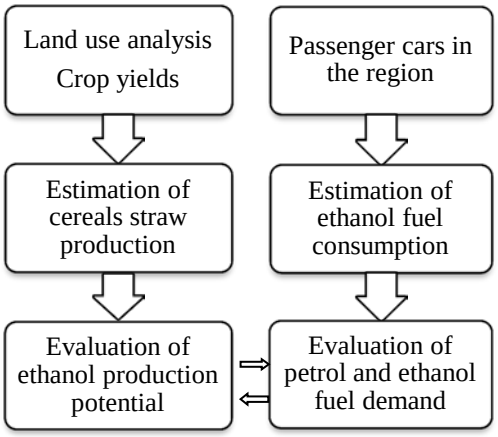

Fig. 1. A schematic flowchart for the local ethanol production study.

This paper focuses on analysing the potential for CO_2 emissions savings in the region by substituting petrol with ethanol fuel in transportation, ignoring the technological aspects of local small scale bioethanol production. The input year of the analysis is 2009. As cereal straw is considered as a feedstock for ethanol production in this study, all estimates are made for straw-based ethanol replacing regional petrol fuel demand. The study only considers fuel use by passenger cars as this is the dominant form of transport in regional road traffic.

In the Sala-Heby region, a total of 25 buses that run on diesel and biogas are used in public transportation. In Sala, the local public transportation company, Västmanlands Lokaltrafik, plans to substitute at least 10 of its 12 buses for biogas fuelled buses by 2014 [14]. In Heby, all 13 buses run on diesel and will be substituted with biogas buses during 2011-2012 according to the company's plan [15]. Buses are therefore excluded from the current analysis as none of the buses currently run on ethanol fuel and there are no plans for them to do so in future. Data on bus transportation in municipalities is obtained from local collective transportation companies as official statistical databases only present data on a regional level.

2.1. Data and assumptions

2.1.1. Straw supply and ethanol production potential

Input data is obtained from official statistics databases presented by the Swedish Board of Agriculture [16]. In this study, straw from wheat, barley and oats are considered as a feedstock for ethanol production as these types of cereals are the most commonly cultivated in the region. These cereals made up nearly 97% of the total cultivation area for cereals in the region in 2009 [16].

The ethanol production potential in the region (B) is calculated for each cereal type (wheat, oats and barley) using Eq. (1):

$$B = \sum_{i=1}^{4} S_i Y_i R_i A Y_{EtOH} \qquad (1)$$

where B is straw-based ethanol production potential (MWh), S_i is the cereals cultivation area (ha), Y_i is the cereals yield in the respective county (kg/ha), R_i is the crop to residue ratio for each cereal type, A is the straw availability, Y_{EtOH} is the ethanol production yield from straw (litre/kg), and i is the type of cereal crop.

Input data for estimation of straw supply and ethanol production potential is presented in Table 1 and in the text below.

Table 1. Input data for straw supply in the Sala-Heby region, 2009.

Parameter	**Unit**	**Type of biomass**				**Reference**
		winter wheat	spring wheat	barley	oats	
$\mathbf{R_i}$	1	1.3	1.3	1.2	1.3	[17]
$\mathbf{C_i}$	tonnes/year	14 733	12 464	41 137	30 549	Based on data from [5,15]

* Cereals production, $C_i = S_i * Y_i$

Cereals production (C_i) is calculated based on cultivation areas and average yields for cereal crop production. Cereal yields (Y_i) for Sala and Heby municipalities correspond to average yields in the counties that the municipalities belong to. As a proportion of straw has to be ploughed back into the soil to maintain the soil fertility and avoid erosion, only about 57% by weight (A in Eq. 1) of the total amount of straw produced can be used for fuel production [17]. The energy content of pure ethanol is 6.24 kWh/litre [18].

The future straw supply in the region is analyzed for the following scenarios:

- Scenario 2020-P1 – all the parameter values remain the same except areas for cereals cultivation. The total straw production is assumed to increase by 20% through use of fallow land for ethanol straw cultivation. Fallow land currently accounts for 29% of arable land for cereals production in the Sala-Heby region.
- Scenario 2020-P2 – all the parameter values remain the same except the yield for ethanol conversion from straw, which is assumed to increase to 0.35 (litre/kg) (Y_{EtOH}) due to improvements in the process technology.
- Scenario 2020-P3 – combines scenarios 2020-P1 and 2020-P2.

2.1.2. Transport fuel demand

There is a lack of statistics on motor fuel usage at the municipal level. We calculate the average distance covered per car and average fuel consumption per kilometre driven, and therefore the use of motor fuel based on the number of passenger cars registered in the municipalities of Sala and Heby. Input data was obtained from Swedish Official Statistics [5, 19]. The Swedish Energy Agency is the state authority responsible for disseminating statistics in the field of energy use in transportation, and Transport Analysis (Trafa) produces statistics on vehicles types and distances covered. The development of passenger car use in Sala-Heby region is shown in Figure 2 (based on data from [19]).

Ethanol fuel demand in the Sala-Heby region (D) is estimated for E5 and E85 ethanol mixtures using Eq. (2):

$$D = \sum_{i=1}^{2} N_i S_i Q_i C_i E \qquad (2)$$

where D is estimated ethanol fuel demand (MWh), N_i is the number of vehicles in use during a year, S_i is the distance covered per vehicle in the respective county in a year (km), Q_i is the fuel consumption per type of fuel and kilometre driven in each county (litre/km), C_i is the ration of pure ethanol to petrol in each type of fuel blend used, and E is the energy content of the fuel (kWh/litre). For E5 fuelled passenger cars i=1, and for E85 fuelled passenger cars i=2.

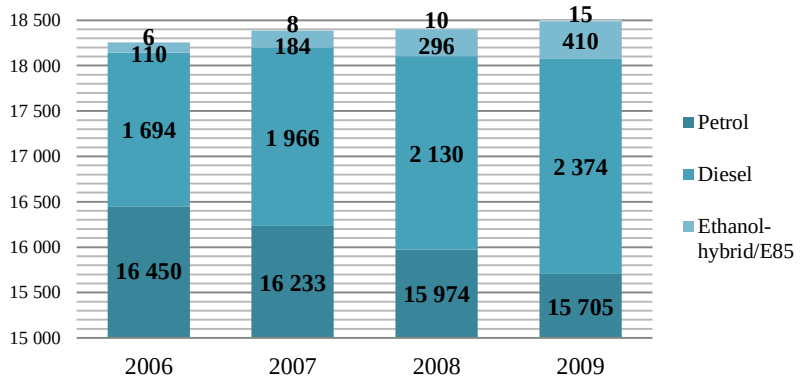

Fig. 2. Passenger cars in use by fuel type in 2006 -2009 in Sala-Heby. Based on data from [19].

It is assumed that all petrol fuel in the region is E5 fuel, as the share of low blend petrol in Sweden is 95% according to [3] and more detailed data on the regional share of E5 fuel and petrol fuel is not available.

To evaluate current and future regional demand on transport the following scenarios were analyzed:

- Scenario 2020-D1 – all the parameters remain the same except the numbers of passenger cars fuelled by petrol and ethanol fuels. The number of E85 fuelled cars increases and the number of E5 fuelled cars decreases, following the same trend as during the period 2006-2009 for each vehicle type. In this way, the total number of E5 and E85 fuelled vehicles is projected to be 17 814, a reasonable increase of 10.5% the 2009 figure.
- Scenario 2020-D2 – all the parameters remain the same except the amount of ethanol blended with petrol fuel, which is assumed to increase from 5% to 10% of the petrol fuel mixture, meaning that passenger cars are fuelled E10 with instead of E5. As in scenario 2020_1, the total number of cars is 17 814, following the trend in car numbers for the period 2006-2009. Petrol fuel consumption per driven kilometre is assumed to decrease following the trend from 2006-2009 (-1.2%), and is 0.074 l/km in 2020.
- Scenario 2020-D3 – this is the most extreme scenario, where it is assumed that all passenger cars are to be fuelled by E85 ethanol fuel.

2.1.3. CO_2 emissions from transportation

Estimates of CO_2 eq. emissions from passenger cars are based on the results presented by Johansson and Fahlberg [18]. Emissions rates in [18] and those presented in Table 2 are lifecycle based and include emissions from fuel combustion, production and distribution. The CO_2 eq. emissions factors on which further calculations are based are presented for E5, E85 and E10 (see Table 2).

Table 2. Total CO_2 eq. emissions factors by type of transport fuel [18].

CO_2 eq. emissions by type of fuel, (g/kWh)	
E5	277.48
E10	269.34
E85	110.54

3. Results and discussion

Regional straw production is estimated using Eq 1 and the input data presented in section 2.1.1. This calculation estimates 98 924 tonnes of straw in 2009. Thus, current straw-based ethanol production potential in Sala-Heby is 13 015 m^3 or 81 210 MWh as presented in Table 3 for 2009 and future Scenarios.

Table 3. Estimate of straw based ethanol production in Sala-Heby region.

Parameter	Unit	2009	2020-P1	2020-P2	2020-P3
$B_{ethanol}$	MWh/year	81 210	97 452	98 012	117 615

Regional ethanol fuel demand is estimated using Eq. 2 and the assumptions from the scenarios presented in section 2.1.2., and is presented in Table 4.

Table 4. Estimate of ethanol fuel demand in Sala-Heby region. Parameters for year 2009 are input parameters obtained from statistical databases and reports. Values in bold are changed from 2009.

Parameter	Unit	2009	2020-D1	2020-D2	2020-D3	Reference
N_1	1	15 705	**13 251***	13 251	**0**	[19]
N_2	1	410	**4 563****	4 563	**17 814**	[19]
S_1	km	14 267	14 267	14 267	14 267	[19]
S_2	km	14 267	14 267	14 267	14 267	[19]
Q_1	l/km	0.084	0.084	**0.074**	not relevant	
Q_2	l/km	0.126	0.126	0.126	0.126	[18]
C_1	1	0.05	0.05	**0.1**	not relevant	
C_2	1	0.85	0.85	0.85	0.85	
E_1	kWh/litre	8.598	8.598	8.474	8.598	[18]
E_2	kWh/litre	6.612	6.612	6.612	6.612	[18]
$D_{ethanol}$	MWh/year	12 234	52 927	57 955	179 977	-

*Average annual decrease in petrol fuelled passenger cars is 1.5%. Based on this rate the number of E5 fuelled passenger cars is estimated at 13 251.
**Average annual increase in E85 fuelled cars during 2006-2009 is 39%, whereas assumed average increase after 2014 is 20%. It is assumed to be unlikely that the early increase of 39% is maintained until 2020.

Distance covered per car and year for the whole Sala-Heby region is calculated from weighted averages of distances covered per car and year in each municipality. Distances covered by car in each municipality are obtained from [19] and are assumed to remain the same over the study period. Fuel consumption per driven km is assumed to decrease following the same trend as 2006-2009. E85 fuel consumption (Q_2) is assumed to remain the same. In scenario 2020-D2 E10 fuel is assumed to be used (C_1=0.1). For Scenario 2020-D2, the energy content of the fuel (E_1) corresponds to the energy content of the E10 ethanol mixture based on the assumption made for this scenario.

Summarized results for straw based ethanol supply and ethanol demand are presented in Figure 3. These figures indicate that the regional transport system can become self-sufficient in ethanol fuel by implementing local small ethanol production from locally produced cereal straw. The system could become fossil fuel free by 2020 using this approach.

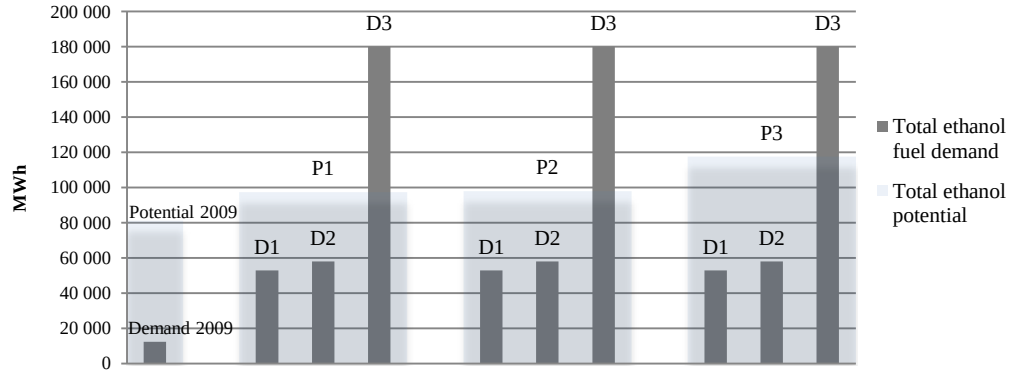

Fig.3. Ethanol supply potential and ethanol fuel demand in the Sala-Heby region (MWh).

The CO_2 eq. emissions from passenger cars were estimated (see Table 5), based on the same scenarios and approach as for the estimate of the ethanol fuel demand (see section 2.1.2.). Current CO_2 eq. emissions from transport are 45 446 tonnes. Assuming that the number of passenger cars in the region continues to increase according to the trend of the last 5 years, and assuming that all cars will run on E85 in 2020, the total CO_2 eq. emissions can be reduced to 23 591 tonnes CO_2 eq., a reduction of 21 855 tonnes CO_2 eq. or 48% from 2009.

Table 5. Estimate of CO_2 eq. emissions from passenger cars in Sala-Heby region.

Parameter	2009	2020-D1	2020-D2	2020-D3
Total CO_2 emission from passenger cars fuelled by petrol and ethanol fuel, tonnes	45 446	43 930	38 938	23 591

Börjesson [8] studied the reduction of GHG emissions obtained from using ethanol instead of petrol, including GHG emissions from producing ethanol. Using wheat grain based ethanol produced in Sweden results in an 80% GHG emission reduction compared to petrol fuel, while ethanol from Brazilian sugarcane gives 85% emission reduction [8]. Börjesson concluded that the results are very much dependent on the structure of the individual system. Assuming some different scenarios for the type of cultivation land, use of by-products from ethanol production, the reduction of using ethanol from current production in Sweden can be as low as 55% [8]. This paper focuses on GHG emission savings from road private traffic if replacing current petrol use with locally produced straw based ethanol assuming different scenarios for future car fleet development and ethanol supply. The CO2 eq. emission factors presented in [18], on which the calculations in this paper are based, correspond to 76% total CO2 eq. emission savings for pure ethanol compared with pure petrol fuel.

4. Conclusions

This study shows that the available cereal straw in the studied region is sufficient to meet local ethanol demand for 2009. However, it is not sufficient for a scenario where all passenger cars are fuelled with E85. If passenger car numbers increase according to the current trend until 2020, 3% CO_2 eq. emissions reductions can be achieved by using locally produced ethanol from cereal straw. CO_2 eq. emissions can be reduced by 14% by replacing all petrol fuel with fuel containing 10% ethanol (E10 fuel), and by 48% if all passenger cars in the studied region use E85 fuel.

This paper analyzes how the regional energy system can contribute to reducing CO_2 eq. emissions by realizing local small scale bioethanol production and substituting petrol with ethanol fuels in road transportation.

Solar Thermal Applications

Environmental Regulation, Solar Energy Technology Components and International Trade

- An Empirical Analysis of Structure and Drivers

Felix Groba[1,*]

[1] *German Institute of Economic Research, Berlin, Germany*
** Corresponding author. Tel: +49 30 89789681, Fax: +49 30 89789113, E-mail: F.Groba@diw.de*

Abstract: Dynamics of the global renewable energy market are mostly described in terms of investment and added capacity. The role and characteristics of cross border trade flows with renewable energy system components, however, remains blurred. While national environmental regulation and innovative capacity is important for the promotion of renewable energies the effect of regulation and innovative efforts on export dynamics remains ambiguous as empirical studies on the pollution haven and the Porter hypothesis reach diverging conclusions and rarely focus on the renewable energy sector. This paper closes the gap by: First, focusing on solar energy technology components, structure and development of international trade since 1996 is analyzed. Second, determinants of OECD exports are identified in an econometric panel study estimating a gravity trade model. The results unveil a highly dynamic global market for solar energy technology components since 2002, with Europe as dominant market and increasingly strong exports from China. Additionally, the analysis supports the Porter hypothesis as countries with a strong framework supporting renewable energies have gained a comparative advantage in exporting solar technology goods. Analyzing the importer side shows that tariff reduction and FDI inflows have increased imports.

Keywords: *Renewable Energies, International Trade, Trade Barriers, Regulation*

1. Introduction

Diffusion and transfer of climate friendly energy technologies remain decisive topics in international climate negotiations as they play an important role in the nexus of economic development and a sustainable energy system transformation. Therefore, the development of the global renewable energy market is monitored in numerous studies. These studies commonly either refer to added capacity or investments into renewable energy projects to describe growth, structure and market development [1]. Although international trade has been identified as a decisive channel for technological change the role of the manufacturing sector, producing necessary components, and the international trade system in this production process is mostly neglected. While the interaction between trade flows and environmental regulation and the issue of clean technology transfer have become prominent literature strands, little effort has been put into accessing drivers and dynamics of global trade with specific renewable energy components. Additionally, current negotiation obstacles in WTO talks on environmental goods liberalization unveil that the relationship between trade, technology transfer and clean energy technologies are relevant.

The objective of this paper is to analyze the structure and identify drivers of clean energy technology trade with a specific focus on solar energy technology components. This step is necessary before trade effects such as technology diffusion and sustainable development can be studied in later research. After outlining the methodology, this paper describes structure and development of the international market for solar energy technology components. Subsequently, potential drivers of these specific technology exports from OECD countries to the world are characterized in a panel study estimating a standard gravity model. Three hypotheses are empirically tested: First, as components for solar energy systems are research intensive, the innovative capacity in exporting countries affects the export performance with respective goods. Second, following the Porter hypothesis, countries with a strong policy

framework of supporting renewable energies have gained a comparative world market advantage as such a framework is likely to support a national renewable energy industry that is a striving for export markets. Third, barriers to trade and an unreliable policy environment in receiving countries are obstacles to clean technology trade as additional costs to exporters are imposed.

2. Data description and methodology

Numerous empirical studies adopted the gravity model to explain the relationship between international trade flows and environmental regulation with respect to various goods and sectors. Introduced by Tinbergen [2] the model became the workhorse of trade relation analysis. The popularity can be explained by its successful empirical performance and by strong theoretical foundations outlined in the literature [3]. The general formulation of the gravity model (1) describes trade flows (F) from exporting country i to destination country j at time t as a function of economic masses (M), distances (D) and an error term (η). It furthermore takes a gravitational constant (G) into account depending on the units of measurement for F_{ijt}, $M_{it,jt.}$

$$(1) \qquad F_{ijt} = G\frac{M_{it}^{\beta_1} M_{jt}^{\beta_2}}{D_{ij}^{\beta_3}\eta_{ijt}}$$

As the aim of the study is to determine the drivers of international trade with solar energy technologies, the dependent panel variable is the bilateral export flow (EXP_{ijt}) from i to j at time t. The i-exporting countries are Australia, Austria, Belgium, Canada, Czech Republic, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Japan, Korea, Netherlands, Norway, Portugal, Spain, Sweden, Switzerland, the United Kingdom and the United States. An analysis of developing country exports such as Chinese exports is excluded due to a lack of data on control variables. Nevertheless, the sample represents approximately 80 % of global exports in 2008. The sample of j-importing countries includes 129 states, including OECD countries. The time period analyzed with the balanced panel goes from 2000 to 2007. Empirical computation requires the gravity model to be transformed into logs, establishing a linear relationship between variables. This also allows interpreting the percentage change in the dependent variable due to a change in explanatory variables. Based on the explanatory variables, as explained in the subsequent sections, the exact gravity model applied has the following from:

$$\begin{aligned}(2) \qquad \ln SolarEXP_{ijt} = {} & \beta_0 + \beta_1 \ln(GDP_{it}GDP_{jt}) + \beta_2 \ln(POP_{it}) + \beta_3 \ln(POP_{jt}) + \beta_4 \ln(Dist_{ij}) \\ & + \beta_5 Border_{ij} + \beta_6 Language_{ij} + \beta_7 Contig_{ij} + \beta_8 Import\_Tariff_{jit} \\ & + \beta_9 \ln(FDI_{jt}) + \beta_{10} RoL_{jt} + \beta_{11} \ln(Envirregulation_{jt}) \\ & + \beta_{12} \ln(EnergyIntensity_{it}) + \beta_{13} \ln(Envirregulation_{jt}) + \beta_{14} \ln(RDBSolar_{it-1}) \\ & + \beta_{15} \ln(PatentStock_{it}) + \alpha_i + \varepsilon_{ijt}\end{aligned}$$

2.1.1. Development of solar energy technology component exports

Solar energy technology components are defined as investment goods and associated products needed in solar energy systems. This includes solar thermal and photovoltaic components. Reliable cross country data on trade flows with renewable energies are hardly available. National industry polls, commonly asking for sales as well as imports and exports, are likely to be biased as the number of companies active in the renewable energy market is unclear and poll return might be interest driven. Therefore, the representativeness of these polls is limited and can only be used as a rough indicator for national branch development. Furthermore,

industry polls do not guarantee data comparability. Therefore, international trade data based on the Harmonized Commodity Description and Coding Systems (HS 1996) using the UNCTAD COMTRADE database serves as the source of the dependent variable.

The classification with respect to environmental goods and energy technologies has been well defined by the OECD [4]. Nevertheless, the aspired solar energy technology differentiation requires addressing data validity. A product group based on 6-digit HS 1996 codes, under which solar system components are traded, has been generated (Table 1). The problem is that data might be inflated as the products environmental end use cannot be monitored, i.e. goods that are used for renewable energy systems and goods that might be used otherwise are traded under a common HS code and the renewable energy goods share under one HS code might vary between countries. However, the method used constructs the best available proxy for cross time cross country analysis as data is available on an international common methodology. Furthermore, contrary to industry polls, imports of inputs are likely to be captured allowing a more comprehensive picture of the market. Finally, product similarity can be assumed making the actual end use irrelevant.

Table 1. Nomenclature of solar energy technologies, HS 1996.

HS Code	Explanation
Solar Thermal	
841911	Instantaneous gas water heaters.
841919	Other instantaneous or storage water heaters, non-electric.
840219(ex)	Steam or other vapor generating boilers [Other vapor generating boilers, including hybrid boilers].
841950(ex)	Heat exchange units [Heat-exchange units for solar thermal or geothermal applications].
900290	Concentrator systems to intensify solar power in solar energy systems, other optical elements of any material mounted
Solar Photovoltaic	
850440(ex)	Static converters [Inverters (for converting DC power to AC power)] - change solar energy into electricity.
850720(ex)	Other lead-acid accumulators [solar batteries], i.e batteries for energy storage in off-grid photovoltaic systems.
854140(ex)	Photosensitive semiconductor devices, including photovoltaic cells whether or not assembled in modules or made up into panels; light emitting diodes.

The data show that exports have grown considerably from 1996 to 2008, whereas the largest growth occurred since 2002. Figure 1 supports the finding that the production of clean technology goods is highly skewed towards high income countries [5]. However, East Asian Pacific countries (LDCEAP), mainly China, have gained considerable market share. Interestingly, the data also show that the share of solar energy technology components in trade with industrial goods has been increasing since 1996. Although still low between 0,5 and 1,5% this indicates a quite dynamic market as the solar component trade growth rate has been larger than industrial goods trade growth rates. Another insight is that although the OECD countries are major exporters, the group runs an increasing net trade deficit hinting to the dominance of only some countries. An analysis of the trade direction between regions underlines that main import markets are in high income OECD countries with most of the trade occurring between OECD countries. Another important trade direction is from developing countries to developed counties. Trade between developing country regions remains marginal. Overall, it becomes obvious that the international market for solar energy

technology components is dominated by Europe and China as the main exporting players. Europe furthermore is the dominating importer with most of the global trade occurring within Europe itself.

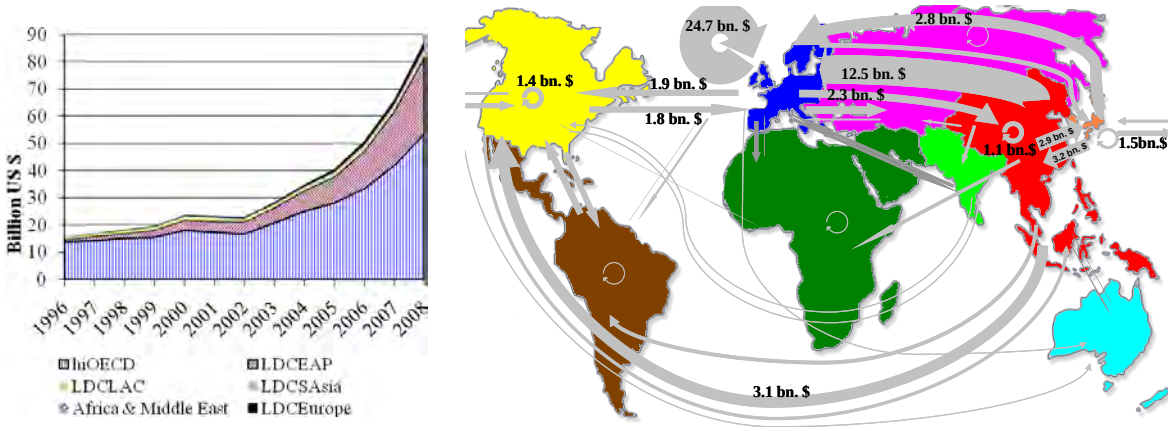

Figure 1. Development of Solar energy technology component exports by country group 1996-2008 and market structure 2008 (Source: UNCOMTRADE)

The analysis of country specific export flows and market shares underlines the dynamics and outlines the dominance of only some counties as well as the increasing importance of developing countries. Although, with a high increase in market volume the development of market export shares over time indicates a crowding out of some OECD exporters mainly due to strong export growth of China.

2.1.2. General parameter of trade analysis

The gravity model predicts that the bilateral trade volume is positively related to a countries' income ($GDP_{it}GDP_{jt}$) [6]. A counter force in this respect is population size as countries with a larger population (POP_{it} , POP_{jt}) are expected to trade less. The reason is that available resources and the domestic market size are expected to be positively correlated with the population size. The anticipated sign is thus negative as the market is able to rather produce goods itself. Theoretically, with increasing distance ($DIST_{ij}$), trade and transportation cost increase, reducing trade volume and causing the expected sign to be negative. Further determinants of bilateral trade flows that are empirically justified are included. Sharing an official language ($LANG$) and having a common border (ADJ_{ij}) is expected to increase bilateral trade flows as goods can be transported at lower costs. Data for these variables have been retrieved from the World Bank World Development Indicators (2009) and from the CEPII's Gravity Dataset (2010).

2.1.3. The role of environmental regulation

The empirical literature on the interaction between trade and environmental regulation remains ambiguous regarding the support of either the polluter haven or the Porter hypothesis [7]. According to the Porter hypothesis, shocks produced by new, stricter regulation creates external pressure on the firms which are subsequently fostered to created new products and processes that positively affect the dynamic behaviour of that economy and hence its international competitiveness. Thus, countries with a stringent environmental regulation may become net exporters of clean technology. The lead market literature, which supports the Porter hypothesis, indicates that an early introduction of adequate technology support policies can create an industry with a competitive world market advantage. A contrary theoretical effect of introducing environmental regulation is that specific clean technology demand is

generated causing additional imports as, in an open economy, foreign producers may provide technology either better or cheaper.

This studies' focus is on the effects of regulation on specific trade flows rather than on overall trade flows. Numerous policy instruments that increase the demand and supply of renewable energy technologies have been identified. The IEA report on 'Renewable energy market and policy trends' provides an overview of policies and time of introduction. Due to the heterogeneous character of these policies across countries the database does not facilitate an evaluation of regulatory stringency or renewable energy supportiveness in a panel context. Therefore, different measures of environmental stringency or renewable energy supportiveness, respectively, are used. In their study on export dynamics of energy technologies, Constantini and Crespil (2008) point out that an indirect measure of environmental stringency, such as CO_2 emissions per unit of GDP is adequate to investigate the Porter hypothesis as well as the political importance of energy saving strategies [7]. The variables $EnergInt_{it}$ and $EnvirREG_{it}$ give the relative environmental strictness in exporting countries. The underlying assumption is that countries implementing stricter environmental regulation exhibit a positive effect on export dynamics of solar energy technology components. The measures are based on the following environmental indicators:

- Level of Energy intensity 1996 – 2008 in tons of oil equivalent per thousand units of purchasing power parity GDP extracted from the IEA Energy Balance database;
- Level of Carbon intensity 1996 – 2008 in kg per thousand units of purchasing power parity GDP extracted from the Carbon Dioxide Information Analysis Center database.

Subsequently, following the literature, sample countries have been ranked on these relative and dynamic measures (1990 =100) assigning the lowest rank to the worst performer. In the given panel structure this ranking method better allows for a comparison of relative environmental strictness than a comparison of levels of energy use and emissions.

The introduction of further variables controlling for environmental regulation and thus a renewable energy friendly policy environment is neglected. Although statistics suggest that the Kyoto Protocol induced more innovation there seems to be no significant effect of the Protocol on technology transfer and thus trade.[5] In addition, other proxies of environmental regulation such as environmental private and public expenditures, environmental tax revenues and public environmental protection expenditures are likely to be captured by applied controls. The same is true for expected returns on energy investment, which is generally best reflected by electricity price trends. But, as total primary energy supply and therefore the energy market size of a country, is included in the estimation, incentives to invest in renewable energies are respected to some extent.

2.1.4. The role of the innovation system in exporting countries

In general, innovation is assumed to be a product of knowledge generating inputs [8]. As this study focuses on highly innovative technology goods, two variables controlling for the role of the innovation system in exporting countries are included.

First, a variable measuring a countries public technology specific research and development spending ($RDBsolar_{it}$) is introduced. In theory, research and development increases exports as new technology might be developed which, in an open economy, is available to the world market as well. The variable enters the analysis lagged by one period assuming that the process of technology development takes some time until a new product is ready for market entry. Data is obtained from the IEA (2010) Energy Technology Research, Development and

Demonstration database. The data show that combined OECD public spending on s olar energy has been constant since 1990 and is decreasing since 2006. Yet, there is substantial country level variation leaving the actual effect on export performance unclear.

Second, productivity of new knowledge is assumed to depend on the existing stock of ideas [8]. The patent stock of a country is the best proxy for knowledge stock in this respect. Therefore, patent counts for renewable energy have been extracted from the OECD (2010) Science, Technology and R&D Statistics database. Aiming at comparability and an unbiased estimation, only patent applications by inventor country issued under the international patent cooperation treaty have been included (Figure 2).

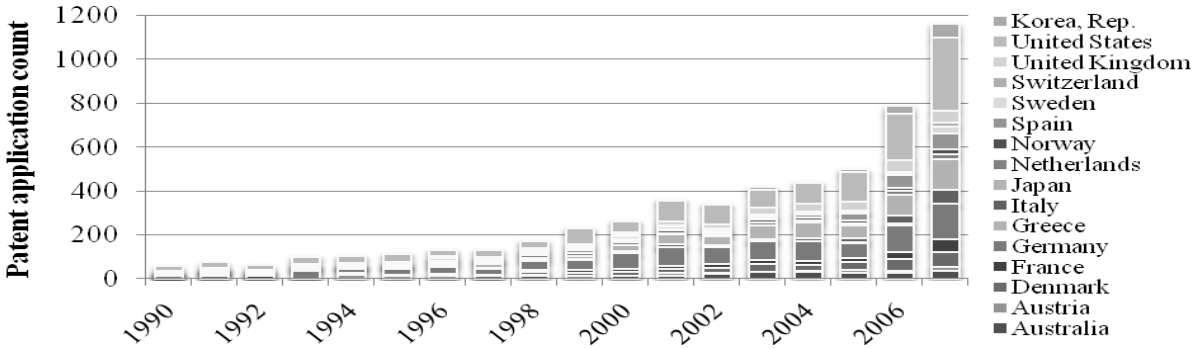

Figure 2: Renewable Energy Patent applications by country of origin 1990 – 2007

Based on the patent counts the countries' patent stock has been calculated with depreciation rate α of 15% as is commonly done in the literature[8]:

(3) $$PatStock_{it} = (1-\alpha)PatStock_{it-1} + Patents_{it}$$

Naturally, the stock of knowledge with respect to renewable energies differs substantially between countries. Therefore, the assumption to be tested empirically is that countries with a higher renewable energy knowledge stock export more to the world market.

2.1.5. The role of barriers to trade and regulation in importing countries

A general assumption is that tariff and non-tariff barriers inhibit trade while a positive general policy environment as well as environmental friendly regulation in importing states supports cross border flows of the specific high technology goods which are the focus of this study. Hence, import tariffs ($Import\_Tariff_{jt}$) applied to the compounded product group of solar goods are introduced as an explanatory variable. Data on the effectively ad valorem tariff applied by the importing country *j* to solar technology component exports from *i* in percent of the import value is obtained from the UNCTAD TRAINS database. The indicator serves as control for the potential impact of a liberalization of environmental goods as discussed in the WTO Doha negotiations and denounces the reduction of additional trade cost over time. The expected coefficient sign is negative as bilateral trade flows are high with lower tariffs as exporters face reduced trade costs. The development of tariffs over time seems to support the theoretical underpinning. While solar energy technology component exports of OECD countries increased significantly, the mean tariff applied by the samples importing counties decreased substantially from 10% in 1996 to 5% in 2008.

Environmental regulation and renewable supportiveness in receiving countries potentially plays a role as demand for clean technologies can be satisfied through the world market.

Hence, the environmental stringency variable $EnergREG_{jt}$ is introduced as control for such regulation using the same method as for exporting countries described above. The study also includes the World Bank's rule of law indicator (ROL_j) as a proxy for the quality of institutions and the capacity to respect legal rules which might be relevant for exporters.

As currently the solar energy market development is often described in terms of investments, controlling for such investments to explain technology component export flows is necessary. Adequate solar technology specific investment data on a cross time cross country level is not yet available. Therefore, the best proxy in this respect is net foreign direct investment inflow in importing countries (FDI_{jt}). Trade flows are tightly linked to foreign direct investments flows [9]. Following the literature on trade flows and foreign direct investments the coefficient should be positive as a higher attractiveness of a county for FDI also exhibits a higher attractiveness for exports.

3. Results

The gravity model as stated in equation (2) has been estimated using random and fixed effects in order to control for country heterogeneity with robust standard errors clustered on country level. However, the significance of the Hausman test clearly indicates that exporting country individual effect (α) and the repressors are correlated. Thus, only the consistent fixed effect estimation coefficients on the repressors are reported in Table 2. Adequate tests for the robustness of the results have been conducted.

Table 2. Gravity model and the role of environmental regulation, innovation and trade parameters

	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
ln GDP_{ijt}	1,57***	1,58***	1,18***	1,59***	1,55***	1,55***	1,65***	1,53***
ln POP_{it}	-6,81*	-7,19*	-6,49*	-6,89*	-8,31*	-6,81	-5,02	-11,63**
ln POP_{jt}	-0,42***	-0,44***	-0,06	-0,45***	-0,43***	-0,43***	-0,46***	-0,41***
ln $DIST_{ij}$	-1,01***	-0,98***	-0,99***	-1,00***	-1,01***	-1,00***	-0,99***	-0,93***
ADJ_{ij}	0,01	0,06	-0,05	-0,01	0,15	0,16	-0,22	0,038
$LANG_{ij}$	1,15***	1,19***	1,01***	1,13***	1,11***	1,10***	1,19***	1,06***
$Import\ Tariff_{ijt}$	-0,01***							
ln FDI_{jt}		0,17***						
RoL_{jt}			0,02***					
ln $EnvirREG_{jt}$				0,11*				
ln $EnergInt_{it}$					0,24*			
ln $EnvirREG_{it}$						0,15*		
ln $RDBsolar_{it-1}$							0,03*	
ln $PatStock_{it}$								0,03
Time dummies	yes	yes	yes	yes	yes	yes	yes	yes
N	22382	21630	22550	22550	21793	19475	21263	36092
R^2	0,68	0,69	0,70	0,68	0,67	0,67	0,70	0,64

note: significance level *** p<0.01, ** p<0.05, * p<0.1

The results show that standard control coefficients of trade flow analysis such as income, population and distance have the expected impact. Thus, this set of controls is taken as basis for the analysis of the remaining control variables. These specific control variables also

behave as expected. A one unit increase in tariffs decreases imports by 0.01 units. Thus, Higher tariffs significantly decrease import flows while the relationship between investment inflows and the institutional quality in receiving countries is positive. The impact of environmental regulation in importing countries on trade flows is weak but positive. The role of the innovation system in exporting countries remains ambiguous. On the one hand public spending in solar energy technology has a positive significant impact on export flows. On the other hand the renewable energy patent stock has no significant impact. The results of the study support the Porter Hypothesis as countries with a more stringent environmental regulation and a better energy intensive score export more solar energy technology components to the world market and thus seem to have gained a competitive advantage.

4. Discussion and Conclusion

This study applies an empirical gravity model to identify the main drivers of trade with solar energy technology components. Finding evidence for the Porter hypothesis and the importance of the innovations system the results are in line with findings of related work on environmental regulation and trade as well as with the OECD`s strategy on environmental regulation, innovation and green growth. Yet, besides the issues related to a potential dual use of products under one HS-code the effects might be biased by the use of rather broad control variable specifications such as general renewable energy patents instead of solar specific patents to construct the knowledge stock. Nevertheless, the results are interesting from a global climate negotiation perspective as it is shown that the regulatory context in receiving countries is decisive for clean technology imports and thus potential technology transfer.

Consequently, the remaining research agenda should focus on technology transfer in trade with these clean energy technologies as well as the study of potential trade effects. Within this context the construction of regulation measures capturing renewable energy supportiveness of a country more directly should be developed.

Abstract: Solar thermal systems are an ecological way of providing domestic hot water. They are experiencing a rapid growth since the beginning of the last decade. This study characterizes the environmental performances of such installations with a life-cycle approach. The methodology is based on the application of the international standards of Life Cycle Assessment. Two types of systems are presented. Firstly a temperate-climate system, with solar thermal collectors and a backup energy as heat sources. Secondly, a tropical system, with thermosiphonic solar thermal system and no backup energy. For temperate-climate systems, two alternatives are presented: the first one with gas backup energy, and the second one with electric backup energy. These two scenarios are compared to two conventional scenarios providing the same service, but without solar thermal systems. Life cycle inventories are based on manufacturer data combined with additional calculations and assumptions. The fabrication of the components for temperate-climate systems has a minor influence on overall impacts. The environmental impacts are mostly explained by the additional energy consumed and therefore depend on the type of energy backup that is used. The study shows that the energy pay-back time of solar systems is lower than 2 years considering gas or electric energy when compared to 100% gas or electric systems.

Keywords: *Environmental impact, LCA, Solar thermal systems*

1. Introduction

Solar thermal systems have encountered a high interest over the last ten years in many locations worldwide [1,2]. Indeed, it is a robust, efficient and simple technology to implement for individual households: solar thermal relies on well known process and materials. Its capacity in reducing energy load for domestic hot water (DHW) is significant in locations with high irradiation level.

Some studies have been carried out on thermosiphon solar water heaters in different countries [3-6] but none was focused on solar thermal systems with auxiliary energy source. This study is focused on this second type of installation since they often are preferred for Northern-European countries (collector and storage with integrated backup).

The main purpose of the work is to characterize the environmental impacts of solar domestic hot water systems, or solar water heaters (SWH), integrating auxiliary heating (electric or gas heaters). Furthermore, this study also aims at identifying the most discriminating parameters to support implementation solutions. These systems' performances are analyzed as case-studies both for temperate climates (typically in France) and for tropical climates (typically in the Caribbean).

Life Cycle Assessment (LCA) methodology is used for this environmental evaluation. Among several LCA impact indicators, this study focuses on primary energy consumption, global warming potential, effect on ecosystem quality and human health issues. Greenhouse gas emissions (expressed in CO_2 equivalent) and non-renewable energy consumption are considered here as key LCA outputs.

Environmental performances of the different SWH with gas-backup, electrical-backup or no backup (for tropical zone's systems) are compared with standard hot water systems without any solar contribution.

2. Methodology

This Life Cycle Assessment (LCA) study was performed in compliance with the ISO standards 14040 and 14044 [7,8].

2.1. Scope of the study

This study has been carried out on individual solar thermal systems applied in the case of temperate and tropical climates. For temperate locations, four systems have been studied, namely two traditional systems without solar systems considering only electricity or gas heater, and two systems with solar system and integrated backup energy (electricity backup see Fig. 1 or gas backup). Due to the irregular solar irradiation all over the year, this kind of solar thermal system requires a backup system to reach the target temperature.
For tropical climates, one thermosiphonic solar system (without backup energy) has been analyzed (Fig. 2).

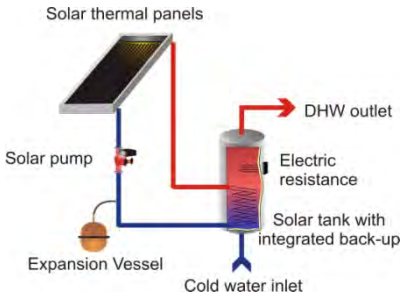

Fig. 1. Sketch-plan of temperate-type solar water heaters (electric backup)

To study both temperate and tropical systems, two climatologically average located places have been determined, namely Lyon (continental France) for temperate climate and Le Lamentin (Martinique, overseas France) for tropical climate.

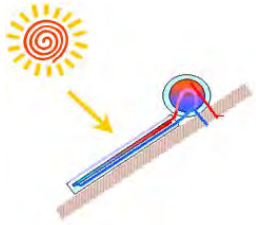

Fig. 2. Sketch-plan of tropical-type solar water heaters

The solar systems configuration and backup energy uses are different according to the climatic conditions. Therefore, two different Functional Units have been defined:

The temperate climate Functional Unit: Production of DHW for a four-person household, (assessed to be 140 litres of 60°C) in temperate climate and 20 years of life expectancy.

The tropical climate Functional Unit: Production of DHW for a four-person household, (assessed to be 200 litres of 50°C) in tropical climate and 20 years of life expectancy.

Given that tropical-type SWH does not include backup energy, the target temperature (50°C) is an indicator required to calculate solar energy but it does not represent the real outlet water temperature.

Corresponding irradiation levels and electricity mixes have been considered.

2.2. Inventory

2.2.1. Inventory building strategy and sources

Many hypotheses are necessary to evaluate the life cycle environmental impacts of DHW production. These hypothesis have been defined with the expertise of the consulting and

engineering partner[1] as well as technical data collected from public industrial actors. Thus, the different systems' component has been determined and sized. On the second hand, inventories for the electricity mix have been determined for the temperate-climate system.

For this study, the ecoinvent 2.0 LCI database [9] was used. Ecoinvent 2.0 contains international industrial life cycle inventory data on a various range of activities (energy supply, resource extraction, transport services,…). However, most of the SWH components are not defined exactly in the existing database. Thus, it has been necessary to modify or create new processes. When components' inventories were available in the database they were assessed in order to determine the validity of this inventory regarding the components' origin and main characteristics (materials used, manufacturing process and weight). When necessary, some inventories were modified by applying a weight or size ratio. Some inventories have also been completed by specific technical data collected within this project. When no inventory was available for a component, a new inventory has been built by the project team to estimate the required data.

As for the construction of the inventory, the composition of each component comes from different sources, which are described in Table 1.

Table 1. Data collection for infrastructures in scenarios

Component	Sources
Solar panel	Ecoinvent modified (to match with the surface defined for the scenarios)
Water Pump	Ecoinvent modified (estimates, from the mass of material)
Expansion Vessel	Ecoinvent (slightly oversized compared to usual design, but minor impact)
Hot water tank	Ecoinvent modified (from a 2000 l tank)
Solar regulation	Rough estimate (from the mass of the material, mostly electronics)
Mounting support	Datasheets from manufacturers, completed by estimates when necessary
Plumbing	Experience and estimates from the consulting and engineering partner
Electrical backup	Ecoinvent (slightly oversized, but minor impact)
Gas backup	Ecoinvent modified (to exclude the impacts related to domestic heating)

2.2.2. System boundaries

The system boundaries are described in Fig. 3. They include the solar panels manufacturing (panels, mounting systems), water tanks, internal heat exchanger, pipes, hydraulic components (pumps, valves, expansion vessel), regulation, cabling and solar fluid. In addition, they also include the use phase (backup energy consumption for temperate-climate SWH) and the recycling of components.

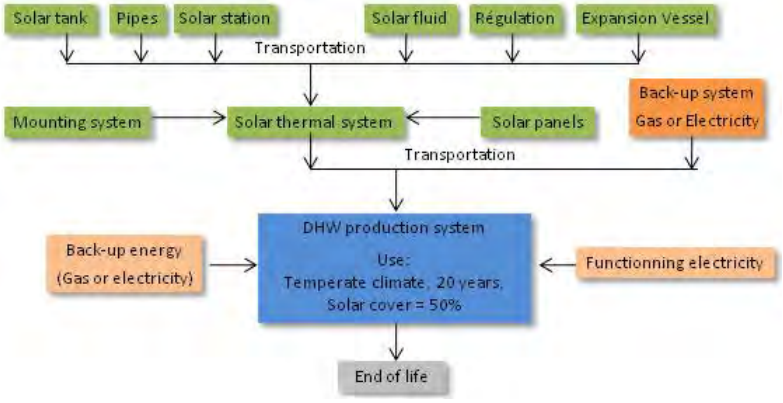

Fig. 3. Scheme of system boundaries

[1] Transénergie, http://www.transenergie.eu

2.2.3. Scenarios

Table 2 describes the four scenarios (scenarios 1-4) built for this study used for temperate climate systems. Scenario 5, standing as a reference for other scenarios results, comes from the ecoinvent 2.0 database.

Table 2. Scenarios for temperate climates

Temperate climate Scenarios					
	Scenario 1	Scenario 2	Scenario 3	Scenario 4	Scenario 5
System	Solar Thermal + Gas	Solar Thermal + Electricity	Gas heater	Electric heater	Solar Thermal + Gas
Solar Panels	Flat plate collectors[2]				Flat plate collectors[3]
Water tank	300 litres vertical tank	300 litres vertical tank			400 litres vertical tank
Backup system	Individual gas heater and heat exchanger[4]	Electric resistance[5]	Individual gas heater	Electric heater tank	Individual gas heater and heat exchanger[5]
Other components	Mounting system, pipes, regulation and solar station		Pipes		Mounting system, pipes, regulation and solar station
Overall lifetime energy consumption	205 000 MJ				~330 000 MJ
Solar coverage	50%		None		58,4%
Life expectancy	20 years				25 years

Table 3 describes the scenario built for this study for tropical SWH which is based on a thermosiphonic solar system. Flat plate collectors inventory is an average of the three main products that exists on the Caribbean market.

Table 3. Scenarios for tropical climate systems

Tropical climate Scenarios	
System	Thermosiphon
Solar Panels	Flat plate collectors[5]
Solar tank	200 l horizontal tank
Other components	Mounting system, pipes
Overall lifetime energy consumption	147 000 MJ
Life expectancy	20 years

2.3. Payback time indicator

Energy Payback Time (EBPT) has been calculated with the following definition:

$$EPBT = \frac{E_p^{fabrication} + E_p^{backup}}{avoidedE_p^{production}} \quad (1)$$

[2] Collector Area = 4,4 m² with solar panel coefficients : B=0,75 ; K=4,5 W/(m².K)
[3] Collector Area = 4 m² with unknown solar panel coefficients
[4] Integrated in the upper part of the tank
[5] Collector Area = 2 m² with solar panel coefficients : B=0,75 ; K=4,5 W/(m².K)

$E_p^{fabrication}$: Non-renewable primary energy used for the fabrication of the installation.

E_p^{backup} : Non-renewable primary energy used for the backup system.

$avoidedE_p^{production}$: Non-renewable primary energy avoided (thanks to the backup energy used, in case of electric backup, specific electricity mix of the country avoided where the SWH is installed.

In the case of electric backup or the comparison with the full electric system, this method of calculating EPBT gives results only valid for the country where the solar panels are installed.

3. Results and analysis

Results have been calculated according to the impact 2002+ (v2.04) [10] method available in SimaPro 7.1 PhD and the database ecoinvent 2.0.

3.1. Temperate climate-type systems

3.1.1. Overall environmental impacts

Scenarios are compared among all impact categories in figure 4. Figures 5 and 6 present the results for the most significant impact categories with the details of their origin.

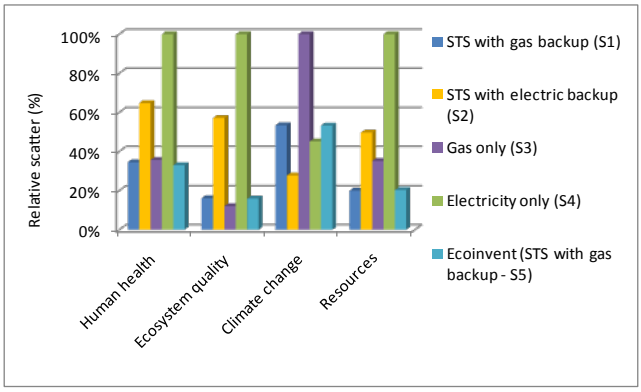

Fig. 4. Comparison of the temperate-climate-type scenarios on the complete lifetime

It strikes that the necessary water auxiliary heating has a strong influence on the overall impact indicators. In the case of a SWH with electric backup (scenario 2), CO_2 equivalent emissions are significantly cut down compared to a SWH with gas backup (scenario 1).
However, considering the other three impact categories, SWH with gas backup appears as the best impact reduction potential option compared to "traditional systems" (scenarios 3 and 4: respectively gas only or electricity only) as well as SWH with electric backup.

It is important here to point out that the electricity mix chosen here influences thoroughly the environmental performances of the ST installation, as well as the comparison with the electricity only scenario. Indeed, according to ecoinvent 2.0, the French electricity mix has particularly low carbon content: 103g/kWh. Thus, the energy backup's choice is critical according to the environmental impact reduction targeted.

3.1.2. Distribution of environmental impacts

The graphs below presents the climate change and non-renewable primary energy impacts. They show the distribution of the impacts of each scenario for the different main life cycle components.

In each of the five scenarios, transports (of materials to the manufacturing plant, as well as of the products to the installation location) play a minor role in non-renewable primary energy consumption. The electricity consumed for the operation of the SWH accounts for a smaller amount of non-renewable primary energy too. Backup energy consumptions stand by far

(>80-90%) for the most important part of for the climate change and non-renewable primary energy consumption impacts. Components of the solar thermal systems (solar thermal panels, pumps, solar tank and regulation system) finally make up for a lesser part of overall impacts, and once produced, consume very little electricity in the operating phase while providing 50% of DHW energetic demand.

In the case of electric backup, CO_2 equivalent emissions are low because the electricity mix chosen is mainly based on nuclear energy (France) and has particularly low CO_2 emissions. On the other hand, the French electricity mix has an important primary energy use (13.6 MJ of primary energy per kWh, according to ecoinvent 2.0), which is why, in this precise configuration (scenario 2), electric backup stands for 91% of non-renewable primary energy (see Fig. 5).

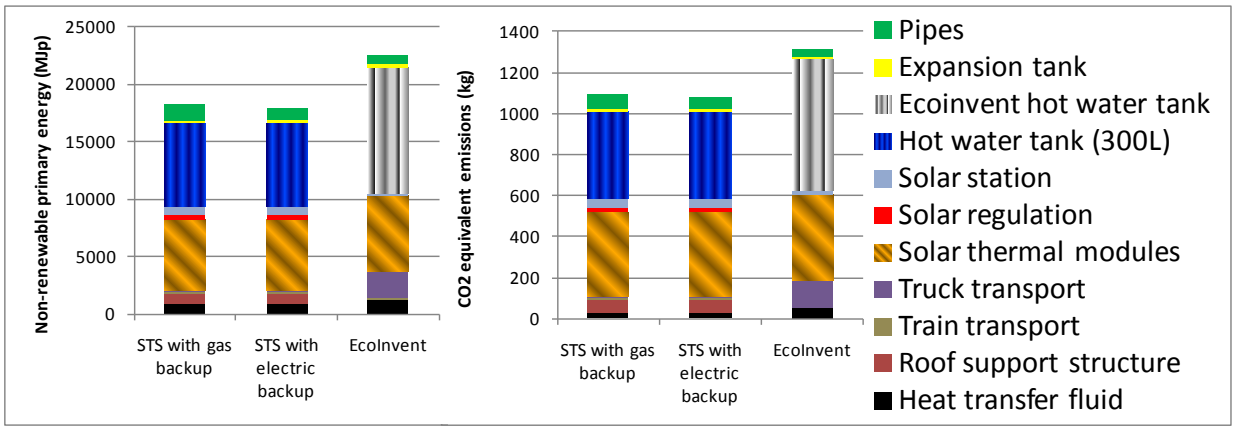

Fig. 5. Distribution of environmental impacts on climate change and non-renewable primary resources for the first four scenarios for temperate-climate-type SWH

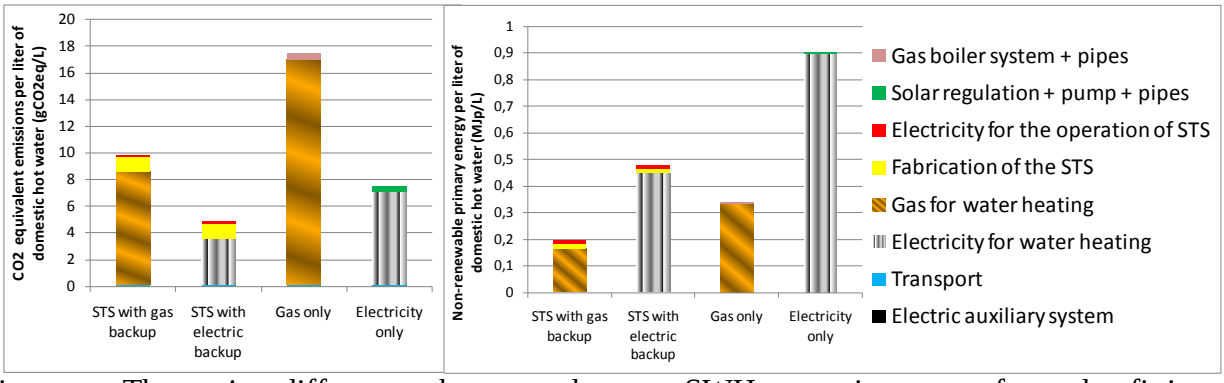
Figure 6 shows the impacts of the fabrication of the solar thermal systems' components for the three scenarios with SWH. The results for those three scenarios show the same trend: solar thermal panels and the hot water tank are the major contributor to the environmental impacts of the two analyzed impact categories. Going further into details, it shows that the use of a large amount of steel stands for the most important part of the impacts of the hot water tank. As for solar thermal panels, it is aluminum (mainly for the frame) that causes most of the



impacts. The major differences between the two SWH scenarios come from the fitting between the hot water tank and the boiler for the gas backup (fitting that is not necessary in the case of electric backup, which is integrated in the hot water tank).

Fig. 6. Detailed environmental impact potential of temperate-climate solar thermal system on climate change and non-renewable primary resources

3.1.3. Comparison with ecoinvent 2.0

Scenario 5 (the ecoinvent scenario) shows significant different results compared to the first two scenarios. This is due to the water tank used which is 1/3 larger in scenario 5 (400 l instead of 300 l). Besides, the transports hypotheses are much less favorable in scenario 5 compared to the first two. On the other hand, the supposed solar coverage ratio (SCR) is noticeably higher in the ecoinvent scenario while the solar thermal panels surface is lower: respectively 58.5% instead of 50% for the SCR, and 4 m² instead of 4.4 m². A further examination indicates that the main differences of results between the two sets of scenarios comes from hypotheses and choice of study parameters (lifetime, SCR, annual energy demand), and therefore shows the coherence between scenarios 1 (gas backup) and 2 (electrical backup) and the ecoinvent scenario (scenario 5).

3.1.4. Energy payback time

Energy payback time (cf. its definition in paragraph 1.3) has been studied in order to compare the energy required for the fabrication of SWH, to the energy avoided thanks to these systems while providing the same service (cf. functional unit). For the sake of clarity, only SWH with gas backup (scenario 1) has been compared to "traditional systems" (scenarios 3 and 4). Energy payback time is 1.5 years when comparing SWH with gas backup to gas only (scenario 1 to scenario 3), and less than 1 year when comparing SWH with gas backup to electricity only (scenario 4).

3.2. Tropical-type scenario

3.2.1. Environmental impacts and distribution

As detailed in Table 2, the solar thermal systems studied here as the tropical-type scenario shows specific differences with the systems used in temperate-climate conditions. Considering that the impact of gas or electricity consumption makes up the major part of overall impacts in the previous scenarios, the impacts of this scenario are significantly different from the previous in terms of distribution.

Fig. 7 shows the distribution of the impacts for each category. The water tank strikes as the major contributor to the impacts of the SWH, between 31% and 60% of each impact.
The other significant contributions are made by the solar thermal panels (about 20% of the impacts), the pipes (mostly because of the copper used), 23% and 31% respectively for human health and quality of ecosystems. The support structure accounts for 7% to 11% according to the impact category.

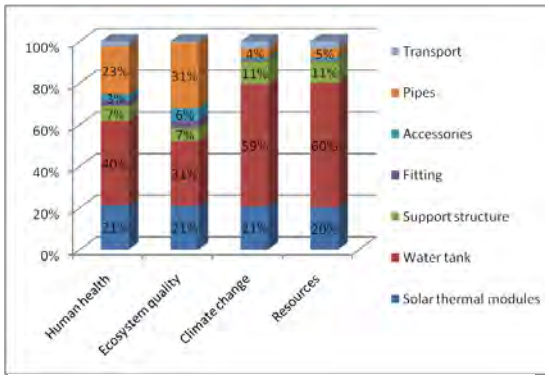


Fig. 7. Distribution of environmental impacts of the tropical-type SWH for each category of impact

3.2.2. Energy Payback Time

Payback time of tropical SWH (with no auxiliary energy) ranges between 5 and 6 months.

4. Conclusions, recommendations and perspectives

This study clearly shows that solar thermal systems are a very interesting solution to reduce the environmental impacts of domestic hot water production.
The impact assessment results for temperate climate systems highlight the backup energy as the major factor on environmental impacts. However, this study does not end with a clear-cut

environmental hierarchy among the different SWH systems: electricity or gas as a backup energy. This is mainly due to characteristics of the French electricity mix that has a low CO_2 content but an important primary energy ratio.
For all SWH, regardless of backup energy, solar panels, water tank and pipes emerge as the key environmental components.

Therefore, considering those results, technical improvement related to the main impacting components can be realized to lower the environmental impacts of the solar thermal part of SWH.

This project has been followed by a LCA on larger solar thermal installations to determine their related environmental impacts and compare with domestic solar systems[6].

Acknowledgments

ADEME (French Environment and Energy Management Agency) is co-financing this project which brings together different French specialists from the solar thermal industry and LCA fields.

Abstract: This study presents the record and analysis of solar radiometry and selected meteorological parameters for Durban, South Africa over a full one-year period from January to December 2007. The results comprise of the key components essential in an assessment of the solar energy resource including global horizontal irradiance, global irradiance on a north-pointing tilted plane at 30° latitude angle, direct normal irradiance and diffuse horizontal irradiance. In addition, the ambient air temperature, humidity and rainfall records are presented and discussed. Selected solar radiometry variables obtained from the STARlab study were compared with data available from various sources including the HelioClim dataset, the NASA SSE database and the literature. The ongoing aim of this study is to build a reliable record of the solar resource for planning, engineering design and effective operation of solar energy systems and applications.

Keywords: *Solar energy potential, Radiometry data, Meteorological data, Renewable energy*

1. Introduction

The development and deployment of sustainable energy technologies across the globe continues at a growing pace, and of the various options available, solar energy remains among the most promising. As a developing nation, South Africa possesses an abundant solar resource, yet the country has traditionally been a carbon-intensive economy. For example, coal provided 70% of its primary energy in 2004, and 90% of the country's electricity [1]. In 2003, a government White Paper on Renewable Energy (WPRE) addressed future energy needs by committing the nation to achieving 4% of its anticipated power requirements from renewable sources by 2013 [2]. This target includes the deployment of end-use technologies such as solar powered water heaters, which South African power utility Eskom estimates could contribute 23% of the target. Eskom has since rolled out a large-scale solar water heating program, offering an incentive to consumers to replace existing electric geysers with the solar alternative [3]. In all these cases, however, an accurate and reliable understanding of the solar resource at the chosen geographic location is essential. Obtaining high-quality irradiation measurements poses a challenge due to the high cost of setting up and maintaining ground-based solar monitoring stations. As a consequence, only a limited number of solar resource assessment studies have been carried out in South Africa in recent years, which either possess inadequate resolution for use in coastal areas, or which have focused on sparsely populated desert regions in the Northern Cape province where concentrating solar power potential is greatest [3-5]. Densely populated urban areas on the east coast have largely been overlooked, yet this is where demand-side reduction programs could contribute greatly to lessening the country's reliance on grid electricity.

Durban is the largest city on the east coast of South Africa and in the province of KwaZulu-Natal (KZN). Despite high population density, growth and energy consumption few comprehensive studies have been done to characterize Durban's solar resource [6,7]. Lefevre et al. [8] compared

satellite-derived data with ground-based irradiance data using 35 ground stations in Africa but only Pretoria and Cape Town are included.

This study is part of a broader radiometric research program at Mangosuthu University of Technology, Durban, South Africa. Data were measured at a ground station located 3 km inland of the Indian Ocean coastline and is considered to be representative of the South Africa east coast region. This paper presents the record and analysis of the solar resource along with meteorological parameters for the period of January to December, 2007. In addition, the ambient air temperature, humidity, wind and rainfall records are presented and discussed. Selected solar radiometry variables obtained from the study are compared with the Meteosat-derived HelioClim dataset, NASA's SSE resource, as well as the literature. The ongoing aim of this study is to build a reliable record of the solar resource for planning, engineering design and effective operation of solar energy systems and applications. The database is also intended to support research in radiometric modeling. We anticipate expanding the database to geographic areas beyond Durban to cover more of the South African eastern coastal region. These efforts are intended to support the deployment of renewable energy resources and reduce the burden on the South African electrical grid.

2. Methodology

The data were recorded at the Solar Thermal Applications Research Laboratory (STARlab) which is an outdoor solar energy research centre in Durban, South Africa (29°58'N; 30°55'E). The station is at 105.5 m above sea level. STARlab is equipped with instrumentation for solar and meteorological monitoring, including thermopile radiometers and a weather station. The serial numbers, mounting and parameters of the radiometry instrumentation are listed in Table 1. The STARlab control room houses solar radiometry and meteorology data logging instrumentation. This includes two Agilent Technologies 34970A data acquisition units (one as back-up) with 34901A 20-channel multiplex modules connected to a desktop computer. Monitoring equipment is connected via an uninterruptible power supply unit. Data logging is controlled by custom-developed LabVIEW application that records point values at 30 sec intervals, with each set of values written to a spreadsheet file that is date- and time-stamped with day, month, year as well as local clock time and a corresponding solar time. In this study the PSA Algorithm was used for locating the solar vector [9] and generating key information such as declination, azimuth, zenith and hour angles. The radiometry data are recorded in terms of solar time, with solar noon occurring when the zenith angle is at a minimum. To obtain irradiation values, the irradiances are integrated over time. Weather variables such as temperature, wind speed and direction, rainfall, humidity and atmospheric pressure are recorded at 30 minute intervals for each 24-hour daily period. STARlab instrumentation is subject to a daily maintenance routine. For the period of this study less than 4% of data were missing due to unavoidable equipment malfunctions. A simple linear interpolation technique, similar to that reported in [6,10] was employed to replace missing information. A flowchart of the solar data monitoring system used in this study is given in Fig. 1.

The results of this study comprise key components essential to an assessment of the solar energy resource including global horizontal irradiance (G_t) global irradiance on a north-pointing tilted plane at 30° latitude angle (G_{tS}), direct normal irradiance (G_{DN}) and diffuse horizontal irradiance (G_d).

Table 1. Specification of STARlab radiometric instrumentation

Instrument	**Serial number**	**Mounting**	**Parameter**
Eppley PSP	# 34332F3	Horizontal plane, unshaded	Total global irradiance (G_t) in the wavelength range 285 nm to 2800 nm
Eppley PSP	#33583F3	Inclined at 30° slope to the horizontal, aligned true north, unshaded	Total global irradiance in the wavelength range at a 30° tilt angle (G_{tS})
Eppley NIP	#31955E6	Mounted on a ST-1 motorised solar tracker	Direct normal irradiance in the visible wavelength range (G_{DN})
Eppley TUVR	#34623	Horizontal plane	Ultra violet irradiance in the range 295 nm to 385 nm

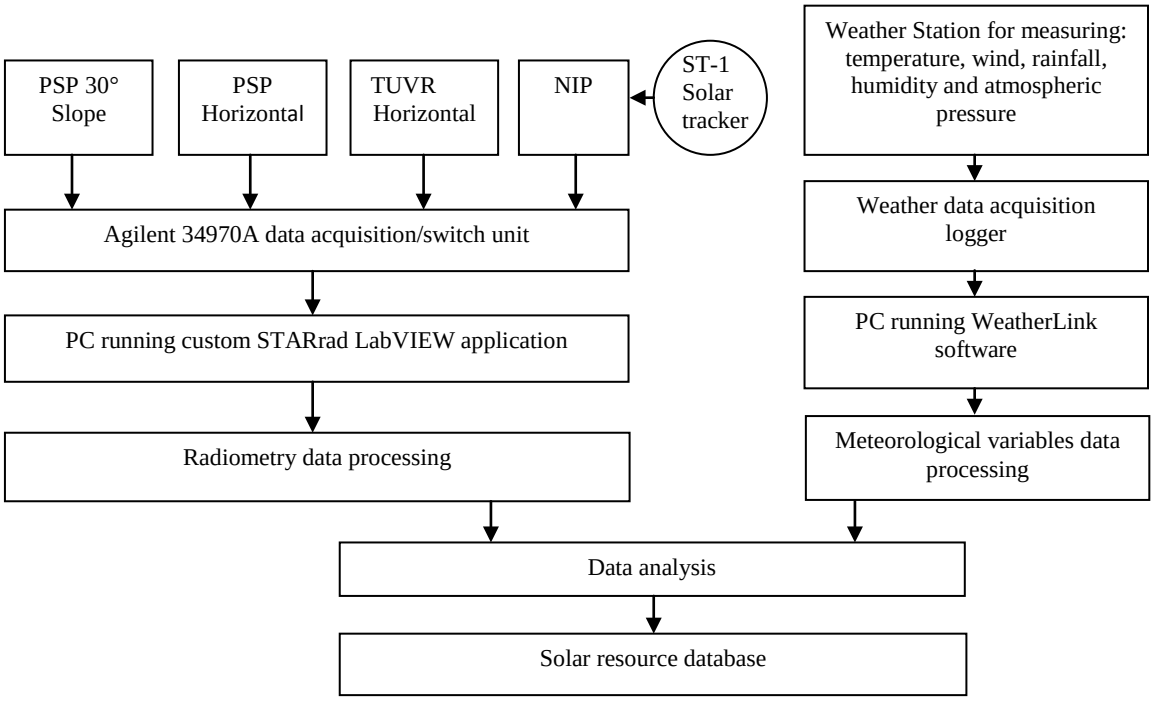

Fig. 1. Flow chart of the method applied in generating the STARlab solar resource database

In addition, the air ambient temperature, humidity, wind and rainfall records are discussed. Selected solar radiometry variables obtained from the STARlab ground-based records are compared with corresponding data available from HelioClim [11], NASA SSE [12] and sources in the literature. Data derived from Meteosat satellites have been used for comparison in a number of studies [8,13] and are currently in use by South African practitioners.

3. Results and Discussion

3.1. Radiometric analysis

Records of global horizontal irradiance G_t (W/m^2), global irradiance on a north-pointing tilted plane at 30º G_{tS} (W/m^2) and direct normal irradiance G_{DN} (W/m^2) were acquired from STARlab radiometers between January and December of 2007. The diffuse solar irradiance G_d (W/m^2) is calculated using the closure equation [14].

$$G_d = G_t - G_{DN} \cos\theta_z \quad (1)$$

where θ_z is the solar zenith angle. Daily cumulative irradiance values for G_t, G_{DN}, G_{tS}, and G_d are obtained by numerical summation of point values, to give H_t, H_{DN}, H_{tS}, and H_d, each representing a measure of energy per square meter (J/m^2). Daily values are averaged for each calendar month in the study to yield monthly average daily irradiation per square meter. Monthly average daily irradiation is often quoted as an indicator of energy availability for renewable energy activities. As a southern hemisphere country, South Africa's daily global horizontal irradiation trends higher between November and March. The winter period between April and October is characterized by clearer skies, but lower solar radiation intensity. The selected Durban results obtained from STARlab are compared with HelioClim-3 database values and NASA SSE datasets using the mean bias error (MBE) and root mean square (RMSE) approach to quantify difference .The MBE and RMSE are defined as follows:

$$MBE = [\sum(H_{sat} - H_{meas})]/n \quad (2)$$

$$RMSE = \{[\sum(H_{sat} - H_{meas})^2]/n\}^{1/2} \quad (3)$$

where H_{sat} is the predicted monthly average daily irradiation value for Durban from either HelioClim dataset or the SSE, H_{meas} is the measured monthly value from STARlab and n is the number of calendar months. The MBE and RMSE percentage values are calculated using the measured annual averages for each irradiation component for Durban. It should be noted that MBE and RMSE represent differences between the measured and modeled values, and not fundamental measurement uncertainty of the instrumentation.

The results show a typical trend for the southern hemisphere. For the eastern coastal region around Durban, two broad seasons can be identified: summer from November through March and winter from April through October. The monthly average of the daily global irradiation on the horizontal surface for summer and winter periods recorded at STARlab for 2007 were 5.62 kWh/m^2 and 3.6 kWh/m^2 respectively with the annual average value of 4.45 kWh/m^2. The highest value of 6.39 kWh/m^2 was recorded in January while the lowest value of 2.81 kWh/m^2 was measured in June. Similarly, the monthly average daily direct normal irradiation for summer and winter periods were measured as 5.25 kWh/m^2 and 4.94 kWh/m^2 respectively, with the maximum value of 5.90 kWh/m^2 recorded in February. The values of irradiation measured on the 30° incline are higher than those on the horizontal from March through October. Between November and February, the values on the horizontal exceed those on the incline. For example, the monthly average daily of the global irradiation on the 30° incline for May, June and July was 5.48, 4.30 and 4.89 kWh/m^2, with an annual average of 5.04 kWh/m^2. The corresponding values on the horizontal were 3.64, 2.81 and 3.17 kWh/m^2 respectively. The annual averages of daily

global irradiation components recorded at STARlab are found to be in reasonably close agreement with values obtained from HelioClim-3 and the NASA SSE datasets. The MBE and RMSE statistics are given in Table 2 and Table 3.

Table 2. Mean bias error and root mean square error for recorded data versus HelioClim data (Durban, 2007)

Solar radiation component	**MBE kWh/m^2**	**MBE %**	**RMSE kWh/m^2**	**RMSE %**
H_t	0.6	13.4	0.7	15.1
H_{DN}	-0.4	-9.1	0.6	15.6
H_d	0.2	9.0	0.3	17.1

Table 3. Mean bias error and root mean square error for recorded data versus NASA SSE data (Durban, 2007)

Solar radiation component	**MBE kWh/m^2**	**MBE %**	**RMSE kWh/m^2**	**RMSE %**
H_t	0.3	5.6	0.6	12.5
H_{tS}	0.1	2.4	0.5	10.1

Solar energy availability is often characterized by the diffuse fraction which provides a useful statistical distribution of the global irradiation at a location [6,14]. The diffuse fraction is particularly helpful in evaluating performance of systems such as flat-plate collectors. The monthly average diffuse fraction K_d is the ratio of monthly average daily diffuse irradiation on a horizontal surface (H_d) to the monthly average daily global total irradiation on a horizontal surface (H_t), as given in equation (4) [14], where H_d and H_t are measured in (kJ/m^2).

$$K_d = \frac{H_d}{H_t} \qquad (4)$$

The ratio of monthly average daily diffuse to global irradiation is presented in Fig. 2. This shows the expected seasonal trend for the Durban coastal region, with the diffuse fraction decreasing over the dry winter season, then increasing towards the humid summer season.

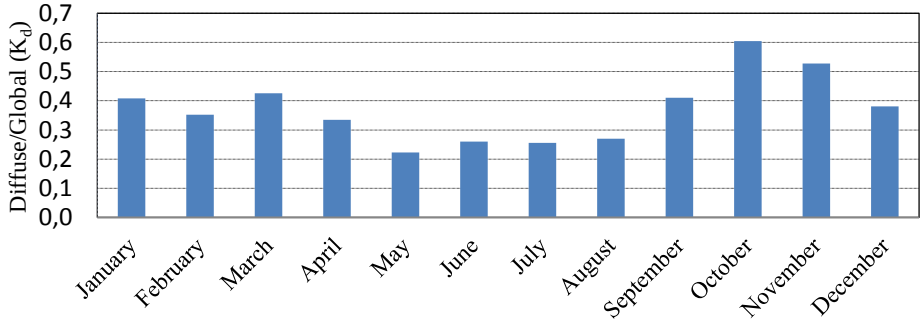

Fig. 2. Monthly average daily diffuse fraction values at STARlab

The measured annual average diffuse fraction for Durban in 2007 was 0.38. The annual cumulative values of solar energy measured in the year under consideration were 5881.85 MJ/m^2 for total global irradiance on a horizontal surface and 6592.09 MJ/m^2 for total global irradiance on a northward pointing 30° incline. The latter represents a 13% increase in energy availability, confirming the value of tilting flat-plate collectors in Durban at an angle equal to the latitude. For this assessment of solar resource potential it is useful to do a comparison with other areas around the world. Table 4 includes measured cumulative total global irradiation in the horizontal plane for 10 global cities, against which the Durban results are compared. It should be noted that not all values in Table 4 for other locations were obtained in 2007. The comparison is nevertheless indicative of Durban's relative solar potential. Arizona's desert is often considered as a benchmark when evaluating a location's solar resource and offers some of the highest solar potential in the world. Although this location has a significantly higher resource compared with Durban, the South African city exhibits similar solar energy potential to Sanary in France, Singapore and Miami (USA). Results suggest that Durban's solar potential is considerably higher than those of Seattle and Coeur d'Alene (USA), as well as Melbourne, Australia.

Table 4. Comparison of Durban measured annual total global irradiation in the horizontal plane with selected other locations

Location	Latitude	Reference	Year	Annual totals [MJ/m^2]	Relative solar resource
Durban, South Africa	29º58'S	STARlab data	2007	5881.9	100%
Coeur d'Alene, Idaho	47º72'N	[15]	1982-86	4485.6	76%
Eugene, Oregon	44º05'N	[15]	1975-97	4791.6	81%
Hermiston, Oregon	45º82'N	[15]	1979-97	5396.4	92%
Ely, Nevada	39º15'N	[16]	1961-90	6462.0	110%
Phoenix, Arizona	33º32'N	[16]	1961-90	7545.6	128%
Seattle, Washington	47º68'N	[16]	1961-90	4392.0	75%
Miami, Florida	25º34'N	[17]	2007	6242.0	104%
Sanary, France	43º08'N	[17]	2007	5996.1	104%
Singapore	01º22'N	[17]	2007	6030.0	103%
Melbourne, Australia	37º49'S	[17]	2007	5385.0	93%

3.2. Meteorological parameters

The meteorological parameters recorded and analyzed in this study were temperature, humidity, wind speed and direction as well as rainfall. Data were collected at 30 minute intervals over each 24 hour daily period. Fig. 3 shows the maximum, minimum and average daily ambient air temperature while Fig. 4 shows maximum, minimum and average daily humidity throughout the year under study. Durban has a subtropical climate with hot and humid summer and mild winter. Maximum monthly average daily temperatures of 24.0 ºC, 24.9 ºC and 23.4 ºC were recorded in January, February and March respectively. The lowest monthly average daily temperatures were recorded in June and July at 18.5 ºC and 18.2 ºC respectively. Humidity remains high for most of the year due to the influence of the warm Mozambique current flowing along KwaZulu-Natal's coast. The annual average monthly daily humidity recorded is 74.9%. Total rainfall recorded for

the year was 972 mm with a maximum value of 231.2 mm recorded in November and minimum of 1.4 mm measured in May.

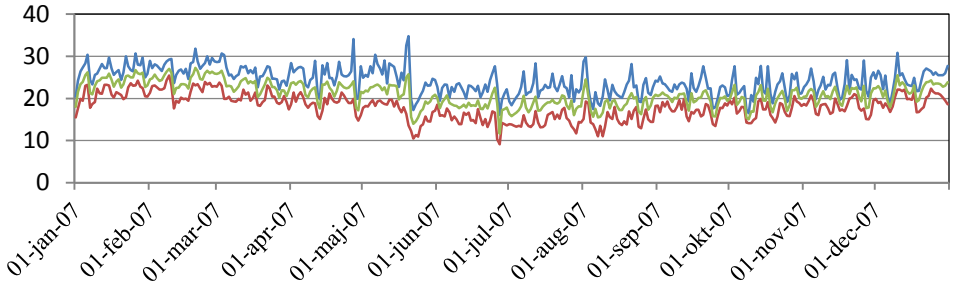

Fig. 3. Durban's daily average, minimum and maximum temperatures throughout the year

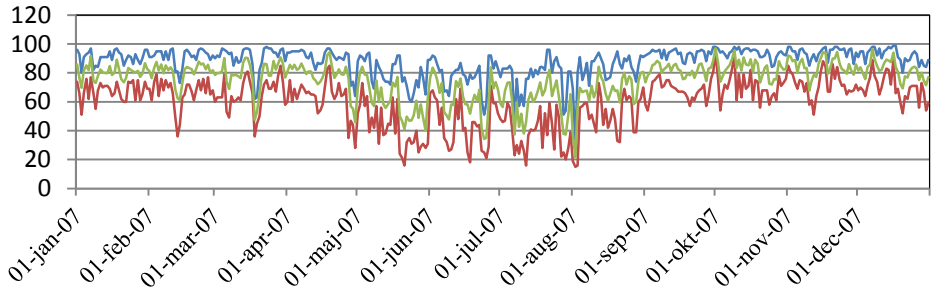

Fig .4. Durban's daily average, minimum and maximum relative humidity throughout the year

4. Conclusions

With a population density exceeding the national average, the east coast of South Africa around the city of Durban offers good potential for reducing demand on the electricity grid by switching to sustainable technologies like domestic solar water heaters and energy-efficient architecture. For urban planners, engineers and equipment suppliers there is a growing need for reliable solar radiation data on which to base technical and economic projections. In this study we show that two satellite-based software tools, HelioClim and NASA SSE offer reasonable estimates of the solar resource and each might be considered a good 'first stop' for estimating available energy. For 2007, mean bias differences in the satellite-based data versus measured values for annual average daily global irradiation were 13.4% for HelioClim and 5.6% for SSE. Random mean square differences were 15.1% and 12.5% respectively, suggesting that the SSE database is slightly more accurate. The HelioClim database tended to underestimate direct normal irradiation by 9.1% with random mean square difference of 15.6%. SSE is also able to predict annual irradiation on a tilted surface. The bias and random errors for the NASA database versus measured readings from a sloping pyranometer at 30° latitude tilt were 2.4% and 10.1% respectively. The measured annual average of daily global horizontal irradiance for 2007 was 4.45 kW/m^2 while the annual cumulative value was 5881.85 MJ/m^2. Overall, the solar resource for Durban is comparable to that of Singapore and Miami, marginally better than Melbourne's and about 28% weaker than that of Phoenix, Arizona. We anticipate expanding measurement activities to cover more of South Africa's eastern seaboard, via the recently established

GRADRAD network. These efforts are intended to aid radiometric research and reduce South Africa's dependence on fossil fuels for power generation.

Abstract: Solar energy is the biggest energy resource on the earth. Latvia environment is very potential for solar usage, but there are many reasons why consumers have skepticism and a perception that the environment in this region is not suitable for solar energy usage.
To have broken this stereotype, this study is conducted. The aim of this program is to explore the suitability of Latvian environment with the use of solar collector. For the attainment of objective monotype house will be modeled, the house will be equipped with the combined solar heat system, which will be placed in different regions. There are various amounts of sunny days in different regions, as well as diverse average temperature, wherewith the amount of heat differs. For the modeling of building, modeling program model of solar collectors will be used, which is provided for several solar heat systems, inter alias for the calculation of combined solar heat supply system and for the solving of several relevant tasks. Program is simulation program for the thermal solar energy systems. It suits both for determination of hot water use and heating system use.
There are countries which are located in sunny regions and which history of solar energy usage is very longstanding, wherewith also technological achievements are high. Yet our contemporary rapid technology development enables to use ever more solar energy in the regions which are not so rich with the solar radiance, for example in Latvia. Interest about the usage of solar energy in Latvia increase – partly it is explicable to unpredictable and essential price rise of fossil firing resources and partly to the desire to invest in technologies which could reduce this rise in price in the future.

1. Introduction

During last few years significance of environmental problems increase. Wherewith, activation of environmental problems increases humans' interest about different environmentally friendly technologies. One of the biggest air polluters are fallouts resulted from burning of fossil firing. That is why urgent becomes utilizations of renewable resources for the energy obtaining, which are less nocuous to environment. Latvia's total final energy consumption is secured from local energy resources and the flow of primary resources from Russia, the CIS countries, the Baltic countries, EU and other countries. Currently, three types of energy resource making up approximately equal proportions dominate in the delivery of Latvia's primary resources – oil products, natural gas and wood-fuel. Like many other European Union countries, Latvia is dependent on imports of primary resources. The share of RES has traditionally been significant in Latvia's energy supply and in 2008 it comprised 29.9% of the total final energy consumption. Interest about the usage of solar energy in Latvia increase – partly it is explicable to unpredictable and essential price rise of fossil firing resources and partly to the desire to invest in technologies which could reduce this rise in price in the future. That is the reason why is it necessary to investigate solar energy potential in Latvian conditions.

Global radiance consists of direct and diffused radiance. Direct radiance is connected with the direction of sunbeams. Diffused radiance develops when molecule and particles in atmosphere disperse sunbeams in all directions. The duration and intensity of solar radiance depends on season, climatic conditions and geographical location. Global radiance of the earth on the horizontal area in the regions of solar zone may reach 2200 kWh/m^2. Maximal volume of solar radiance in North Europe is 1100 kWh/m^2. We can conclude that even in such

small country as Latvia are several different solar sliding duration zones. In the zone along the Baltic Sea is the longest solar sliding duration – more than 1900 hours, in its turn in Vidzeme heights it is the least – less than 1700 hours. Volume of Solar radiance is the main factor of solar energy usage in Latvia. [2]

2. Methodology

In order to define, how great volume of heat from building total use of the heat is possible to secure using solar heat energy, the model of the building will be created using modeling program. With the help of this program it is possible to carry out research, the modeling, the calculation of heat supply solar systems. Simulation of all type heating supply solar system is based on independent meteorological data. Time step of simulation is possible starting with one second even until one hour, it depends on situation, in its turn, there are a lot of versions of model simulation time periods – starting from one day until several years. The calculation basis in program has been integrated from subprogram Meteonorm. Using preferences of simulation program have been cleared up most effective location for solar collector in Latvian conditions. Comparatively, effective solar radiation may catch solar collector that is placed 55° anent to horizon or slope and 0° anent to the South or orientation and which has clean horizon, nothing puts a slur and otherwise do not affect the activity of collector, that is why received amount of solar heat takes as average from all models that are placed in corresponding place and location. However first of all foreseeable tables has been made. Data about the volume of receivable heat from 1 m^2 solar collector that depends from location, to be more precise in what angle as to the ground it has been put and in what orientation as to the South solar collector will catch the greatest volume of heat, has been put in the table.

Table 1. Percipient heat volume from 1 m^2 of solar collector in Riga dependence of location, kWh/m^2.

Orient. \slope	0°	15°	30°	45°	55°	60°	75°	90°
0°	259	325	382	417	**426**	425	401	348
15°	259	320	376	412	422	423	406	359
30°	259	325	380	412	417	414	385	324
45°	259	310	362	396	407	408	395	357
60°	259	322	370	396	397	393	358	294
75°	259	297	341	370	380	381	370	335
90°	259	314	355	373	369	363	325	262

Such location is the most effective and in the table 1 there are the same data, then we can conclude that program is comparatively precise for the calculation in the Latvia conditions. The least received heat volume is when the solar collector is located 0° anent to the Earth horizon. This location is the most inappropriate for the detection of solar radiance. To 0° anent to horizon at any orientation, the volume of received heat is constant, because ray angle falling form the Sun anent to the area is constant at any orientation of solar collector. In the Table 1 it is clearly seen how volume of received heat change and its changes are twice as much bigger. Therefore the precise setting up of solar collector has significant meaning. Although this calculation was done only for one type collectors, though the calculation corresponds to previously defined, we can conclude that in wholesale it is similar to all collectors.

The collector efficiency mainly depends on the difference between the mean collector temperature and the ambient temperature *Tm - Ta*. If this difference is high then the heat radiation and the convection losses are high. At small temperature differences the efficiency can reach 90%. If the mean collector temperature drops below ambient temperature because of a cold heat transfer medium then the efficiency can exceed even 100%. In this case the heat transfer medium is not only heated by the sun, it's also heated by the ambient air. [1] The efficiency is described by the efficiency curve. The temperature difference (*Tm - Ta*) divided by the irradiation normal to the collector (*Gk*) is the variable (*x*).

$$X = \frac{Tm - Ta}{Gk} \qquad (1.)$$

Following a typical efficiency curve of a regular glazed flat collector:

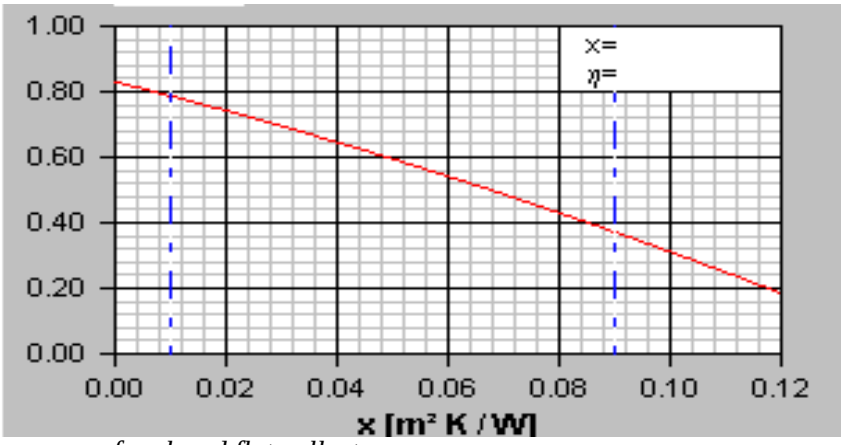

Fig. 1. Efficiency curve of a glazed flat collector.

The higher the mean collector temperature lowers the efficiency. The irradiation is 800 W·m^{-2}. This curve is described by a 2nd order Polynom with sufficient accuracy. This Polynom is clearly defined by three parameters, c_0, c_1, c_2 (or a_0, a_1, a_2; values measured under wind speed of 2-4 m·s^{-1}):

$$\eta = c_0 - c_1 x - c_2 G_k x^2 \qquad (2.)$$

where η – efficiency of collector; c_0, c_1, c_2 – coefficient of polynomial set in model; G_k – tightness of solar radiation, that falls athwart to the surface of collector,

The efficiency value amounts to c_0, if the mean collector temperature and the ambient temperature are equal. This value should be high. c_1 and c_2 describe a combination of different loss factors. These values are low if a collector is well insulated. It is worth to mention that such polynomial is used in modeling program for the calculation of efficiency. [1]

3. Results

Since program isn't potted to the conditions of Latvia, there isn't meteorological data, which are necessary for activity simulating of the combined heat supply of solar system in the Latvian conditions in its data basis. Since this program contains meteorological data from all world, in order to get this necessary information, accurate coordinates from different towns of Latvia, which are located in different zones of sun shining: Riga, Liepaja, Daugavpils has been entered. For the more visible efficiency determination of heat supply solar system, also

coordinates of typical sunny south city Bremen (Germany) and cool northern city Boden (Sweden). Wherewith, computer models will be created for different climatic zones and conditions in the European Union countries.

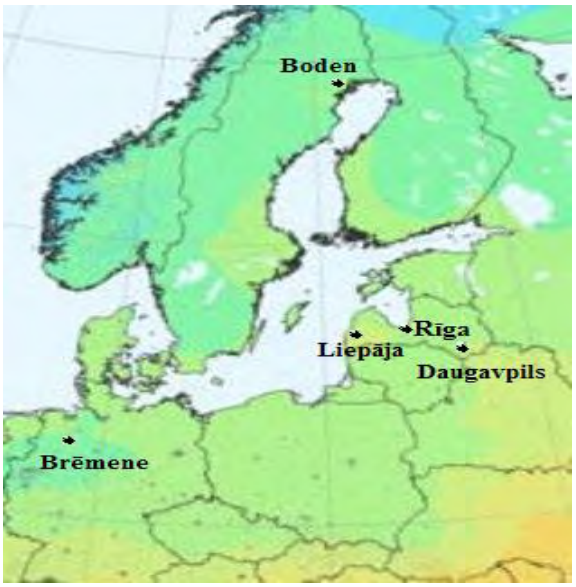

Fig. 2. Locations of cities that are used for modeling

Those data of communities that are used for the modeling of combined solar heat supply system are shown in table 2.

Table 2. Meteorological data for Meteonorm

Place of location	Latitude	Degrees of longitude	Elevation above sea level, m
Riga, Latvia	56,88°	24,13°	14
Liepaja, Latvia	56,49°	21,02°	1
Daugavpils, Latvia	55,87°	26,52°	105
Boden, Sweden	72,80°	12,58°	121
Bremen, Germany	65,78°	21,67°	31

Initially model one family building with the floor space 150 m^2, 4 persons will live in that building. Heat loss through demarcation constructions of building (external walls, roof, windows etc.) makes essential part form total use of heat energy. Power efficiency of demarcation constructions is able to evaluate when thermal coefficient of given construction is U ($W/m^2 \cdot K$). Because in Latvia there is relatively cool climatic conditions, than building must be well isolated with heavy constructions. Walls are made from bricks and from outside they have 0.2 m heavy insulation. Air exchange 0.6 l/h, and radiant 400W. Require heating capacity 6.1 kW at -8°C. Looking closely at balance sheet of used and acquired heat of each place we can conclude that in all chosen places development of heat use during year is similar, only volume of heat differs.

Table 3. Heat energy consumption for space heating depending from location, kWh/m^2 per year.

Place of location	Common use of heat energy for room heating (kWh per year)	Use of heat energy for room heating on 1 m^2 (kWh/m^2 per year)
Riga, Latvia	12 650	85
Liepaja, Latvia	12 500	80
Daugavpils, Latvia	13 615	92
Bremen, Germany	9 652	65
Boden, Sweden	27 342	182

In warmer climatic zone use of thermal energy reduces. Because Bremen is located closer to equator and its average temperature is superlative for all viewed cities, for that reason required volume of thermal energy is the least. Yet looking closely at Boden, which is located close to the North, it is contrary. Distinction among Riga, Liepaja and Daugavpils brings about location of those towns' towards the sea. Temperature at the sea in winter is warmer wherewith volume of thermal energy for room heating is different, yet towns are located relatively close to each other, wherewith volume of thermal energy is not very different. As in the building lives 4 persons and it is known that on one person provides 2 m^2 solar collectors, than for the building model use 8 m^2 flat area collectors. Previously we found out that solar collector works most effective when its slope angle is 55°C anent to horizon and 0°C anent to the South. We estimate position along vertical of solar collector modules. Wherewith, we can define thermal conductivity and thermal capacity of pipes, as well as the stream speed in pipes. Pump and system described values are calculated automatic after input of necessary data. In this case inputted values are the following: flow of pump, flow speed of their process 120 l·h^{-1} and back process 0, 06 m ·s^{-1}. Also one more important parameter of efficiency determination of combined solar heat supply system is heat carrier data of used solar collector. Usually water is used like heat carrier, due to its availability, low price and suitable physical qualities. In combined heat supply solar systems, water can be used only in the inner supply of heat and water. For the very reason in Latvia conditions pipes are excluded as heat carrier in exterior contour. Therefore glycol solutions must be chosen as the heat carrier in pretence model. Necessary volume of heat for the preparation of hot water in all climatic conditions is nearly identical 4069 kWh in a year. In some places suspended volume of solar heat is different.

Table 5. Perceptive solar heat volume, kWh/in a year.

Place of location	Common use of heat energy for room heating (kWh per year)	Use of heat energy for room heating on 1 m^2 (kWh·m^{-2} per year)
Riga, Latvia	3 200	400
Liepaja, Latvia	3 345	418
Daugavpils, Latvia	3165	395
Bremen, Germany	2930	366
Boden, Sweden	2890	360

It is not possible to unequivocal assert that solar collectors works more effective closer to the South and to the North they do not work effective. The most effective works solar collector that is located in Riga and not the solar collector in Bremen that is closer to the South. It is explained by the less requirement of system for heating, because during the year in all models the volume of warm water for the preparation of hot water and containers heat loss is equal. In a period when heating is necessary but available volume of solar heat

energy is sufficient not only for the preparation of hot water but also for the room heating, combined solar system has been used valuable. In the Northern models such periods are longer, wherewith the volume of used solar energy is greater. Riga's model in comparison with Bremen model volume of used solar energy is greater, because the air temperature in Bremen at the beginning and at the end of the year is a bit lower, but available solar heat is greater, wherewith the volume of used solar thermal energy increase. In all versions the volume of produced heat in auxiliary boiler is greater than necessary for the building. It is explained by the extra load of auxiliary boiler for the production of hot water. Because several simulations with different combinations has been carried out with different capacity auxiliary boilers and electricity, then average result has been accepted as the volume of produced heat of auxiliary boiler.

Table 6. Heat volume from auxiliary boiler, kWh/year.

Place of location	Heat volume from auxiliary boiler (kWh in a year)
Riga	15 400
Liepaja	14 800
Daugavpils	16 080
Boden	11980
Bremen	27120

In existing versions of auxiliary boilers more to the North, the volume of produced heat increase on the count of necessary volume of the heat for the production of hot water. At the beginning of colder season auxiliary boiler has been started later, because sufficient volume of the heat is stocked up in the container, which ensures room heating and preparation of hot water for the short period. In that way heat has been stocked up for the later use, which is one of the formation preconditions of the combined heat supply solar system. It is not important to evaluate the productivity of solar collector but the relations of produced capacity in the power balance of the building. As models of Riga, Daugavpils and Liepajas is relatively similar and let the chart is more obvious only Riga, Bremen and Boden will be compared.

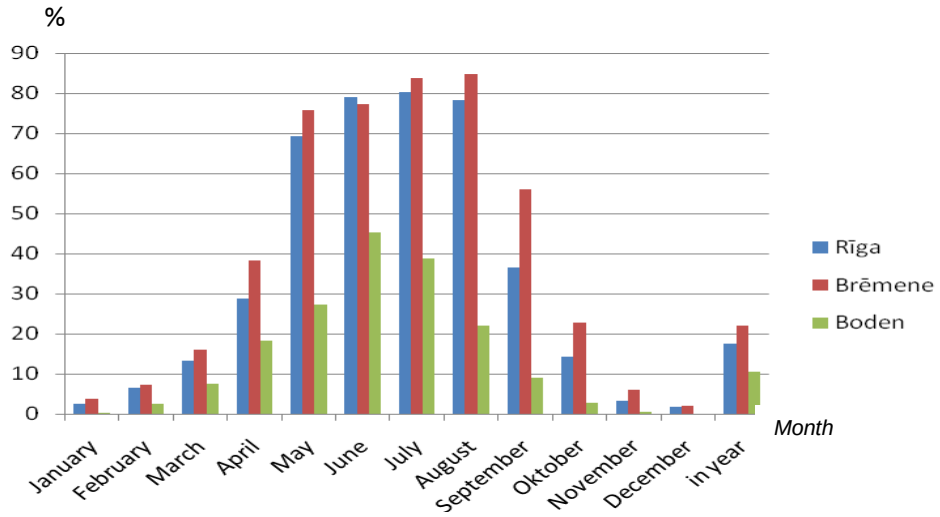

Fig.3. Percentage of produced heat from solar collector, %

Solar collectors may cover the necessary volume of heat during the summer month. Capacity of heat is not necessary for the room heating during the summer month, capacity of heat is necessary only for the preparation of hot water. It is important that solar collectors of Riga's

model produce practically the same volume of heat energy from building heat balance as it is in Bremen. To be more precise solar collectors in Riga's model produce more heat energy than Bremen model but heat loss of building is greater in Riga. The decrease of heat volume necessary for room heating reflects not only in the volume of used heat but also partly in not received volume of solar heat. In its turn, the volume of solar heat that is used in the preparation of hot water is growing, because the volume of solar heat is available. For that reason the bigger part of the solar heat energy is observed in used volume of heat. Important conclusion in that during the winter month volume of received heat is minimal and very similar to all viewed models. Consequently during those months combined solar heat supply system has reduction of usefulness. Probable it is worth to consider on solar collector unlock during the cooler season, in such a way raising its usefulness. Though already in early spring solar collectors may provide 30% from the use of building heat for the room heating and hot water. The volume of suspended solar heat do not show real possible volume of solar heat energy that may be used, because conveying of solar heat energy to the storing container happens during almost all light period of day, only disconnecting circulation pumps of model in short periods.

The Developed models were viewed on the other side. Heat exchanger effect on System efficiency was determinate. The system affects the handling characteristics, such as heat exchangers. They fulfill the important function as a heat-transfer. The resulting solar collector heat storage tank is given by the mixing of heat already is there or whether the fluid is more effective when the heat from the solar collector storage tank into the system through a heat exchanger. The heat storage tank heat loss is smallest when the system has been equipped with heat exchanger for Domestic hot water. Previously was found how to place the solar collectors to receive the maximum amount of solar radiation.

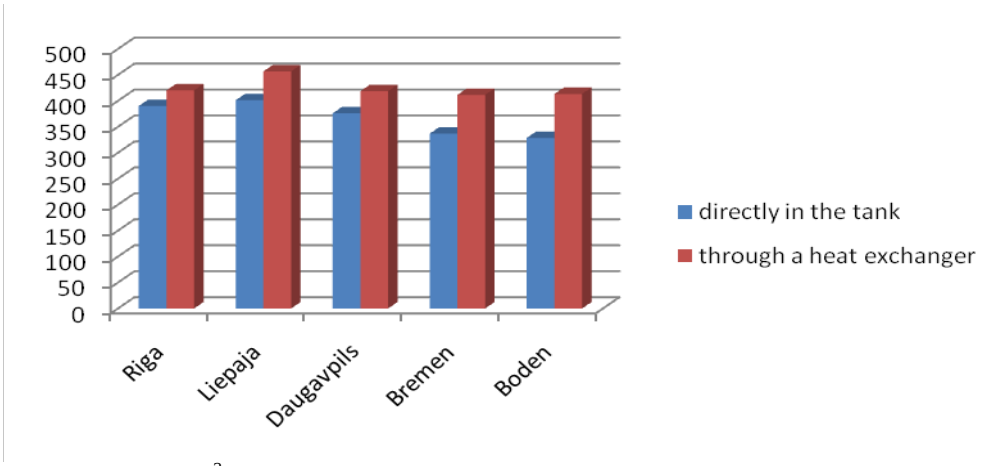

Fig. 4. Heat quantity W/m^2 depending of heat transforms type in system

The heat transfer from the solar collector system to the heat storage tank through a heat exchanger is about 14% efficiently than in cases where heat transfer occurs mixing of solar collector fluid transforms the heat in the tank. This is explained by the fact that the liquid flowing through the heat exchanger is less than the local losses. As well as more efficient heat exchange takes place.

4. Conclusions

The activity of the system depends on the weather conditions of particular place, which have an impact of the geographical fix, available volume of solar heat. It depends also on the individualities of particular place: the hills, the sea, the wind direction etc. In addition, the

great importance has the users of combined solar heat supply system, their way of life. Wherewith, comparing of simulation models located in different places is conventional.

The greatest volume of perceived solar heat in Riga is in the situation when solar collector is placed 55° against horizon and 0° orientation against the South

The combined solar heating system provides for constant domestic hot water and seasonally variable space heating demand ensuring in annual terms. As well as changing hot water and constant heating demand ensuring in daily. Combined solar heating system operation depends on various technical specifications and performance characteristics of system components, such as the installed area of solar collectors, size of thermal storage tank, heat conductivity, as well as other parameters of system. During the winter months such a system is not useful, but it pays off in the summer months, producing enough heat for domestic hot water and pre warming for space heating. Effect on system's efficiency gives availability and location of heat exchanger. The heat transfer from the solar collector system to the heat storage tank through a heat exchanger is about 14% efficiently than in cases where heat transfer occurs mixing of solar collector fluid transforms the heat in the tank.

Difference between accumulated solar collector's heat of the Latvian, Sweden (Boden) and Germany (Bremen) models are not significant. But Consumed heat for space heating and domestic hot water is drastically different. Hence contribution varies of solar thermal system in consumer balance sheets. As the building model of Boden has the highest heat consumption, than solar collector contribution in balance sheet are relative the smallest.

Abstract: The solar pond is considered one of the most reliable and economic solar systems. The collecting and storing of the solar energy is in one system, so the heat in summer can be utilised in winter in the same system. To predict the potential of solar pond at any part of the world a mathematical model is established to calculate the parameters affecting the performance of the solar pond through a computer programme.. The solar radiation input to the pond is calculated using the daily monthly average method. One dimensional steady state and transient assumptions in the gradient zone are used to predict the effect of any parameter on the solar pond performance. The results show excellent agreement with the experimental data under the steady state assumption. Many parameters affecting the performance of the solar pond such as shading effect, depths of the upper, gradient and storage zones, ground temperature and covered insulation for different climates and different latitudes have been studied. The results show that the solar pond has high potential even for colder climates such as that of the UK, where the heat could be used for a number of applications including domestic and industrial.

1. Introduction

Natural water temperature gradients was observed and reported first time by Kalecsinsky in the Medve Lake in Transylvania in 1902 [1,2]. This observation suggested the possibility of constructing and using the ponds as solar energy collectors and storage areas. Tabor (1964), Weinberger (1964), and Tabor and Matz (1965) reported a series of theoretical and experimental studies of these salt gradient ponds [3].

The solar pond is one of the simplest methods that can directly collect and convert solar energy to thermal power. Moreover, it is a solar power collector and a thermal storage unit at the same time. All Ponds convert solar radiation to heat although most of them lose that heat as a result of convection and evaporation. In nature when the sun's rays fall on the lake or the pond, the temperature of water increases gradually towards the bottom of the pond. Therefore, the water in the bottom becomes warmer then it rises to the surface and loses its heat to the atmosphere, a phenomenon called convection. However, the solar pond technology inhibits this phenomenon by dissolving salt into the bottom layer of this pond, making the fluid too heavy to rise to the surface, even when being hot. This idea can increase the temperature of the bottom layer up to more than 100 oC [4]. Once a high temperature is obtained, the bottom layer can be used as a heat source to provide continuous heat through a heat exchanger at any time. The solar pond principle is to prevent vertical convection and/or evaporation according to the type of the solar ponds [5].

A typical salinity-gradient solar pond consists of three main zones as shown in Fig. 1:

- The Upper Convecting Zone (UCZ) which has the least cost, salinity, temperature, and is close to ambient temperature. The thickness of this zone is typically 0.3 m and it should be kept as thin as possible. The cost of constructing the UCZ is usually reasonable.

- The Non-Convecting Zone (NCZ) which is located between the upper and the lower zones of the pond. Since the temperature and salinity increase with depth, this layer is not homogeneous. If the salinity gradient is large enough, the NCZ inhabits a convection phenomenon even when the lower zone is hotter.

- The Lower Convecting Zone (LCZ), which is a homogenous layer and has a relatively high salinity and high temperature. Heat is stored in this zone and can be exchanged in or out of the pond. As the LCZ's depth increases, the heat capacity increases and the temperature variation decreases.

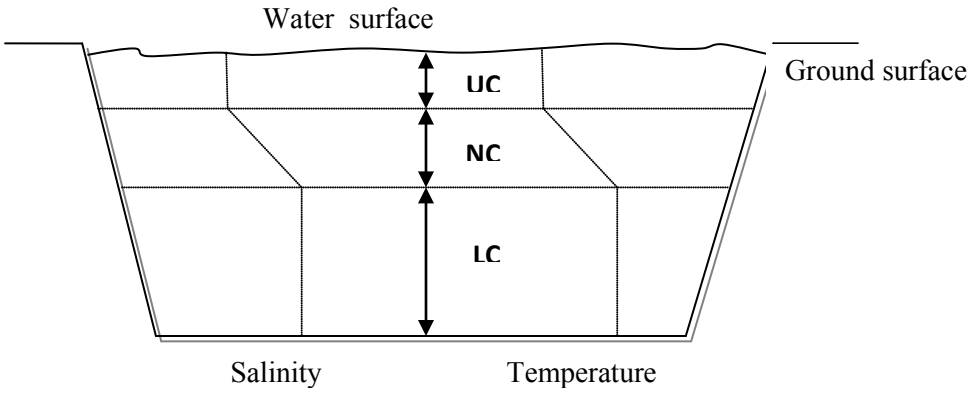

Fig. 1. Salinity and temperature profiles through the salinity gradient solar pond zones.

Non-convective solar ponds can provide heat for domestic, agricultural, industrial, power generation and desalination purposes. More details about solar pond c onstruction and limitation can be obtain from [1], [2] and [4].

2. Methodology

Solar irradiation data have been widely measured and recorded for almost every region in each country in the world for many years. Nevertheless, the predictions and calculations of the irradiation are sometimes required to obtain a good approximation of the irradiation.

According to a solar pond l ocation, the sun path in the sky is changed seasonally thus the sun's altitude and azimuth angle and the daily sunshine period are varied and cause a great effect on the amount of the incident solar radiation and then on the performance of the solar collector.

It is found that monthly averaged data are the most effective for representing the climate changes and calculations, since hourly and daily calculations and measurements are changed from year to another and are quite short to represent a general impression about the climate. In addition to this, seasonal and yearly readings cannot accurately represent the climate computations. Thus, averaged monthly measurements or computations have been adapted in this study.

Matlab computer software has been used to build a multi-scripts programme to solve ordinary differential equations by finite difference method for steady state models. This programme takes into account the changes of boundary conditions and surround factors with time.

This solar radiation computation program requires only a latitude value to predict sunrise, sunset and sunshine period to compute the solar radiation equations. A new predicted empirical equation has been added to this script to give a good agreement and it has been tested for three different locations in the middle east which are Kuwait, Riyadh and Jerusalem. The incident solar radiation values, based on m onthly average daily amounts can be obtained from the available references or the 22 years average values which are recorded in NASA website [6].

Since the earth-sun distance varies each season, the apparent extraterrestrial solar irradiation changes during the year. Therefore, the solar irradiation intensity depends on t he number of the day in the year. The average daily extraterrestrial solar irradiance is given by

$$I_o = I_{sc}\left[1 + 0.0033\cos\left(\frac{360N}{370}\right)\right] \qquad (1)$$

Solar constant (Isc) value has been measured by many researchers since the beginning of the 20th century. Abbot [7] and his team in Smithsonian Institute after many research proposed the value of 1353 W/m^2 to be the value of the solar constant. Many further investigations were made on ground-base and high altitude measurements and eventually 1353 W/m^2 has been accepted to be the standard for the solar constant. NASA, after many measurements on the space, has recommended this value as well [8]. It has very recently been published in NASA's

website that the generally accepted value of the solar constant is 1368 W/m^2 as a satellite measured yearly average, which is close to the standard value.

The total daily extraterrestrial radiation on a horizontal surface can be computed by

$$H_{oT} = \frac{I_{od}}{\pi}\left[\cos\theta\cos\delta\ \sin\omega_s + \frac{2\pi\omega_s}{360}\ \sin\varphi\sin\delta\right] \qquad (2)$$

Where I_{od} is daily total direct normal extraterrestrial radiation and can be obtained by yielding the value of extraterrestrial radiation solar irradiation throughout the day as the following

$$I_{od} = 24I_o \qquad (3)$$

To use these equations for computation of the monthly daily-average total extraterrestrial radiation on a horizontal surface $\bar{H}_{oT}$, the month representative-day is needed and given by lunde[9] in addition to other useful equations in solar radiation calculations. The new empirical equation which works with available solar radiation equations to estimate the solar radiation based on a single input parameter is

$$IBF = \frac{1.5\varphi - 14.25}{\varphi}\ Fc \qquad (4)$$

Where Fc is a predicted monthly correction factor validated accurately for the Middle East with NASA published date and the above equation can be utilized in the following formula;

$$\bar{H}_T = IBF(\bar{H}_{oT}) \qquad (5)$$

Eq(5) is a well known formula in the solar radiation equations which are expansively explained in [9] based on the cloudiness (or clearness) index, however, the index here is substituted by the predicted factor ,IBF, which is obtained by linking the field solar radiation data with longitudes in a special computer programme.

The steady state model for a solar pond has been widely adopted by the most famous researchers in the SGSP field such as Weinberger [10], Rabl and Nielsen [11], Kooi [12], Ali [13], Wang and Akbarzadeh [14] and many of other researchers. A downward one-dimensional flux model is often used for simplification purposes. The convective zones (upper and storage layers) are assumed to be well thermally mixed i.e. lumped systems. The upper layer steady state equation is:

$$\rho_u\, C_{pu}\, A\, x_u \frac{dT_u}{dt} = Q_{sru} + Q_{ub} - Q_{uc} - Q_{ur} - Q_{ue} \qquad (6)$$

The gradient layer is considered as a conduction slab and all absorbed solar radiation is consumed in building and maintaining the temperature profile in this layer. The storage zone steady state correlation will be

$$\rho_s\, C_{ps}\, A\, x_s \frac{dT_s}{dt} = Q_{srs} - Q_{st} - Q_{sb} - Q_{sw} - Q_{se} \qquad (7)$$

More details about each parameter in Eq(6) and Eq(7) are given by Lunde[9], Rable and Nielson[11] and Ali[13].Model validation is possibly the most essential step in the model building stages. In this study, the model validation is applied to Ali's study in Kuwait [13].

3. Results

The single input program is used to calculate the solar radiation in Kuwait, Riyadh and Jerusalem. The output of this script is compared with NASA average 22 year measurements data and the results are really good and shown in Fig. 2 for Kuwait, Fig. 3 for Riyadh and Fig. 4 for Jerusalem solar radiations.

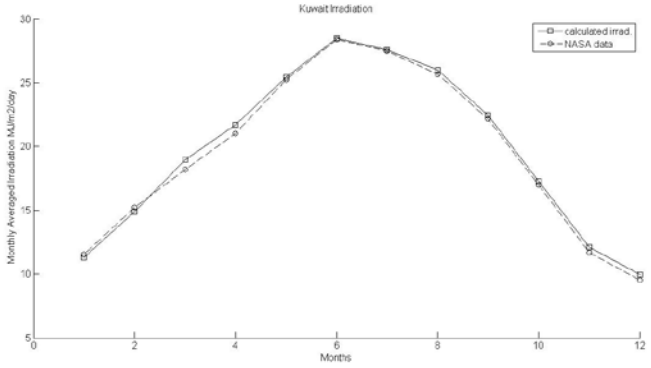

Fig. 2. NASA data and calculated solar irradiation for Kuwait.

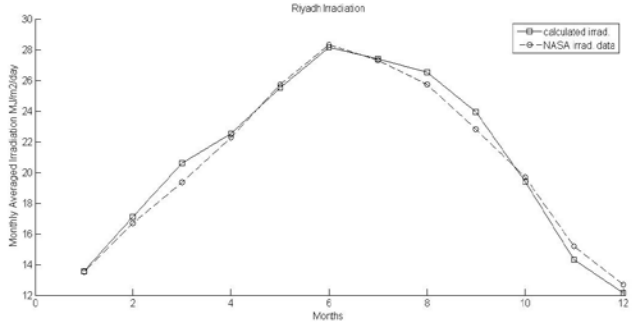

Fig. 3. NASA data and calculated solar irradiation for Saudi Arabia, Riyadh.

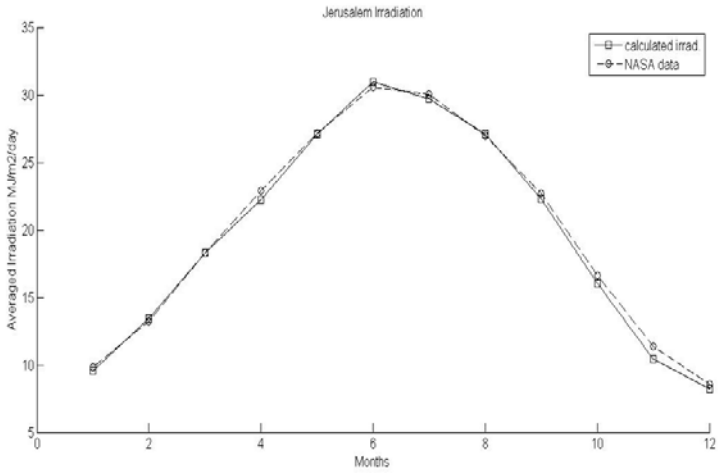

Fig. 4. NASA data and calculated solar irradiation for Jerusalem.

The obtained solar radiation data is used for one-dimensional time-dependent steady state program to predict the solar pond temperature behaviour in the storage zone during a year and an excellent agreement is obtained comparing with real temperature measurements by Ali [13] and this output and measured data are illustrated in Fig. 5.

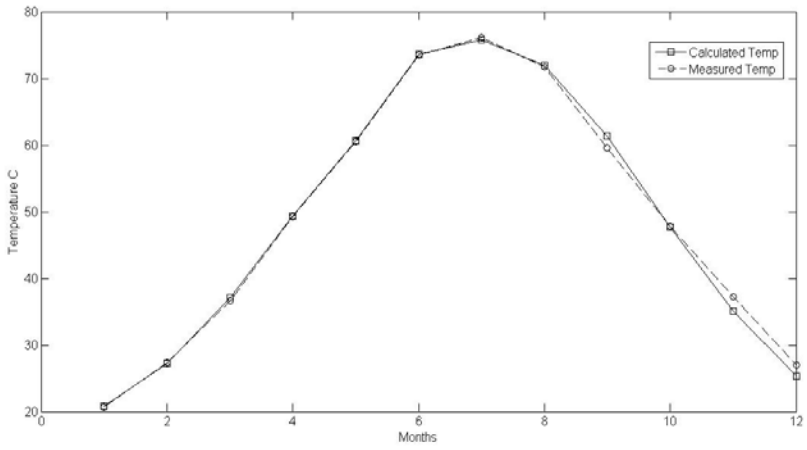

Fig. 5. Measured and calculated storage zone temperature in Kuwait solar pond.

The program can predict the performance of a solar pond in a cold climate location and for this purpose the University of Surrey in the UK has been chosen. The result is plotted in Fig. 6 and the storage zone temperature behaviour can be improved by changing the depth of the solar pond layers to reach 80 ^{o}C .

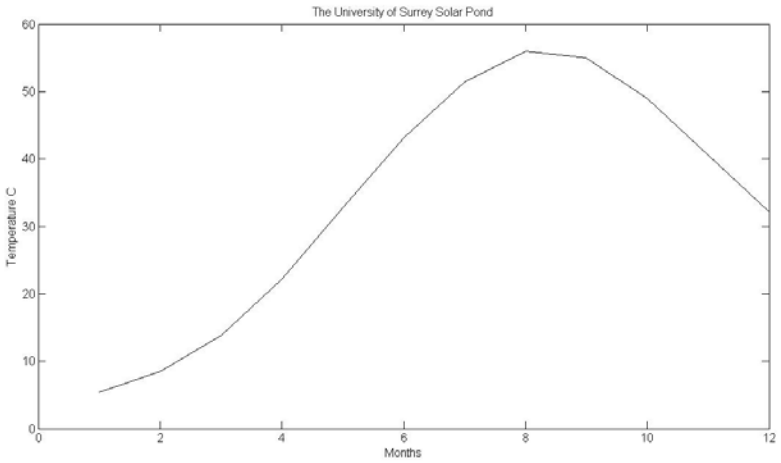

Fig. 6. Surrey storage zone(1m) temperature at 1m depth of gradient zone.

4. Conclusions

The proposed method provides an accurate prediction of the solar radiation based on a single input data which is the location latitude. The predicted results are validated by comparison with NASA 22 years averaged data in three various locations in the Middle East, where very close agreement has been obtained. The one-dimensional time-dependant steady state model has shown excellent agreement with Kuwait solar pond m easurement data. The transient model was investigated as well. However, it was found that the steady state model provided more realistic results. The solar pond performance in cold climate locations such as the UK has been studied and the pond temperature can reach 80 ^{o}C levels using some designs.

Abstract: The potential of renewable energies varies significantly from North to South Europe. Southern Europe has a high solar potential and is ideal for the implementation of solar concentrated power plants. To this group of solar thermal power systems belong the solar tower, parabolic trough, solar dish and linear Fresnel systems. North European countries, especially the Scandinavian countries, have a high biomass and hydropower potential. This paper focuses on calculation of the power production for hybrid systems of solar tower with gas turbine in Southern Europe and biogas-only operation in Northern Europe.
The solar tower system consists of a heliostat field, which concentrates direct solar irradiation on an open volumetric central receiver. The receiver heats up ambient air to temperatures of around 700°C. The hot air's heat energy is transferred to a steam Rankine cycle in a heat recovery steam generator (HRSG). The steam drives a steam turbine, which in turn drives a generator for producing electricity. In order to increase the operational hours of a solar tower power plant, a heat storage system and/ or hybridization may be considered.
The advantage of solar-fossil hybrid power plants, compared to solar-only systems, lies in low additional investment costs due to an adaptable solar share and reduced technical and economical risks. On sunny days the hybrid system operates in a solar-only mode with the central receiver and on cloudy days and at night with the gas turbine only. As an alternative to methane gas, environmentally neutral biogas can be used for operating the gas turbine. Hence, the hybrid system is operated to 100% from renewable energy sources.
An advanced software tool library has been developed for modelling such solar hybrid power plants. This library includes the components of the solar-heated hot gas cycle and the steam cycle. Moreover, a choice of different gas turbine and duct burner components is given. When developing a simulation model for the calculation of a small hybrid power plant, components from the library are inserted into the model. The software tool features the possibility of either calculating the energy output of individual operating points or of time intervals in the range of days up to an entire year.
With this simulation tool, hybrid solar tower systems are calculated for various locations with high solar potential within Europe. In addition, locations in North Scandinavian countries with high biomass potential are investigated and power plants with biogas as fuel without solar input are calculated.

Keywords: *solar tower, central receiver, hybridization, biogas, renewable energy*

1. Introduction

The potential of renewable energies varies significantly from North to South Europe. Southern Europe has a high solar potential and is ideal for the implementation of solar concentrated power plants. North European countries, especially the Scandinavian countries, have a high biomass and hydropower potential.

Since 1980s, power production with solar thermal power plants and the increasing use of biogas has been a promising option for reducing the consumption of fossil fuels.

The development of solar thermal technologies has gone into many directions, which can be exemplified with the various heat transfer media that are deployed in existing systems. Many solar thermal power plants contribute to the electricity generation in various European countries. To this group of solar thermal power plants belong the solar tower, parabolic trough, solar dish and linear Fresnel systems. Parabolic trough and solar tower systems are the most developed technologies as well as the most economical solar thermal plants at this moment of time.

A solar tower consists mainly of a heliostat field, a central receiver and a conventional steam Rankine cycle. Various central receiver technologies have been developed throughout the world. The software tool described in this paper models a solar tower with a open volumetric receiver. This type receiver has been deployed in the Solar Tower Jülich (STJ), Germany, since its completion in 2008. The subsequent explanations are valid for this type receiver only. At the STJ, the heliostat field, a field of sun-tracking mirrors, reflects and concentrates the direct solar irradiation onto the open volumetric receiver. This receiver consists of porous ceramic absorber modules. Incident sun rays enter the porous receiver, are absorbed inside and heat it up. To remove the heat, ambient air is continuously sucked through the porous receiver and is heated up to almost 700°C. The hot air is passed through a heat recovery steam generator (HRSG) in which it passes its heat to a water-steam cycle. The steam is expanded in a steam turbine and the rotation of the turbine's shaft drives a generator to produce electricity. Utilization of air as heat transfer fluid (HTF) secures a high plant efficiency due to the reason that air can be heated to very high temperatures, which in turn enables higher steam temperatures in the Rankine cycle and thus a better Carnot efficiency. Moreover, it allows a fast start-up to operating conditions; it is non-toxic and is available at no costs in unlimited amounts.

In order to increase the operational hours of a solar tower power plant, a heat storage system and/ or hybridization e.g. with biofuels must be considered.

As an alternative to methane gas, environmentally neutral biogas can be used as fuel for operating a gas turbine. Hence, the hybrid system is operated to 100% from renewable energy sources. The gas turbine not only delivers electricity but also heat in the waste gas, which can be reused.

2. Methodology

This paper focuses on the calculation of different important characteristic quantities, which include the annular power production, the solar share and the annual fuel consumption. The combination of two renewable technologies, namely biogas and solar concentrated energy, is investigated. Therefore the operation of a hybrid system consisting of a solar tower power plant and biogas-fuelled gas turbine is investigated.

2.1. Considered technologies

2.1.1. Solar tower plant

Germany's first solar tower power plant, which has a rated power output of 1.5 MW_e, was constructed and completed in 2008 in the town of Jülich [1]. It commenced solar operation in spring of 2009. The plant was built by the general contractor Kraftanlagen München and is operated by the local utility Stadtwerke Jülich. The Solar-Institut Jülich (SIJ) and the German Aerospace Center (DLR) conduct the accompanying research. The project is funded by the economic ministries of the German states of Northrhine-Westphalia and Bavaria, as well as by the German Federal Ministry for the Environment, Nature Conservation and Nuclear Safety.

The objective of the power tower project in Jülich is to demonstrate the entire system in commercial-like operation over a longer period of time, to develop control and plant management strategies and to further improve performance and reliability of the key components. Jülich was chosen as the favoured location because it is situated close to the involved research institutions and due to its fluctuating direct solar irradiation conditions. The latter reason has the advantage that it allows and requires the investigation into the system

operation strategy under transient conditions, especially with regard to optimizing the charging and discharging process of the thermal storage [2].

2.1.2. Biogas

Biogas is produced by the biological breakdown of organic matter in the absence of oxygen. It can be produced by anaerobic digestion or the fermentation of biodegradable materials such as biomass, manure or sewage, municipal waste, green waste and energy crops. Biogas is composed of 45-85% methane and 15-45% carbon dioxide, depending on the conditions during production. Moreover, biogas comprises small amounts of hydrogen sulphide, ammonia and nitrogen. Its field of application includes combustion engines, burners as well as gas turbines for electricity generation and co-generation of heat and power. Biogas can be further enhanced from low-quality to natural gas quality before it is fed in the public gas grid. This article considers biogas-fuelled gas turbines only.

2.1.3. Biogas potential

In all Scandinavian countries, biomass has a high potential. In the TRANS-CSP study [3] the theoretical potential of biomass is estimated for Norway at 26 TWh/a, for Sweden at 80 TWh/a and for Finland at 54 TWh/a.

Taking Sweden as an example, the country has approximately 233 biogas facilities with a total biogas production of 1.3 TWh/a [4]. Biogas can be produced at large-scale centralized plants, where different feed stocks materials are digested, and at small farm-based plants, which use and digest mainly agricultural feed stocks.

The theoretical potential of biogas production in Sweden lies at around 14-17 TWh/a, which is more than 10 times that of the present annual production [5]. From the feed stocks materials 70% is manure and farm waste, 13% is industrial waste, 9% is household waste and the remainder is garden waste and sewage sludge.

For Italy, the best biogas performance is recorded in the northern part of the country especially in the regions of Lombardy, Emilia Romagna, Trentino A.A, Veneto and Piedmont. With a share of 23.8%, the region of Lombardy is the biggest producer of biogas in Italy and dominates the biogas market. Moreover, Lombardy has the biggest biogas potential, which is estimated at 4,643 GW. As for the production of biogas from manure, 3,800,000 pigs and 1,600,000 heads of cattle were counted for the region of Lombardy in the ISTAT census in 2001. Together this amounts to 44% of the total domestic animal breed in Italy [6].

2.1.4. Hybrid system

To improve the availability and the capacity factor of a solar tower power plant, a hybridization of the plant is considered. In regions with very high irradiation, solar thermal power plants with heat storage facilities can reach a maximum of 3,000 to 4,000 nominal load hours per year. Hybridization, for example with the combustion of biogas, enables the operator to produce electricity day and night for up to 8,600 hours per year. It is expected that such hybrid power plants will have a high potential for the market introduction in the next decade.

The upgrade of a solar tower power with air receiver technology to a hybrid system by combining it with a gas turbine is shown in Fig. 1.

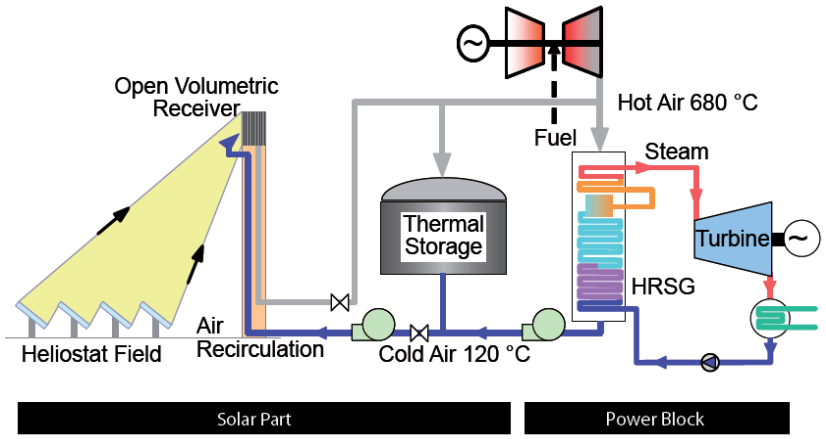

Fig. 1: Schematic diagram of a solar tower demonstration plant hybridised with a gas turbine

The operating strategy for the hybrid plant involves an alternating operation of the gas turbine and the air receiver. On sunny days the air receiver is operated in a solar-only mode. On days with very low direct solar irradiation (very cloudy conditions) the thermal energy provided by the heliostat field is not sufficient for operating the plant. On those days the gas turbine must be operated. The hot exhaust gas from the gas turbine is directed through the heat recovery steam generator (HRSG) for steam generation [7]. Throughout the nights, solely the gas turbine is operated.

2.2. Simulation

2.2.1. Implementation of the model

The implementation of the solar tower power plant model has been realised in the MATLAB/Simulink environment. MATLAB is a high-performance language for technical computing. It integrates computation, visualization, and programming in an easy-to-use environment, where problems and solutions are expressed in familiar mathematical notation. Simulink is a toolbox in MATLAB that provides an environment for modelling, simulating, and analyzing dynamic systems. It supports linear and nonlinear systems, modelled in continuous time or a sampled time. The implementation of systems can also occur at a multi-rate, i.e. have different parts that are sampled or updated at different rates [8].

2.2.2. Model library

The simulation models are based on thermodynamic theory using assumptions for simplification in order to maintain a fast simulation time while retaining good accuracy. Several components like the steam turbine, generator, burner, solar receiver, heliostat field, etc. are included in the model library. They include mostly energy and mass balance equations as well as additional algebraic equations. Most components models are optimized for steady-state operation. However, components with high thermal inertia, such as a part of the HRSG, are implemented as dynamic models.

The model library (Fig. 2) was developed with consideration of the following characteristics [9]:

- compatibility of the components related to the connection of one to the other
- possibility of choosing different geographical locations for performing the calculations
- applicability for different power plant sizes
- adjustability to different transport media: e.g. air, gas, exhaust gas

- ease of modification
- usability for short time intervals (minutes)

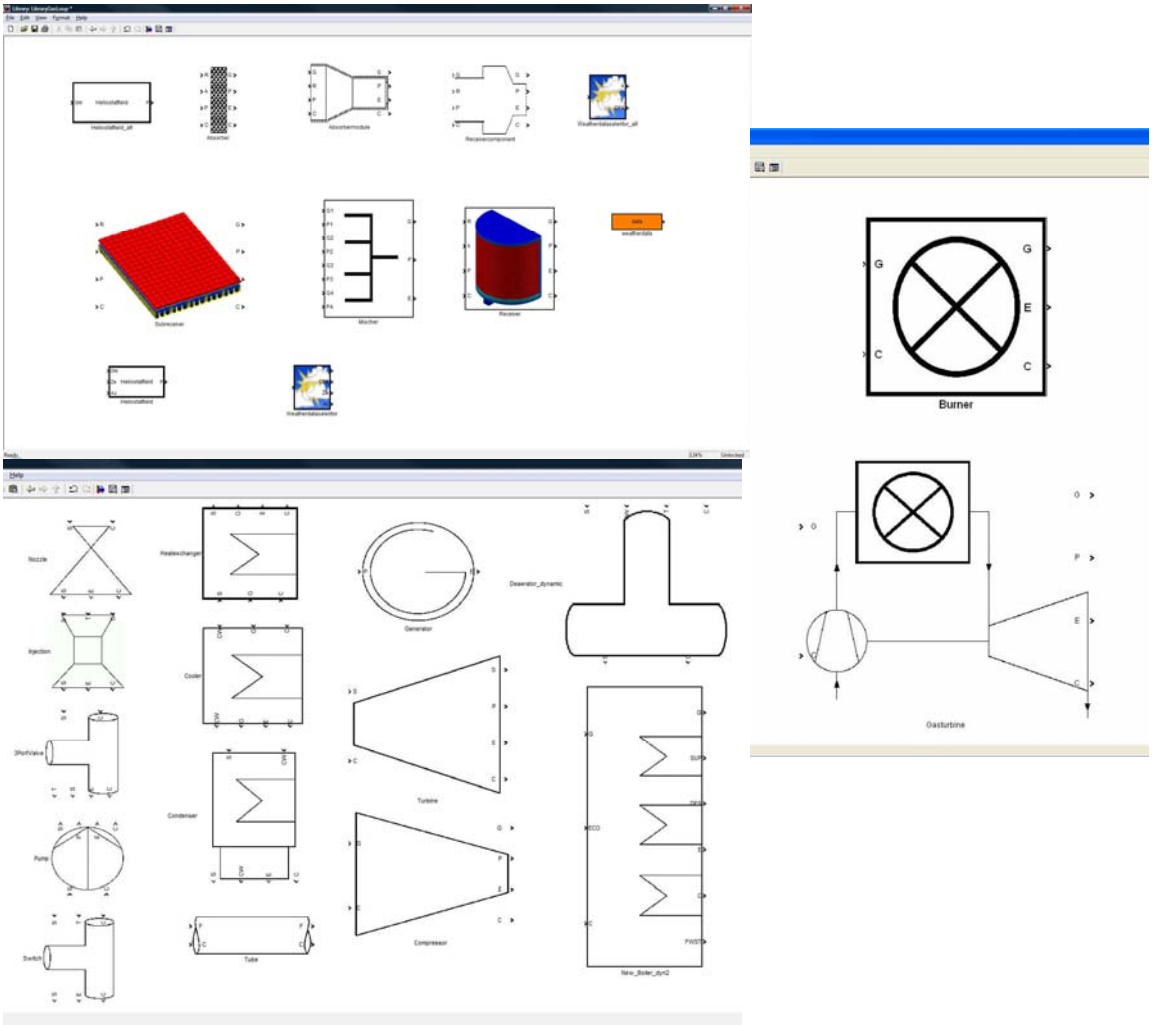

Fig. 2: Model libraries for the steam cycle, the solar and hybridization components

Gas and steam properties can be integrated in each model. The various state variables for water and steam are computed with polynomials taken from the industry standard IAPWS-IF97. For calculating the state variables for different gas mixtures, algorithms stated in the VDI (Verein Deutscher Ingenieure - engl.: Association of German Engineers) guideline 4670 [10] and provided by NASA Technical Memorandum 4513 [11] are integrated.

With the developed software, the annual performance and the electrical power output of small solar hybrid tower plants, combined cycle with gas turbine and solar-only operated solar tower with or without storage can be calculated.

2.2.3. Validation of library components

The components of the model library were validated mainly with calculation results of other simulation software [12]. They were also verified with results from different design points. The three thermodynamic cycles, namely the steam, air and water cooling cycle, were tested separately before they were combined to a complete power plant system.

3. Results

A comparison of energy production and fuel consumption was made for a combined-cycle plant in Sweden and a hybrid solar tower power plant located both in Jülich and North Italy. The combined-cycle plant in Sweden was taken as reference. It operates with a gas turbine, which utilizes biogas as fuel. The selected gas turbine is a Centrax 501-KB3 [13], which generates a nominal power of 2.68 MW_e. The hot exhaust gases are directed through a boiler for steam generation. In the steam cycle, the steam is expanded in a steam turbine. The generator, which is driven by the steam turbine, produces an additional 1.34 MW_e.

For all states and power plants, the biogas is composed of 56% methane, 40% carbon dioxide and other constituents. The configurations and main simulation parameters are shown in Table 1.

Table 1. Main simulation parameters

Place	Scandinavia	Jülich	Northern Italy
Nominal Power GT [MW_e]	2.68	2.68	2.68
Nominal Power ST [MW_e]	1.34	1.50	1.50
Heliostats [-]	0	2,150	2,150
Mirror area [m²]	-	8	8
Maximum air/flue gas temperature [°C]	571	680	680

Original weather data has been used for the locations Jülich and Milano (Italy). For Jülich, data from the year 2007 in a time resolution of 15 min was integrated. For Milano, data of the year 2006 in a one hour resolution has been used. The quasi-steady-state simulations are computed in time steps of maximum 60 seconds. The steam turbine and generator of the steam cycle for both locations have a generation capacity of about 1.5 MW_e. For the hybrid mode, the same gas turbine as simulated for the combined-cycle plant in Sweden (2.68 MW_e) was integrated.

The calculation for the location in Scandinavia (Sweden) was performed for a nominal plant operation with 8,760 hours of gas turbine operation. For the hybrid solar tower power plants, the calculation was realized with alternating operating mode. Hence, in the solar-only mode, nominal parameters could not always be reached. The results presented in Table 2 have an estimated error of about ±10%.

Table 2. Simulation results for the three sites.

Place	Energy Production [GWh]	Fuel Consumption [t]
Scandinavia	35.21	20,385
Jülich	25.17	14,004
Northern Italy	21.30	11,761

The results show that a Conventional Combined Power Plant in Scandinavia generates the estimated energy of 35.21 GWh at a fuel consumption of 20,385 t. The hybrid solar tower power plants instead produce less electrical energy, because only the steam turbine generates energy in daytime. Thus again means, that also less fuel is consumed. The difference between the two locations Jülich and Italy reflects this coherence. Locations with high insolation are associated with the less fuel consumption and less electricity production. This effect occurs if an alternate hybrid operation is considered.

In Fig. 3, which shows a good day regarding solar radiation (DNI), a typical operation of the hybrid plant in alternate mode is illustrated. The specific electrical (index EL) power of the steam turbine resp. gas turbine are shown. Furthermore, the thermal (index TH) power of the receiver (index Rec) and the heat input at the HRSG (index HRSG).

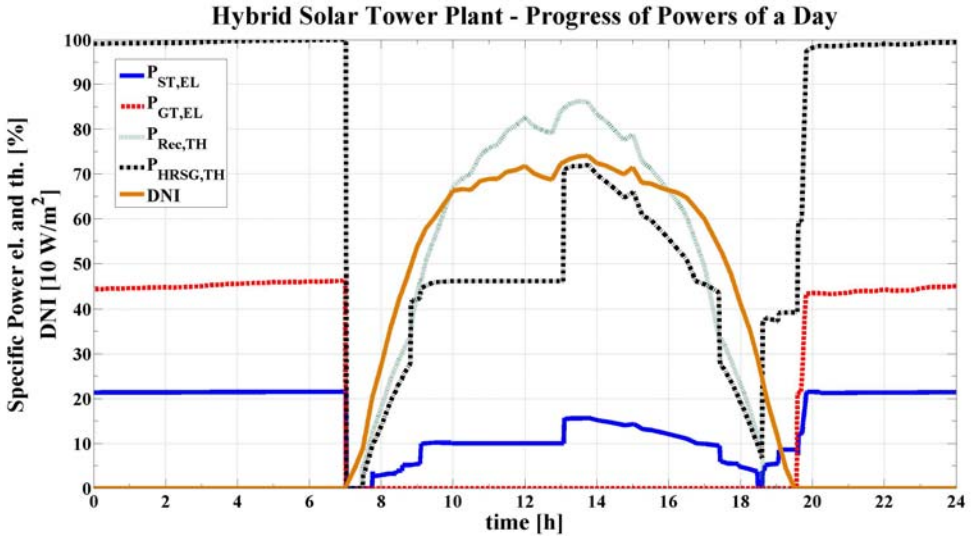

Fig. 3: Hybrid solar power tower plant operation for the 27th March 2007

At night the gas turbine provides continuous electricity and heat to the HRSG, so that a combined-cycle operation is conducted. When solar irradiation increases the gas turbine is shut down. Because of the clear switch to solar operation the electricity generation by the steam turbine may diminish. When solar radiation increases the electricity production increases, too. At a certain stage, by the receiver produced heat is send to the storage. The heat input to the HRSG is kept constant. When the storage is charged to a certain level, the charging is terminated and the full heat input is provided by the receiver (cf. fig 3. Jump at 13 h). When the sunset starts the storage is discharged slowly and the heat for the HRSG is supplied by the storage. In the evening the shift from storage operation to gas turbine operation is executed. This demonstrated operation strategy needs still optimization to ensure a maximum yield of power production and a continuous operation. Therefore weather dependent operation strategies and controlling has to be developed.

4. Discussion and Conclusions

Numerical procedures should be applied for the calculation of the annual energy yield of solar tower power plants. With the simulation tool, hybrid solar towers at different locations with high solar potential in Europe are calculated. Moreover, locations with high biogas potential in North Scandinavian countries are considered and power plants with biogas as fuel without solar input are investigated. The results of the simulation analysis show that the created model library is a solid basis for the simulation of hybrid concepts for solar tower systems.

In next steps a detailed investigation and analysis of the simulation results is planed. The simulation models and especially the operation strategies will be optimized in order to get even more accurate results.

In further steps an additional site in South Europe, for example in South Italy on the island of Sicily, will be investigated. For that reason weather data will be selected and a solar-only operation of a solar tower power plant will be regarded.

Acknowledgments

The authors gratefully acknowledge the financial support of the German Federal Ministry for the Environment, Nature Conservation and Nuclear Safety (BMU), the ministries of economic affairs of the German states of North Rhine-Westphalia (NRW) and Bavaria in the solar tower demonstration project. The research into hybridization is supported by the German Federal Ministry of Education and Research (BMBF).

Abstract: The present study intends to develop building-integrated solar collector (BISC). The storage tank inside is designed in multi-function. BISC combines the solar collector and the water storage tank together with one face acting as the solar absorber. A double-glazing design is adopted to reduce the heat loss. A PC-based automatic operating system is designed and built to monitor the long-term performance of the BISC system with 8 collector units. Hot water discharge is controlled from 18:00 until 22:00 to simulate the hot water load of a family. The discharge rate is at 60 L/hr. A 30 L backup electric water heater was connected to the BISC system. The long-term test results in winter season show that about 50 % energy saving was achieved in clear days. The monitored results have also shown that the daily-total solar irradiation on a 75° tilted surface (the BISC installed angle) is higher than the horizontal surface, about 40-50 % higher at Ht > 10 MJ/m^2day. This assures that BISC will produce more hot water in winter. This proves that the use of BISC as parapet or sun-shading canopy of a building (installation angle > 75°) is technically feasible. The characteristic efficiency of the installed BISC with different colors is 0.34-0.39.

1. Introduction

The solar building involves advanced solar collector technology for heating and hot water supply. Our research intends to develop a building-integrated solar collector (BISC) as parapet or sun-shading canopy of a building, Figure 1.1. BISC has a dual function of solar utilization and building constructing material, which can greatly reduce the cost.

As part of the building constructing material, the design of BISC needs to consider the thermal performance, the mechanical strength, installation method on building, and outlook. We focus on the research of the thermal performance including heat utilization efficiency of hot water and the heat insulation of the front side.

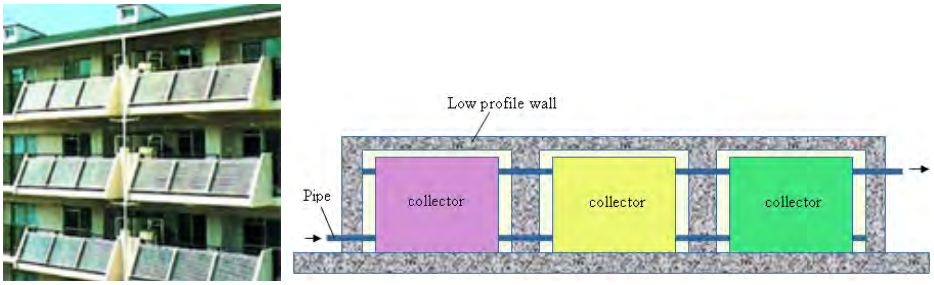

Fig. 1.1 BISC for parapet or sun canopy of a building

We have developed the first generation product of BISC. The special design features of BISC include:

1) Color glass cover: BISC uses the color glass cover in order to be compatible with building. It will match the architecture appearance by choosing the glass color.
2) Modular design: The solar water heater is designed as a module and easy to install. It only needs to fix on the wall or the ground and connect the water supply lines.
3) Multi-function water storage tank: The BISC combines the solar collector and the water storage tank together. It combines the solar collector and the water storage tank together. One surface of the water storage tank is the solar absorber which absorbs solar energy and directly conducts to the water inside the storage tank.
4) Double air-layer insulation: The BISC has a double-layer insulation, with two air gaps in front of the collector. This can reduce the heat loss.

2. Methodology

Design of BISC

The design specification of the BISC unit is as follows:

- outside dimension: 100cm x 70cm x 20cm
- solar absorber dimension: 90cm x 60cm
- storage tank: 90cm x 60cm x 7.5cm
- water storage: 40 liter
- glazing: 2 layers, 4mm color glass + 6mm PC
- glass color: clear, ocean blue, French green
- front double air layer insulation: 3cm/3cm
- heat exchanger: PC 6mm, 60cm x 90cm, 3 rows, 3.2m^2

There were 8 units of BISC were installed in the building for demonstration and field test. Figure 2.1 is the 3D drawings of BISC. Figure 2.2 is the real BISC. Figure 2.3 is the building installation of BISC.

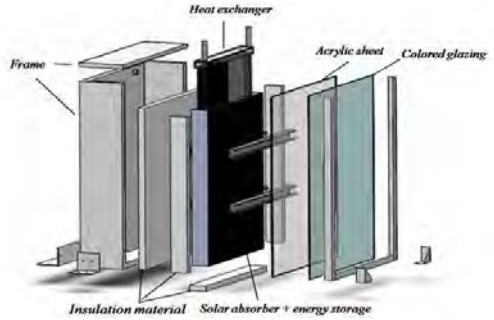

Fig. 2.1 3D drawings of BISC.

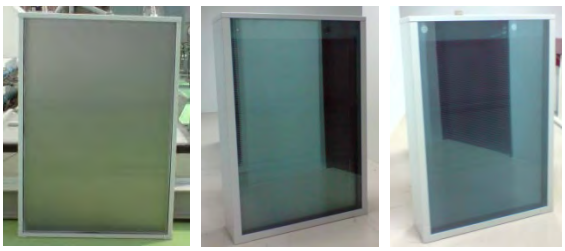

Fig.2.2 Color glass: clear, green, blue.

Equations (1) and (2) are used to determine the daily-total thermal efficiency of BISC (equation 1) and heat removal efficiency (equation 2):

$$\eta=\alpha_o - U_s \frac{T_i - T_a}{H_T} \quad (1)$$

$$\eta_{dc}=\frac{\int_0^{\tau_f} m_e C_p [T_e(t) - T_{Wi}]dt}{M_t C_p (T_{inital} - T_{Wi})} \quad (2)$$

The heat removal efficiency η_{dc} is defined as the ratio of the withdraw of total amount of useful heat compared to the total heat stored at sunset. Testing equipment for the measurement of daily-total thermal efficiency of BISC was designed and built in the research.

The equipment setups are shown in Figure 2.4. This testing equipment is automatic from early in the morning to sunset.

Design of a BISC system for a family

Design of BISC system automatic monitoring system

A PC-based automatic operating and control system is designed and built to monitor the long-term performance of the BISC system built in the research. The operating system (Figure 2.6) monitors the instantaneous performance of the BISC system all day. Hot water discharge is controlled from 18:00 to simulate the hot water load of a family. The discharge rate is 30 L at every 15 minutes with 15 minutes stop after each discharge until 22:00. That is, the discharge rate is at 60 L/hr. A 30 L backup electric water heater was connected to the BISC system. The temperature setting of the backup heater is 55 ^{o}C.

3. Results

3.1. Measurement of daily thermal performance of BISC installed in building

Daily-total thermal efficiency test at 75° tilt

The data collected from the BISC system installed in building can be used to analyze the thermal performance of BICS at the installed tilt angle (75°), using the testing standard CNS B7277 developed by Huang [1-5]. The daily-total thermal efficiency tests were performed for BISC installed at 75° tilted angle with different color glazing, all facing south.

The daily-total efficiency is calculated using the measurement of daily-total energy stored in the storage tank and the total solar irradiation. Figure 3.1-1~Figure 3.1-5 and Table 3.1-1 present the daily-total thermal efficiency of BISC. The test results show that the characteristic efficiency of BISC with different colors which are installed in building with 75° tilt angle is 0.34-0.39 which is lower than the conventional solar water heater (0.50) with clear glass and tilted at lower angle (25°).

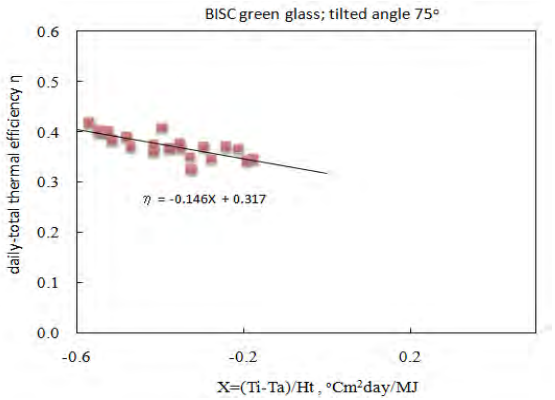

Fig. 3.1-2 Daily-total efficiency of BISC (green glass).

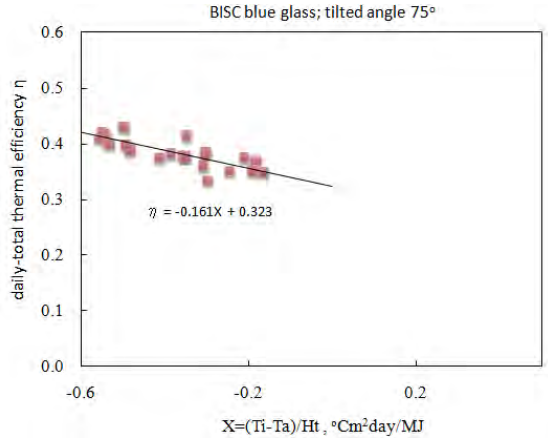

Fig. 3.1-3 Daily-total efficiency of BISC (blue glass).

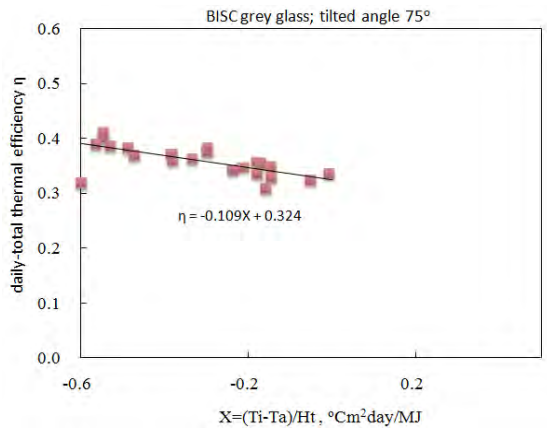

Fig. 3.1-4 Daily-total efficiency of BISC (grey glass).

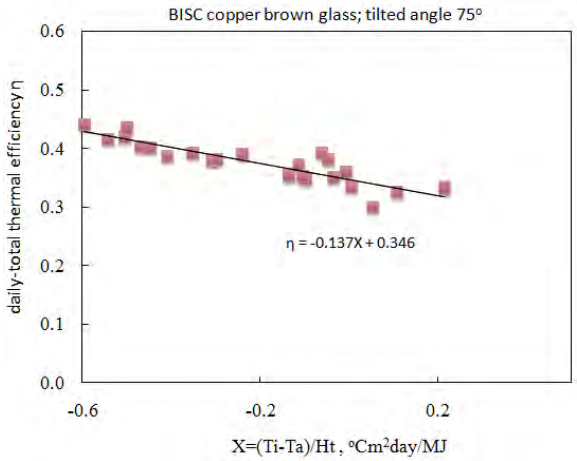

Fig. 3.1-5 Daily-total efficiency of BISC (brown glass).

Table 3.1-1 Test results of daily-total efficiency of BISC.

BISC facing South	U_s	α_o	η^*
Diffuse glass, tilted 75°	0.207	0.348	0.39
Green glass, tilted 75°	0.147	0.318	0.35
Blue glass, tilted 75°	0.161	0.323	0.35
Grey glass, tilted 75°	0.109	0.325	0.34
Copper-brown glass, tilted 75°	0.137	0.346	0.36

3.2. Long-term thermal performance test of BISC

The BISC system installed in building is tested by simulating the daily operation for a family. To estimate the energy saving of the backup electric heater, a baseline test was carried out to measure the daily energy consumption of the electric heater without using BISC. At daily solar irradiation 0.62 MJ/m^2 which is assumed as no s olar radiation (rainy, the daily electricity consumption is 11.1 k Wh. At daily solar irradiation 21.7 MJ/m^2 (the best weather), the daily electricity consumption is 4.0 kWh.

The first long-term performance monitoring is in winter season. Figure 3.2-1 shows the long-term monitoring results of BISC. It is shown that BISC can save 40 % to 50 % of electricity per day in winter. Figure 3.2-2 shows the variation of daily energy consumption and collected water temperature with solar irradiation in winter season. In spring season, the test results are shown in Figure 3.2-3 and Figure 3.2-4.

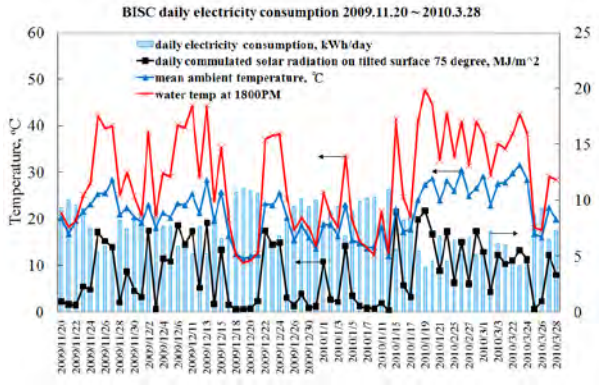

Fig. 3.2-1 Long-term monitoring results of BISC at Taipei 2009.11.20~2010.3.28.

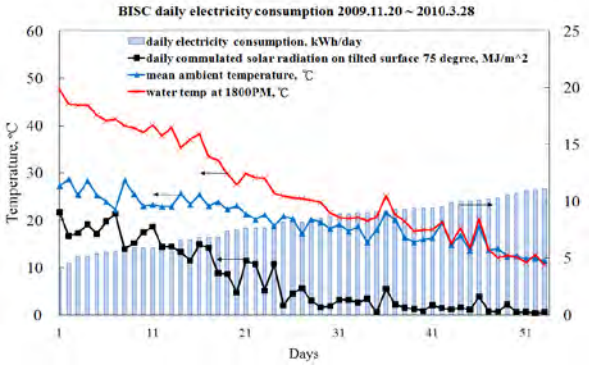

Fig. 3.2-2 Variation of daily energy consumption and collected water temperature with solar irradiation at Taipei 200911.20~2010.3.28

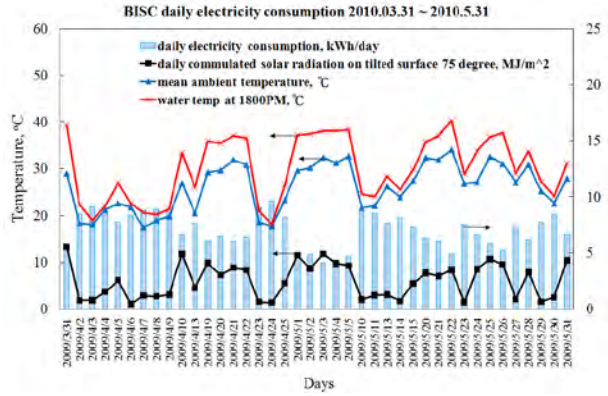

Fig. 3.2-3 Long-term monitoring results of BISC at Taipei 2010.3.31~2010.5.31

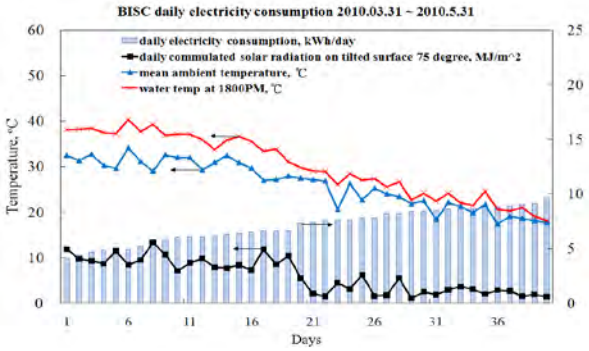

Fig. 3.2-4 Variation of daily energy consumption and collected water temperature with solar irradiation at Taipei 2010.3.31~2010.5.31

Figure 3.2-5 and Figure 3.2-6 shows the variation of daily-total solar irradiation on 75° and horizontal surfaces. The monitored results have also shown that the daily-total solar irradiation on a 75° tilted surface (the BISC installed angle in building) is higher than the horizontal surface, about 40-50 % higher at Ht>10 MJ/m^2day. This verifies that the use of BISC for parapet or sun-shading canopy of a building (installation angle > 75°) is feasible. In summer, it is expected that the solar irradiation on 75° surface will be less than the horizontal one and the heat collection efficiency will be lower. However, the hot water load in summer decreases about 50 % in summer. Therefore, the use of BISC as parapet or sun-shading canopy of a building is feasible.

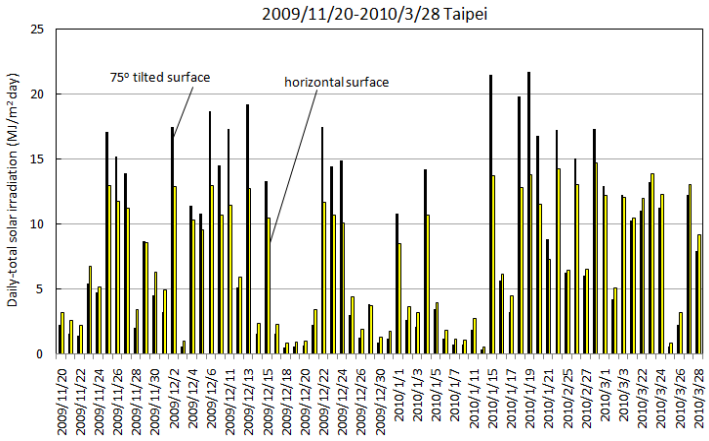

Fig. 3.2-5 Variation of daily-total solar irradiation 75° and horizontal surfaces.

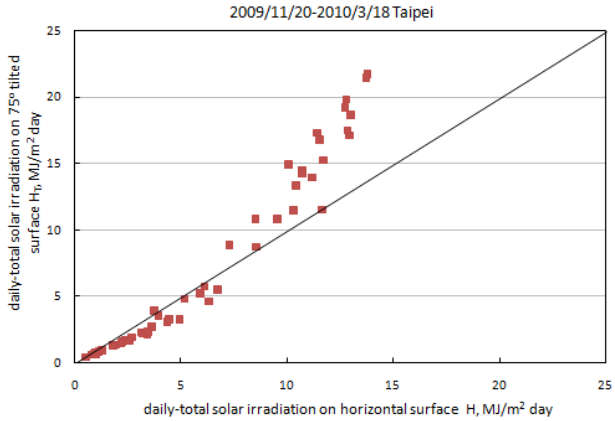

Fig. 3.2-6 Variation of daily-total solar irradiation on 75° and horizontal surfaces.

3.3. Heat removal efficiency test

The heat removal efficiency test is carried out to determine how much energy can be extracted from the tank rated at the total water extraction identical with the storage volume. With the Figure 3.4-1 By the equation (2), we can see the numerator is the real instantaneous removal heat (similar a trapezoid area), and the denominator is the total storage heat (rectangle area), then the heat removal efficiency calculate about 0.72.

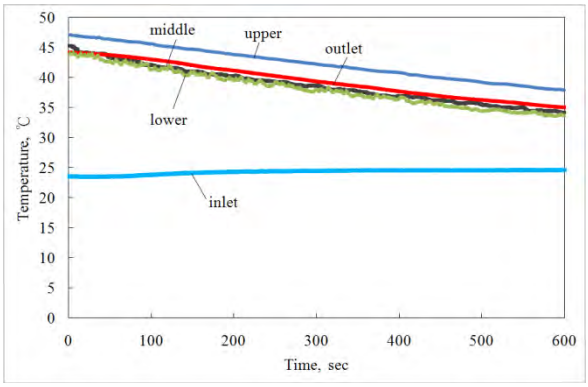

Fig. 3.4-1 Heat removal efficiency test.

4. Discussion and Conclusions

Our research intends to develop building-integrated solar collector (BISC). The BISC is designed to be part of construction material of a building. The storage tank inside is designed

in multi-function. BISC combines the solar collector and the water storage tank together with one face acting as the solar absorber which absorbs solar energy and directly conducts to the water inside the storage tank. A double-glazing design is adopted to reduce the heat loss. The outer transparent cover (glass) is made of color glass for architecture requirement. 8 units were installed on the roof of the lab at the Innovation and Incubation Center of NTU for field demonstration and test.

A PC-based automatic operating and control system is designed and built to monitor the long-term performance of the BISC system installed in the research. The system monitors the instantaneous performance of the BISC system all days. Hot water discharge is controlled from 18:00 to simulate the hot water load of a family. The discharge rate is 30 L at every 15 minutes with 15 minutes stop after each discharge until 22:00. That is, the discharge rate is at 60 L/hr. A 30 L backup electric water heater was connected to the BISC system. The temperature setting of the backup heater is at 55 ℃ which is fixed. The long-term test results in winter season show that about 50 % energy saving was achieved in clear days. The monitored results have also shown that the daily-total solar irradiation on a 75° tilted surface (the BISC installed angle in building) is higher than the horizontal surface, about 40-50 % higher at Ht>10 MJ/m^2day. This assures that BISC will produce more hot water in winter. This proves that the use of BISC as parapet or sun-shading canopy of a building (installation angle > 75°) is technically feasible. The test results show that the characteristic efficiency of BISC with different colors which are installed in building with 75° tilt angle is 0.34-0.39, lower than the conventional solar water heater (0.50).

The monitoring of long-term performance will be continued to find out the defects and efficiency of the system. Since BISC is part of the building, it needs a BISC with high quality in art design, high thermal performance, good manufacturing technique, and long service life (reliability). The reliability issue will be the focus of forthcoming research.

Abstract: The survey focuses on the passive solar schools units that have been built to date in Greece. It investigates on the one hand the bioclimatic principles applied to several school units with regard both to the building shell and the layout of the schoolyard area, and on the other hand the energy saving schemes that have been introduced to reduce energy consumption. This investigation is followed by a comparison with conventional schools in order to assess the economic and environmental benefits that the implementation of passive solar design bring to Greek schools.
The present survey relies on statistical data collected from passive solar design and conventional school buildings taking into account, among others, energy consumption, school building plots and implemented bioclimatic principles. Furthermore, in order to collect information about various issues and the cost of these new school units, the survey relies on personal interviews with staff members of the School Building Organization which is responsible for the construction of these schools.
The survey has shown that passive solar design used in the building of schools in conjunction with the installation of electronic control equipment to reduce consumption and the use of renewable energy, achieves a larger degree of environmental protection.

Keywords: *Passive solar design in schools, Save energy.*

1. Introduction

In Greece, school buildings, according to past interventions for energy saving and protection are divided into neoclassical buildings of the interwar period until 1950, school buildings built prior to the application of the General Building Rules (GBR)(1950-1980), school buildings constructed under the new implementation of the (GBR) (1979) [1] until 1998 when new measures were taken and terms were set to improve energy efficiency of buildings [2]. After Directive 2002/91/EC [3] of the European Union for the energy performance of buildings new measures were taken to reduce energy consumption in buildings, more specifically law 3661 [4], the Regulation of Energy Efficiency of Buildings [5] and law 3855 [6] in accordance with the directives of the European Union for energy saving.

Initially, the proposals for interventions in school buildings (from 1950 to 1980) refer to the closure of open corridors, to the insulation of the roof, replacement of window and door frames, the addition of RES, ventilation cooling and shading. Thermal bridges reduction was added to school buildings from 1980 to 1998 [7]. The bioclimatic design in school buildings was implemented on a pilot basis. Generally, the measures applied were thermal insulation, green roofs, and minimization of northern openings exposure during the winter,. On the other hand, during the summer, the measures applied were the minimization of western openings, shading and cross ventilation. Other passive systems such as solar atriums, skylights, cooling chimneys and soil pipes, were implemented [8].

Take into account that most schools have been built before the year 2000, it is shown that heat losses are much larger than those of school buildings constructed after 2000, which have implemented more stringent requirements for insulation and appropriate choice of materials.

Especially from 2007 and onwards, all schools in Greece are built in accordance with the principles of bioclimatic design related to both the architectural design and the choice of

location of the school. Also the extension of bioclimatic design in courtyards contributes more to the improvement of environmental conditions in schools and the better use of space and climate conditions.

In addition, the pilot application for the introduction of technology on energy saving systems in schools such as BMS systems, opens new horizons in energy saving.

Generally, the new design of schools, taking into account the bioclimatic principles both in the building shell and in the exterior space as well as energy-saving technologies in conjunction with the strictest standards for heat insulation, will contribute to good weather conditions with the minimum of energy consumption. The degree to which this new way of designing schools unit contributes to energy saving, will be analyzed below.

We note that the new standards for energy conservation should not be in conflict with bioclimatic design principles, but to complement them.

2. Methodology

First a reference to the policies implemented so far for the construction of schools in Greece is made. Next, the survey compares the fuel consumption between conventional schools and new schools with passive systems. Taking into account the thermal and climatic conditions in the region, the implementation or not of bioclimatic principles, an effort to estimate to which degree the use of passive solar systems can contribute to saving energy and protect the environment is made.

Thus, statistical data on the area and fuel consumption in selected schools are used in the survey. Also, the survey was supplemented with new data on the current policy for the construction of schools units. This information have been obtained through personal interviews of the directors of the School Building Organization, which is responsible for the construction of schools in Greece. The creation of maps is achieved by using data from Geographic Information Systems (GIS).

3. Results

The survey focused on schools units which are built according to the principles of bioclimatic design, as well as on conventional schools. Specifically, the research focused on the energy consumption for heating, taking into account the thermal, climatic conditions in the area and the buildings were designed.

From a survey made to the staff of the School Building Organization which are responsible for the construction of schools in Greece it is found that:

- Nowadays, the lack of suitable land in areas with increased urbanization, creates problems in the design of schools according to the principles of bioclimatic design.
- The old schools units need both maintenance and upgrading of heat insulation and sun protection.
- All schools built since 2007, and onwards follow the bioclimatic design principles, taking into account the location and orientation of the building. Techniques for sun protection, natural lighting, shading, natural ventilation (ventilation, traction phenomenon, solar chimney and cooling tower) and thermal insulation are applied. Green materials, wooden structures as well as green roofs and high planting are used (Fig. 1).
- Introduction of new insulating materials and automation programs for saving energy.

- Expansion of the use of natural gas in schools units in order to save energy and reduce emission of pollutants.
- Exploitation of strong sunlight via the use of photovoltaic systems. Due to good weather conditions and sunshine, in Greece, the design of school buildings different from those of northern European Union countries with different climatic conditions.
- Introduction of geothermal energy for heating and cooling in special school units, which are constructed for children with special needs, requiring greater energy consumption.
- Introduction of the new regulation on the energy performance of buildings in school buildings in order to obtain an energy building certification.

3.1. Schools units in Greece

New passive solar building constructed from 2007 onwards in Greece are presented in the following map (Fig. 1).

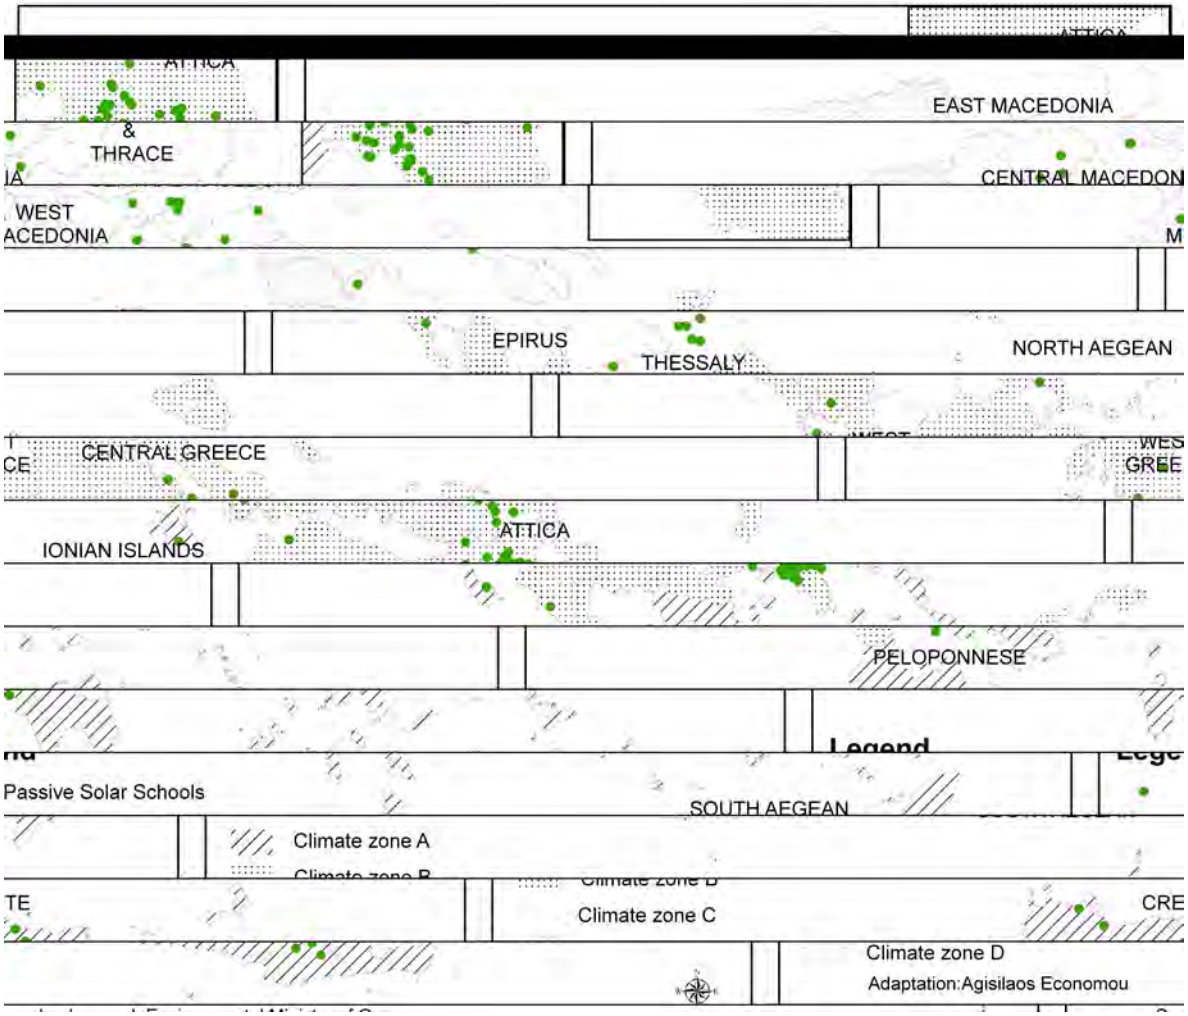

Fig. 1. Passive solar schools in Greece from 2007 up-today.

3.2. Schools units in Athens

As conventional schools, schools in Athens which are listed in the table below have been selected (Fig. 2), (Table 1). On the other hand, from the new modern schools the 6th Nursery school in Paleo Faliro, which is the first school designed with passive systems was selected. It features specific provisions for sun protection, shading, ventilation with carbon dioxide sensors to upgrade and clean the air, greenhouse and two green roofs.Also, it has lighting

control systems which take into account the sunshine outside and for heating, natural gas is used. Also a photovoltaic systems has been installed on the school for electricity production.

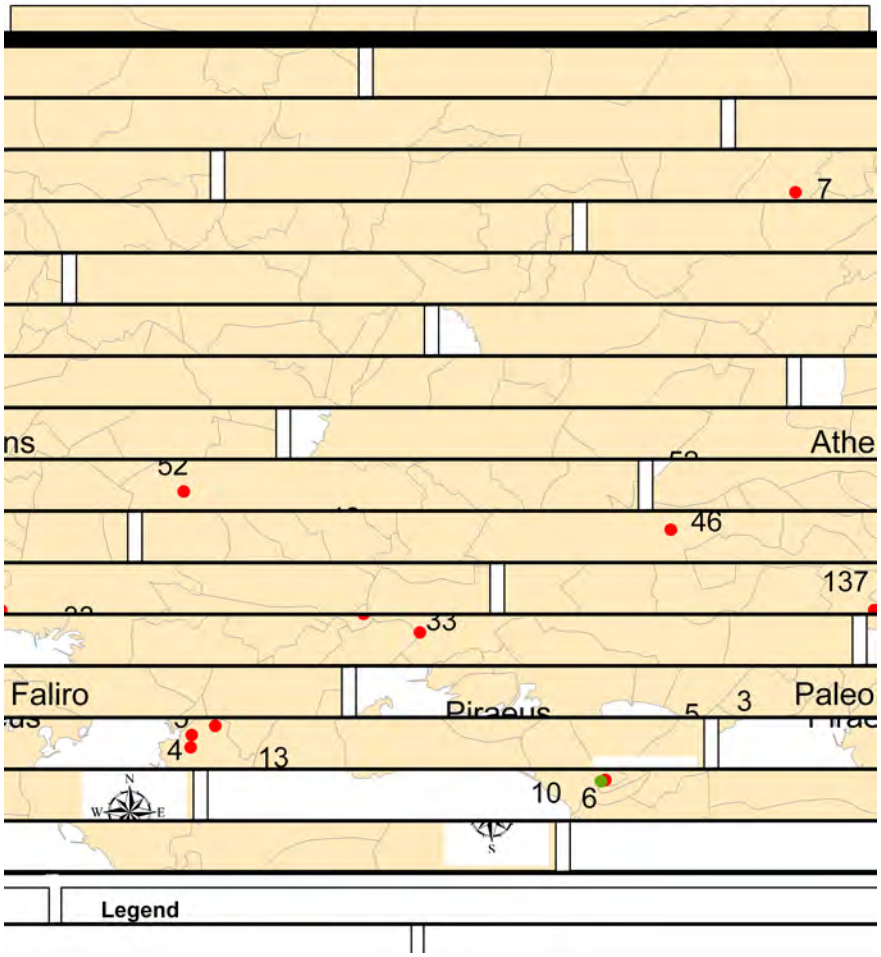

Fig. 2.Schools units in Athens

The survey found that in conventional school units there are different levels of consumption, depending on heat insulation and on the time period during which the boiler is operating for heating purposes.

In contrast in the 6st nursery school of Paleo Faliro (passive solar) a significant decrease in fuel consumption, compared to other schools in the same period was found.

Similar reductions were made to other schools in the past. For example, in the school unit of A. Kapon in Andros in 1989, which has an area of 513.5 m^2 with Tromble walls and 10 cm polystyrene insulation, the consumption was 12.36 Kwh/m^2. While in the school unit of I. Kalligeris in Rethymno in 1987, which has an area of 893.7m^2, through the use of greenhouses and shading, the consumption was at 6.73 Kwh/m^2.[8]. In other school units systems for solar gain, solar terraces, double glazing and others have been implemented.

Table 1. Use of natural gas for heating in school units in Athens during the period time 9/2009-8/2010 [9,10]

Schools units	**Year of construction**	**Total floor area (m^2)**	**Total volume of building**	**Consumption of natural gas (Kwh)**	**(Kwh/ m^2)**
46 High School of Athens	1917	2698.00	9421.00	70990.85	26.31
52 High School of Athens	1970	2714.45	9734.35	50091.29	18.45
7 Secondary of Metamorfosi	1980	1244.00	4552.00	62691.07	50.39
33 High School of Athens	1984	2451.07	12429.12	42235.80	17.23
5 High School of Paleo Faliro	1986	3835.80	7448.85	42012.18	10.95
13 Secondary of Paleo Faliro	1992	1896.24	7600.00	48663.39	25.66
3 Nursery of Paleo Faliro	1993	210.50	800.00	5444.56	25.86
137 Secondary of Athens	1993	1626.00	5962.00	36700.86	22.57
10 Secondary of Paleo Faliro	1995	1700.00	6652.00	38724.61	22.77
4 High School of Paleo Faliro	2000	3835.80	7448.85	21728.73	5.66
6 Nursery of Paleo Faliro	2005	600.20	2640.90	3063.00	5.10

Also, the use of natural gas in the schools units has further reduced the emissions of CO_2 in contrast to oil (Table 2)

Emission of CO_2, natural gas 0.20 kg/kWh, diesel fuel oil 0.26 kg/kWh) [11]

4. Discussion

Fuel consumption for heating of school grounds, varies depending on:

The climatic conditions of each region: Based on heating degree days and altitude, we have four climatic zones. From the hottest to the coolest (Fig. 1).

Heating time: The duration of the heating season ranged from 60 days to the region of Crete and reaches 210 days in the areas of Macedonia and Thrace [5].

Heat insulation: The heat insulation of buildings and the way of construction such as the orientation of the building, insulation of walls, floors and roofs, thermal insulation materials used and the use of openings.

Also, many schools and big complexes are attached to the operation of one boiler, which means that the above operation of a school or a department requires the operation of the boiler for more time as a result of which school units are heated unnecessarily.

Nowadays, in conventional schools interventions are made in order to increase the insulation during the winter and to ensure sun protection, ventilation and cooling during the summer months.

Table 2. Consumption in school units and emission of CO_2

Schools units	Consumption of natural gas[10] (Kwh)	Emission of CO_2 (ton) (if we used natural gas) (ton)	Emission of CO_2 (if we used oil) (ton)
46 High School of Athens	70990.85	14.19	18.45
5 High School of Paleo Faliro	50091.29	10.01	13.02
7 Secondary of Metamorfosi	62691.07	12.53	16.30
33 High School of Athens	42235.8	8.44	10.98
5 High School of Paleo Faliro	42012.18	8.40	10.92
13 Secondary of Paleo Faliro	48663.39	9.73	12.65
3 Nursery of Paleo Faliro	5444.56	1.08	1.41
137 Secondary of Athens	36700.86	7.34	9.54
10 Secondary of Paleo Faliro	38724.61	7.74	10.06
4 High School of Paleo Faliro	21728.73	4.34	5.64
6 Nursery of Paleo Faliro	3063	0.61	0.79

The above data shows (Table 1) that new schools planned in accordance with the principles of bioclimatic design and new energy saving measures, require less energy to operate than conventional schools.

In addition, the use of natural gas has reduced energy consumption due to the higher calorific value of gas compared to oil. Even the use of renewable energy sources in new school units it will contribute more to the protection of the environment.

5. Conclusions

New school units require less energy than conventional schools. An important role in energy consumption is played by the location of the school unit, thermal insulation as well as the use of passive solar systems. As it turned out, the implementation of new laws on heat insulation has increased significantly the reduction of energy consumption.

The survey showed that the existing conventional schools who consume large amounts of energy, are in need of improvement.

Also, the use of renewable energy sources such as photovoltaic systems, saves important natural resources, while the introduction of geothermal energy to schools, will reduce energy consumption even further.

Conclusively, not only do passive solar schools contribute to energy consumption reduction, but they also contribute to the conservation of natural resources and the reduction greenhouse gases emissions to the atmosphere. Nowadays, new techniques applied in schools and new energy-saving systems create a new field of research in the forthcoming years.

Abstract: The Seawater Greenhouse system uses sunlight, seawater and air to provide freshwater and cooled and humid air, so that in addition to provide the water required for greenhouse, supply more sustainable environmental condition from cultivation of crops in arid coastal regions. In this system ambient air is passed through the two evaporative cooling pads, which plant growth area is placed between those pads, by fans that placed end of the building, and then returned taking humidity on the tube-and-fin condenser. In order to decrease the entrance heating load to the plants, use pipe arrays to provide shade. This paper tries to describe simulation the Seawater Greenhouse considering condition of the Bandar Abbas City in IRAN. it shows that by increasing entrance air relative humidity, the water production and floor temperature increases and the differential temperature decreases. Also with increasing seawater flow rate, the water production increases and differential temperature and floor temperature decreases. With increasing entrance air flow rate, the water production water production and floor temperature decreases and differential temperature increases. Different cycle is developed and investigate in this paper and shows that in cycle that is water exist from first evaporator is passed under the greenhouse floor, is the effective cycle and produces more water than other cycle.

1. Introduction

The earliest solar distillation plant on record was designed and built in 1872 by Charles Wilson in Chile [1]. It was further developed at the University of Arizona in 1961 in cooperation with the Georgia Institute of Technology and the University of Sonora, Mexico at Puerto Peñasco,New Mexico. A well detailed study about sun fresh water making plans and

policies was investigated [2, 3, 5, 6]. But, the seawater Greenhouse history returned to 1991. The first experimental project started in Tenerife in 1994. This prototype Seawater Greenhouse was planned in England and constructed in Tenerife[7].

The increasing water requesting growth and water providing resources shortage are two certain and predictable problems in 21 century. Now, the great areas in the world suffer from drought. The deserts are developing and in comparison, raining has a fixed movement. While water requesting have been two times in present 20 years, request forwarding from refreshing resources amount is following at the same way. About 70% total water uses are in farming and then water crisis can be review in so close relationship with food materials producing and economy development and creating. Custom and traditional farming which just need few hundred liters water just produces one kg output and it is because of this farming style inefficiency in water management. The farming and its increasing water requesting will be an important pressure point in which seawater Greenhouse will help using and incorporating natural processes in order to provide low-cost resolution for presenting permanent and similar model in arid coastal regions to decrease this pressure. Seawater Greenhouse provides an ambient in which plants sweating is as low as possible. So, Greenhouse produces its needed sufficient water during sun distillation operation.

2. Seawater greenhouse process description

The greenhouse seawater system uses the sun, the sea and the atmosphere to produce fresh water and cooled air to the growth of crops in the greenhouse. The idea of its operation depends on creating the natural water cycle in controlled environment. First seawater pumped into a cold seawater tank after filtration. The seawater pumped to the condenser before reaching the first cooling pad evaporator at the front side of the greenhouse. The seawater greenhouse consist of two evaporator that planting area is located between them. The seawater passes through first evaporator from top to bottom, while air passes perpendicular direction to the flow of water. This evaporator faces the prevailing wind. Also fan assist and control air movement. The humidified and cooled air passes through planting area and combined with hot dry air from the cavity under the roof. The mixture passes through a second evaporator and creating hot saturated air which then flows through the condenser. The seawater is pumped to a pipe array which is installed in the cavity below the plastic cover and warmed up by solar energy and passes through second evaporator from top to bottom. It noted that only small fraction of solar radiation involved in photosynthesis since the roof traps infrared heat while allowing light through to promote photosynthesis. The saturated humid air from second evaporator passes through the condenser which is cooled by seawater flow. The temperature difference creates fresh water to condense out of air stream. The resulting condensate collected for using in irrigation of crops.

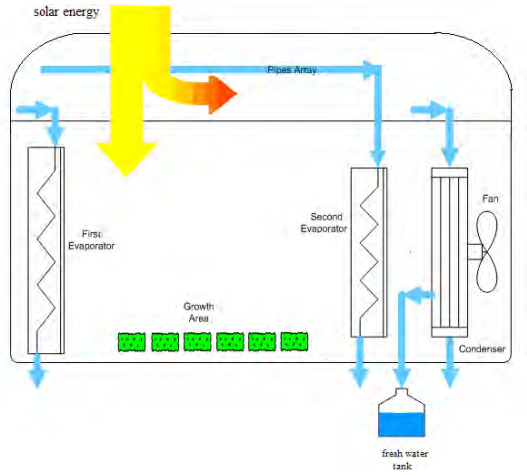

Fig1. Seawater greenhouse process schematic diagram

3. Modelling and Optimisation

Seawater greenhouse is consist of two evaporator, which is planting area located between them, condenser, and pipe array, which is feed the second evaporative pad through water which heated by the sun, is located in cavity under the greenhouse plastic cover. In analyzing the green house all of these parts must be modeling.

The first evaporator:

Energy and mass balance for evaporator cooling pad in the front of greenhouse gives:

$$\dot{m}_1 h_1 + \dot{m}_2 h_2 = \dot{m}_3 h_3 + \dot{m}_4 h_4 \quad (1)$$

$$\dot{m}_1 + \dot{m}_2 = \dot{m}_3 + \dot{m}_4 \quad (2)$$

The entrance air mass obtained with equation 3:

$$\dot{m}_{Air} = \frac{\dot{m}_1}{1+\omega_1} \quad (3)$$

The evaporative water amount will take from:

$$\dot{m}_4 - \dot{m}_1 = \dot{m}_{Air}(\omega_4 - \omega_1) \quad (4)$$

$$h_1 = f(T_1, P_{Ambient}, \omega_1) \quad (5)$$

$$\omega_1 = f(T_1, P_{Ambient}, \varphi_1) \quad (6)$$

$$h_2 = f(T_2, P_{Ambient}) \quad (7)$$

$$h_3 = f(T_3, P_{Ambient}) \quad (8)$$

$$T_4 = f(h_4, P_{Ambient}, \varphi_4) \quad (9)$$

$$\omega_4 = f(T_4, P_{Ambient}, \varphi_4) \quad (10)$$

The growth area:

Air after passing through the evaporator enters the growth space. Before air entering in plants growth space, part of it directs to the space in up. This part has an important role in freshwater production and simulate as follow:

The roof:

$$\alpha_{Body} I - h_{Out}(T_{Roof} - T_1) - h_{Up}(T_{Roof} - T_{Up}) - F_{Roof.Pipe}.\sigma.\varepsilon_{Body}(T_{Roof}^4 - T_{Pipe}^4) - F_{Roof.Sky}.\sigma.\varepsilon_{Body}(T_{Roof}^4 - T_{Sky}^4) = 0 \quad (11)$$

The left:

$$\alpha_{Body} I - h_{Out}(T_{Left} - T_1) - h_{Down}(T_{Left} - T_{Down}) - F_{Left.Pipe}.\sigma.\varepsilon_{Body}(T_{Left}^4 - T_{Pipe}^4) - F_{Left.Sky}.\sigma.\varepsilon_{Body}(T_{Left}^4 - T_{Sky}^4) - F_{Left.Floor}.\sigma.\varepsilon_{Body}(T_{Left}^4 - T_{Floor}^4) = 0 \quad (12)$$

The right:

$$\alpha_{Body} I - h_{Out}(T_{Right} - T_1) - h_{Down}(T_{Right} - T_{Down}) - F_{Right.Pipe}.\sigma.\varepsilon_{Body}(T_{Right}^4 - T_{Pipe}^4) - F_{Right.Sky}.\sigma.\varepsilon_{Body}(T_{Right}^4 - T_{Sky}^4) - F_{Right.Floor}.\sigma.\varepsilon_{Body}(T_{Right}^4 - T_{Floor}^4) = 0 \quad (13)$$

Pipes carrying seawater:

$$\alpha_{Pipe}.\rho_{Body}.I - h_{Pipe}(2T_{Pipe} - T_{Up} - T_{Down}) - F_{Pipe,Left}.\sigma.\varepsilon_{Pipe}(T_{Pipe}^4 - T_{Left}^4) - F_{Pipe,Right}.\sigma.\varepsilon_{Pipe}(T_{Pipe}^4 - T_{Right}^4) - F_{Pipe,Floor}.\sigma.\varepsilon_{Pipe}(T_{Pipe}^4 - T_{Floor}^4) - F_{Pipe,Roof}.\sigma.\varepsilon_{Pipe}(T_{Pipe}^4 - T_{Roof}^4) - \frac{2T_{Water} - T_{Up} - T_{Down}}{\frac{1}{h_{Water}} + \frac{e}{k}} \quad (14)$$

The Floor:

$$\alpha_{Floor}.(\rho_{Body}.\rho_{Pipe} + 2\rho_{Body})I - h_{Down}(T_{Floor} - T_{Down}) - F_{Floor,Left}.\sigma.\varepsilon_{Floor}(T_{Floor}^4 - T_{Left}^4) - F_{Floor.Right}.\sigma.\varepsilon_{Floor}(T_{Floor}^4 - T_{Right}^4) - F_{Floor,Pipe}.\sigma.\varepsilon_{Floor}(T_{Floor}^4 - T_{Pipe}^4) \quad (15)$$

The Greenhouse out air h:

$$h_{Out} = \frac{Nu_{Out}.k_{Out}}{L} \quad (16)$$

$$Nu_{Out} = (0.037\,\mathrm{Re}_{L,Out}^{4/5} - 871)\,\mathrm{Pr}_{Out}^{1/3} \quad (17)$$

$$\mathrm{Pr}_{Out} = f(T_1) \quad (18)$$

$$\mathrm{Re}_{L,Out} = \frac{V_{Out}.L}{\mu_{Out}} \quad (19)$$

$$\mu_{Out} = f(T_1, P_{Ambient}, \omega_1) \quad (20)$$

$$V_{Out} = \rho_1.\dot{m}_1 \quad (21)$$

$$\rho_1 = f(T_1, P_{Ambient}, \omega_1) \quad (22)$$

$$k_{Out} = f(T_1, P_{Ambient}, \omega_1) \quad (23)$$

The passing water h from the pipes:

$$h_{Water} = \frac{Nu_{Water} k_{Water}}{D_{Pipe}} \quad (24)$$

$$Nu_{Water} = 3.66 + \frac{0.0668\frac{D_{Pipe}}{L}\mathrm{Pr}_{Water}\,\mathrm{Re}_D}{1 + 0.04(D_{Pipe}\,\mathrm{Pr}_{Water}\frac{\mathrm{Re}_D}{L})^{2/3}} \quad (25)$$

$$\mathrm{Pr}_{Water} = f(T_{Water}, P_{Ambient}) \quad (26)$$

$$\mathrm{Re}_D = \frac{4\dot{m}_{10}}{\pi D_{Pipe}\mu_{Water}} \quad (27)$$

$$\mu_{Water} = f(T_{Water}, P_{Ambient}) \quad (28)$$

$$k_{Water} = f(T_{Water}, P_{Ambient}) \quad (29)$$

In this stage, by taking two control volumes around the Greenhouse up and down space that separating by the pipes carrying seawater, we have the following equations.

$$\dot{m}_6 h_6 + h_{Up}(T_{Roof} - T_{Up}) + h_{Pipe}(T_{Pipe} - T_{Up}) - \dot{m}_8 h_8 = 0 \quad (30)$$

$$\dot{m}_7 h_7 + h_{Down}(T_{Floor} + T_{Left} + T_{Right} - 3T_{Down}) + h_{Pipe}(T_{Pipe} - T_{Down}) - \dot{m}_9 h_9 = 0 \quad (31)$$

$$T_8 = f(h_8, P_{Ambient}, \omega_8) \quad (32)$$

$$T_9 = f(h_9, P_{Ambient}, \omega_9) \quad (33)$$

$$T_{Up} = \frac{1}{2}(T_6 + T_8) \quad (34)$$

$$T_{Down} = \frac{1}{2}(T_7 + T_9) \quad (35)$$

$$T_{Water} = \frac{1}{2}(T_5 + T_{10}) \quad (36)$$

The entering air divided into two branches that flowing down branch has the duty of humidification and cooling of the ambient and the up branch has the duty of by removing the heat gained from sun by pipe arrays and applying it increasing humidity capacity of air in exit. These two branches were mixed by near the second evaporator and caused increasing air temperature and moisture capacity. These combinations write as follow:

$$\varphi_{11} = f(T_{11}, P_{Ambient}, \omega_{11}) \quad (37)$$

$$h_{11} = f(T_{11}, P_{Ambient}, \omega_{11}) \quad (38)$$

The second evaporator:
This evaporator analyzes such as the first one

Condenser:
According figure 3, the governing equations are as following:

$$\dot{m}_{13}h_{13} + \dot{m}_{14}h_{14} = \dot{m}_{15}h_{15} + \dot{m}_{16}h_{16} + \dot{m}_{17}h_{17} \quad (39)$$

$$\dot{m}_{13} - \dot{m}_{17} = \dot{m}_{Air}(\omega_{13} - \omega_{17}) \quad (40)$$

$$\dot{m}_{13} = \dot{m}_{16} + \dot{m}_{17} \quad (41)$$

$$h_{14} = f(T_{14}, P_{Ambient}) \quad (42)$$

$$T_{15} = f(h_{15}, P_{Ambient}) \quad (43)$$

$$h_{16} = f(T_{16}, P_{Ambient}) \quad (44)$$

$$\omega_{17} = f(T_{17}, P_{Ambient}, \varphi_{17}) \quad (45)$$

$$h_{17} = f(T_{17}, P_{Ambient}, \omega_{17}) \quad (46)$$

Finally, all of these equations stimulate and solved by EES program.

4. Result and conclusion

Bandar Abbas have chosen as stimulation reference, and was simulated based on the following the following conditions[8]:

$P_{Ambient} = 100KPa$, $V_{Out} = 10m/s$, $I = 250W/m^2$, $L = 42m$, $\varphi = 0.64$, $\dot{m}_1 = 20kg/s$, $\dot{m}_2 = 3Lit/s$

Figure 2 shows the difference temperature between the inlet and outlet of the first evaporator as function of the mass flow rate and relative humidity of entrance air. With increasing mass flow rate, Re and h was increased and it caused more evaporation and the temperature of air was decreased.

Figure 3 shows the difference temperature between the inlet and outlet of the first evaporator as function of the mass flow rate of sea water and the relative humidity of entrance air. As shown in the figure, the more increasing mass flow is lead to the more decreasing temperature drop. Furthermore, the more increasing humid, the more decreasing temperature difference. Figure 4 shows water producing according to entrance air mass flow and various air humid. As you see in this figure, entrance air increasing has affected water producing tendency increasingly and has had an important step toward its decrease.

Figure 5 shows water producing mass flow based on seawater mass flow and various airs humidity. As have shown seawater mass flow increasing causes differential temperature dropping, then more warm air goes to the roof and its entrance will be warmer and caused the exit water will be warmer, this increases water inclination to evaporation and humid absorbing more. These events in addition to warmer air gets condense better in condenser will increase producing water in it and also we see clearly increasing in seawater mass flow will increase the producing water.

Figure 6 shows the temperature of Greenhouse floor as a function of seawater mass flow and various airs humid. It is cleared that the increasing water producing mass flow has increased soil temperature. It happens more in much humid

Figure 7 shows Greenhouse floor temperature based on entering air mass flow and various air humid. As have considered, increasing entrance air mass flow will decrease the outlet temperature of the first evaporator, and it results in more heat transfer to greenhouse floor and

decrease its temperature. In addition, entrance air mass flow increase affects Re and Nu and increasing h and absorbs multiple heat, so we can say the higher humid will be as the same as more soil temperature. As we see in this figure, entrance mass flow increasing has decrease heat, and more humid, will increase Greenhouse floor in a certain air mass flow.

.The difference cycles was simulated here to find the optimum cycles in this Greenhouse. The stimulations were done according the Bandar Abbas conditions. The first cycle which has shown by C1 in the figures, is the simplest one and the other plan is based on changes changes in this plan. C2 is a plan for decreasing the greenhouse floor temperature. The air which exits the condenser will be passed the under of the growth space in order to decrease Greenhouse floor temperature. C3 is a similar plan with the same goal by another approach. In this cycle, the water which exit the first evaporator is passed the under of Greenhouse floor space, like previous plan, for decreasing the temperature. C4, C5 and C6 have considered in order to low cost and each of them includes these changes: condenser feeding from the first evaporator exit water, pipes array feeding through condenser exit and finally pipes array feeding by the second evaporator exit. Now, we study these graphs in detail: Considering present cycles we can see with increasing humidity the water producing was increased. Another important result will obtain from this graph is C3>C2>C6>C5>C4>C1

Figure 8 shows water producing in different cycles according to various air humid, and describe cycle 3 is the best in water production and providing pleasure heat for greenhouse floor (in this way and through thermal transmitting increasing to the air produces water) and also says condenser feeding through exit water from operator just low cost and hasn't so profits in water producing. Figure 9 shows water producing in different cycles based on various entrance air mass flow rate. This graph interpretation is like graph 8 and the alone point which isn't mentioned is in all cycles increasing entrance air mass flow water producing is decreased. Figure 10 shows the location of different places in basic cycle.

5. Conclusion

The seawater greenhouse was investigated in the Bandar Abass wether conditions.it shows that by increasing entrance air relative humidity, the water production and floor temperature increases and the differential temperature decreases. Also with increasing seawater flow rate, the water production increases and differential temperature and floor temperature decreases. With increasing entrance air flow rate, the water production water production and floor temperature decreases and differential temperature increases. Also different cycle is developed and investigates in this paper and shows that in cycle C3 which is water exist from first evaporator is passed under the greenhouse floor, is the effective cycle and produces more water than other cycle.

Abstract: It is good for the consumer to have solar cookers of various varieties in terms of geometrical designs, performance and price but it is a challenge to develop a uniform test standard for evaluating the thermal performance of the cookers irrespective of their geometrical construction. Due to the lack of uniform test protocol, consumer cannot compare the quantitative performance of the cookers of different configuration and become confused. For this end, we plotted graphs between exergy output and temperature difference, for solar cookers of different designs and it resembled a parabolic curve for each design. The peak exergy (vertex of the parabola), can be accepted as a measure of devices' fuel ratings. The ratio of the peak exergy gained to the exergy lost at that instant of time can be considered as the quality factor of the solar cooker. Besides, the exergy lost is found to vary linearly with temperature difference irrespective of the topology of the device and the slope of the straight line obtained through curve fitting represents the heat loss coefficient of the cooker. The proposed parameters can lead to development of unified test protocol for solar cookers of diversified designs.

1. Introduction

Solar cookers are a very useful and popular thermal device which is available throughout the world. It is one of the few renewable energy thermal gazettes which are portable, user friendly, easily operable, meant to fulfil the very basic need and economically competitive. Its affordable price makes it very attractive commercially, especially among the rural populace in the developing countries. In order to meet the demands of broad spectrum of the society and penetrate the market, different novel varieties of solar cookers have become available in accordance with peoples' need and purchasing capacity. Solar box type cookers (SBC) are available for domestic as well as community based applications. Similarly, SK-14, SK-10 and Scheffler paraboloid type concentrating cooker are also present in the market for fast cooking for domestic/community and industrial applications. In addition parabolic trough type concentrating cookers are being reported in recent studies for both domestic as well community type applications. Depending on the topology of the cooker construction, different test procedures and thermal indicators have been established, which act as benchmark thermal performance evaluators for various geometrical varieties of the cooker. On one hand it is good for the customer to have solar cookers of diversified designs in terms of geometry, performance and price but on the other hand it is a challenge to develop a uniform test standard for evaluating the thermal performance of the cookers irrespective of their geometrical construction. In the absence of such unified test/standard protocol, it is very confusing for the customer to compare the performance of these devices. In addition, to

promote renewable energy technologies (RETs), many governments throughout the world, are adopting environment friendly policies. This includes the provision of providing direct/indirect subsidies and other benefits to the user on the usage of the RETs. Many a times, manufacturers are not able to receive the subsidy benefits because the parameters set for eligibility criterion matches one design of solar cooker and not the others. Through the present manuscript, we propose an exergy based unified test protocol for solar cookers of different geometries. In this protocol, the test methodology for conducting full load test for solar cookers remains the same but the analyzing procedure has been altered so as to fulfill the above necessities. In order to develop a realistic and unified test protocol, we utilize the reported data from different well known published manuscripts and analyze it comprehensively to cater to the above mentioned needs.

2. Methodology

In order to test the performance of the solar box type cooker, two figures of merit (FOM) viz. F_1 and F_2 are generally calculated, as given by Mullick [1]. The first FOM, F_1 is defined as the ratio of optical efficiency to the heat loss factor by bottom absorbing plate and is a measure of the differential temperature gained by the absorbing plate at a particular level of solar insolation. The second FOM, F_2 is more or less independent of climatic conditions and gives an indication of heat transfer from absorbing plate to the water in the containers placed on the plate. Bureau of Indian standards have also accepted these parameters as performance indicators for SBC [2]. However, as per international test protocol for solar box cookers, the performance should be estimated in terms of its standardized cooking power as given by Funk [3], which is calculated through extrapolation of the curve/data. The value of the cooking power determined through this procedure comes out to be high and does not represent the actual cooking potential of the cooker. Internationally, the procedure for measuring the efficacy of cooking of solar cookers based on parabolic trough and Scheffler concentrating type topology is not very well known, nevertheless Scheffler concentrators are generally employed for very large scale cooking/industrial operations. As per Ministry of New and Renewable Energy (India), thermal performance of SK-14/SK-10 type cookers should be determined by its heat loss factor, optical efficiency and cooking power [4]. In all above mentioned thermal performance evaluation processes, energy based approach is employed. But, the benchmark parameters derived from the energy based method does not provide complete information and are inadequate performance indicators because their values can be misleadingly high or low depending on the temperature difference between source and sink, even though input energy condition may remain same. Exergy is a measure of the potential of the system to extract heat from the surroundings, as the system moves closer to the equilibrium with its environment [5]. After the system and the surroundings reach equilibrium, the exergy becomes zero. In the present manuscript, we would take the case of each of the different solar cookers of the above mentioned geometries and apply the exergy based approach so as to reach a holistic/uniform approach for deciding the common thermal indicators irrespective of the cooker design topology. The exergy of solar radiation, as the exergy input E_{Xi} to the solar cooker, can be calculated using the available solar energy flux ($GA\Delta t$) and is expressible through Eq. (1) which has the widest acceptability [5, 6].

$$E_{Xi} = G\left[1+\frac{1}{3}\left(\frac{T_{am}}{T_s}\right)^4 - \frac{4T_{am}}{3T_s}\right]A\Delta t \qquad (1)$$

where T_{am} is instantaneous ambient temperature, T_s is surface temperature of sun, G is instantaneous solar insolation, A is aperture area of cooker, and Δt is time interval. The sun's black body temperature of 5762 K results in a solar spectrum concentrated primarily in the 0.3−3.0 μm wavelength band [5, 7, 8]. Although the surface temperature of the sun (T_s) varies due to the spectral distribution of sunlight on the earth's surface, the value of 5800 K has been considered for the T_s. The energy gained by water in the vessel, kept inside the cooker, due to rise in temperature can be considered as the output energy (E_o) of the system and is mathematically given as

$$E_o = mc(T_f - T_i) \tag{2}$$

In the expression above, the output energy depends only on the difference in initial and final values of temperatures $(T_f - T_i)$ but in actual practice, ambient temperature as well as the initial and final temperature values also play the role in deciding the efficiency of the system, and this kind of qualitative effect can not be accommodated in the energy based approach. The exergy gained by water in the vessel kept inside the cooker due to rise in temperature can be considered as the output exergy (E_{X0}) [5, 6, 7, 9] of the system and is expressible through

$$E_{Xo} = E_o - mcT_{am} \ln\frac{T_f}{T_i} \tag{3}$$

The beauty of the exergy analysis/approach is self evident in the expression above as it considers the effect of ambient temperature as well as the absolute values of initial and final temperature in addition to $(T_f - T_i)$. The second term on the right hand side of this expression signifies the exergy losses elucidating the true potential of the system in converting the input energy. Thus, exergy analysis is a more complete synthesis tool because it accounts for the temperatures associated with energy transfers to and from the cooker, as well as the quantities of energy transferred, and consequently provides a measure of how nearly the cooker approaches ideal efficiency. Here, we propose to plot a graph between output exergy power and temperature difference and fit the data points with second order polynomial; temperature difference is the difference in the instantaneous water temperature and ambient temperature. From the fitted curve, it is easier to obtain the peak value of exergy, which is very near to the actual value of the peak exergy. The temperature difference gap corresponding to the half exergy points of the curve can be determined. The exergy lost during the test period can also be plotted against temperature difference so as to estimate the overall heat loss coefficient of the cooker. In order to determine the above mentioned parameters, we are taking the data from various manuscripts for each of the different solar cookers geometries.

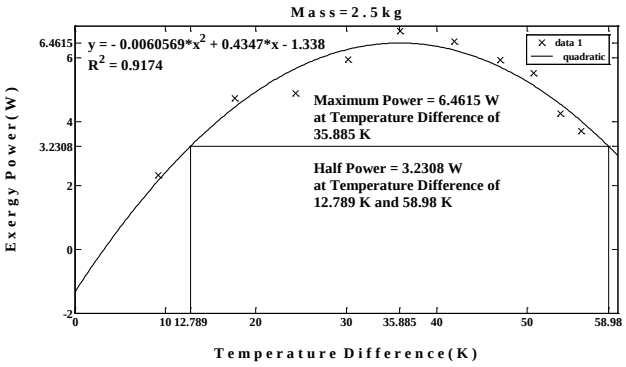
3. Results and Discussion

Four different geometries of solar cookers are considered for depicting their thermal performance on the basis of exergy based parameters. These geometries are domestic box type cooker, domestic SK-14 type cooker, Scheffler community type cooker, parabolic trough type cooker. The proposed four exergy based parameters, which can be considered as the benchmark indicators of the performance of the cookers are as follows, (i) Peak Exergy, (ii) Quality factor, (iii) Exergy temperature difference gap product, (iv) Heat loss coefficient. Peak exergy is the highest/maximum exergy output power obtained through curve fitting by plotting the graph between exergy output power and temperature difference. This can be realistically considered as a measure of its fuel ratings. The ratio of the peak exergy gained to the exergy lost at that instant of time can be considered as the quality factor of the solar cooker. A higher quality factor is always desirable. The product of the temperature

difference gap corresponding to the half power points and the peak exergy power can also considered to be another benchmark indicator in this kind of analysis. Higher temperature difference gap means the lesser heat losses from the cooker. This kind of scheme is generally considered in electronics for expressing the performance of a BJT amplifier, as gain bandwidth product and also a quality factor in case of a notch/band pass filter. The heat loss coefficient of the device can be calculated by dividing the value of the slope of the line, obtained through linear curve fitting of exergy lost variations with temperature difference, by the value of glazing/focal area. In this approach, we are not dependent much on extrapolation and all the parameters were realistically calculated from the graphs/data. Calculations of the above mentioned topologies of the solar cooker are described in the subsequent sub-sections.

3.1. Domestic solar box type cooker

The variation in the exergy output as a function of temperature difference for domestic SBC of aperture area 0.25 m^2 is presented in Fig. 1, which depicts the case when the amount of water inside the cooking vessels/pots is 2.5 Kg. The maximum exergy power obtained through curve fitting is 6.46 W and the temperature difference gap corresponding to the half power points is 46.2 K. The peak exergy and temperature difference gap product for this case is found to be 298.5 WK. The experimental data, for performing calculation and obtaining the thermal parameters, is taken from Kumar [11].



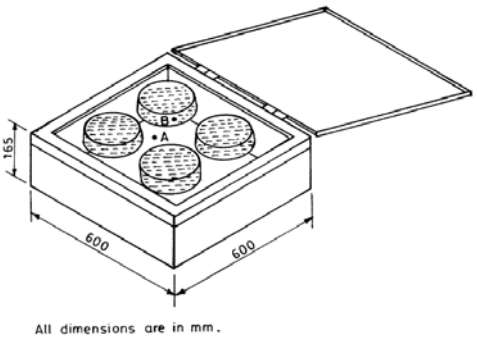


Fig. 1. Variation of Exergy output power with Temperature Difference for Domestic SBC with its schematics.

The curve between the exergy lost v/s temperature difference is plotted in Fig. 2. Heat loss coefficient is obtained by dividing the slope of the curve (which depicts the exergy lost per change in temperature, i.e., W/K), by the gross aperture area. The heat loss coefficient and quality factor, for 2.5 kg mass of water, are found to be 5.24 W/K m^2 and 0.123, respectively. The specific heat loss coefficient for this cooker is found to be 2.096 W/K m^2 kg.

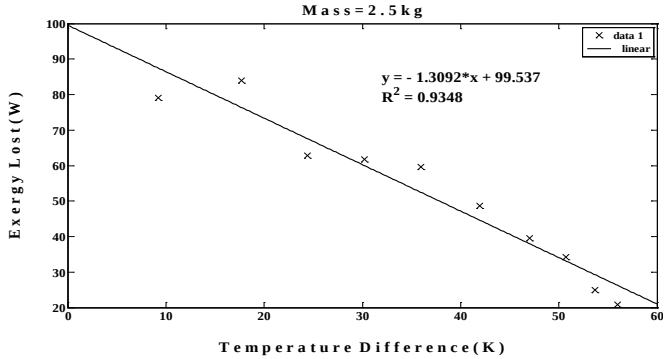

Fig. 2. Variation of Exergy power lost with Temperature Difference for Domestic SBC.

3.2. SK-14 type cooker

The variation in the exergy output as a function of temperature difference for domestic SK - 14 type of gross aperture area 1.47 m^2 and a focal area of 0.134m^2 is presented in Fig. 3, which depicts the case when the amount of water inside the cooking vessels/pots is 5 Kg. The reflective area of the cooker is 1.47 m^2 with its focal length equal to 0.28 m. The maximum exergy power obtained through curve fitting is 18.21 W and the temperature difference gap corresponding to the half power points is 40.374 K. The peak exergy and temperature difference gap product for the two cases is found to be 735.3 WK. The experimental data, for performing calculation and obtaining the thermal parameters, is taken from Kaushik [7]. The curve between the exergy lost v/s temperature difference is plotted in Fig. 4. The heat loss coefficient and quality factor, for 5 kg mass of water, are found to be 40.35 W/K m^2 and 0.106, respectively. The specific heat loss coefficient for this cooker is found to be 8.07 W/K m^2 kg.

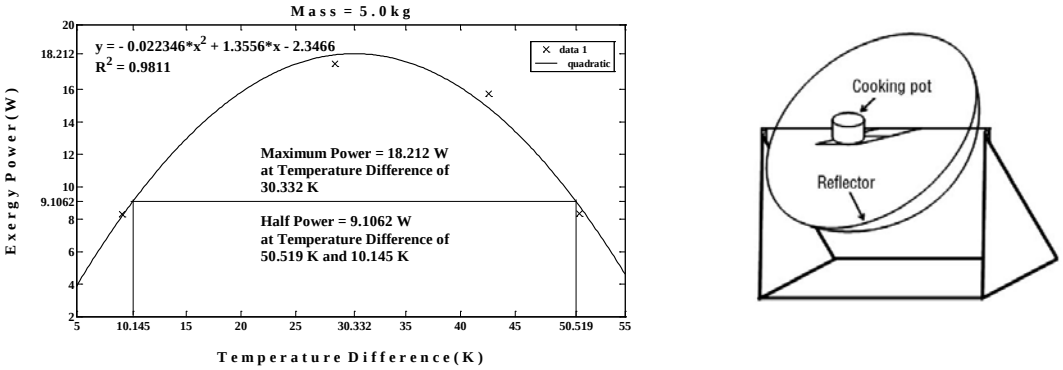

Fig. 3. Variation of Exergy output power with Temperature Difference for SK-14 type cooker with its schematics.

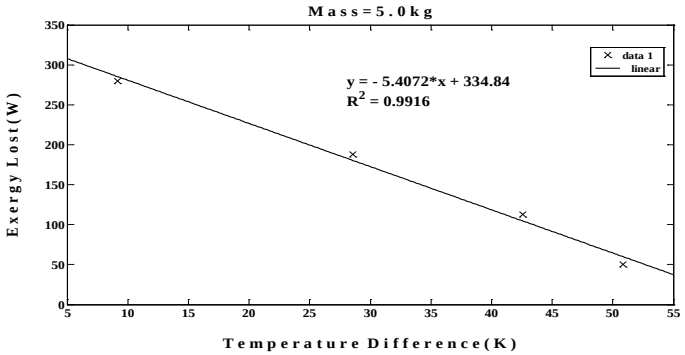

Fig. 4. Variation of Exergy power lost with Temperature Difference for SK-14 type cooker.

3.3. Scheffler Community type cooker

The variation in the exergy output as a function of temperature difference for Scheffler community type of gross aperture area 8.21 m^2 and a secondary focal area of 0.36 m^2 is presented in Fig. 5, which depicts the case when the amount of water inside the cooking vessels/pots is 20 Kg. The primary reflector area of the concentrator is 7.3 $m^2$with aperture diameters of 3.8 m lengthwise and 2.75 m widthwise and has depth of 0.3 m. The reflective area of secondary reflector is 0.36 m^2. The maximum exergy power obtained through curve fitting is 55.75 W and the temperature difference gap corresponding to the half power points is 39.62 K. The peak exergy and temperature difference gap product for the two cases is found to be 2208.815 WK. The experimental data, for performing calculation and obtaining the thermal parameters, is taken from Kaushik [7]. The curve between the exergy lost v/s temperature difference is plotted in Fig. 6. The heat loss coefficient and quality factor, for 20 kg mass of water, are found to be 54.125 W/K m^2 and 0.099, respectively. The specific heat loss coefficient for this cooker is found to be 2.706 W/K m^2 kg.

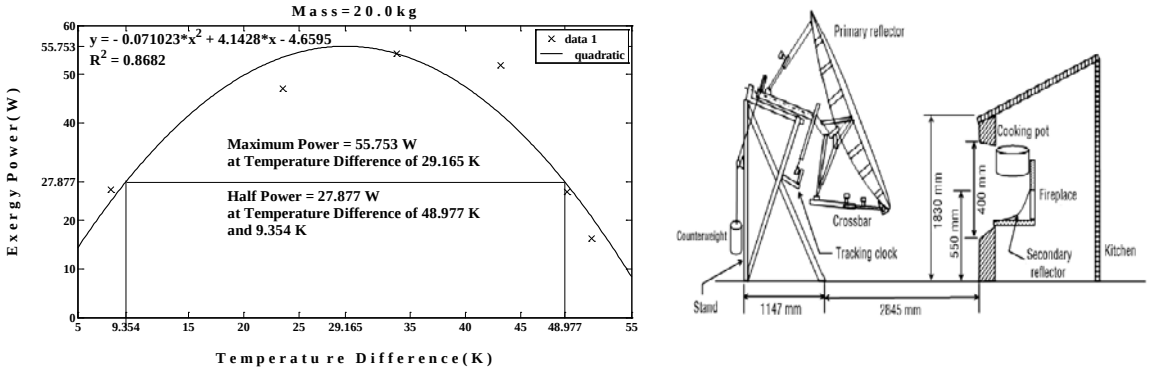

Fig. 5. Variation of Exergy output power with Temperature Difference for Scheffler type cooker with its schematics.

.

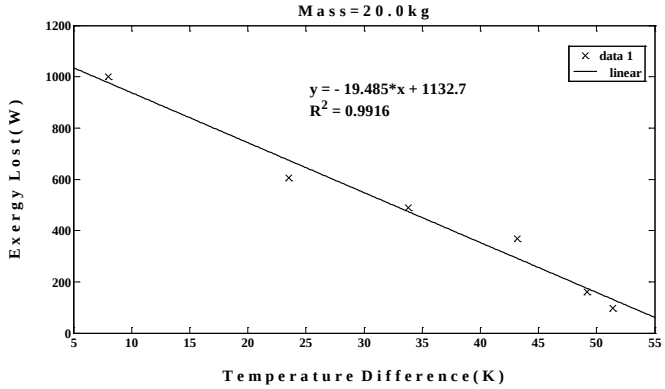

Fig. 6. Variation of Exergy power lost with Temperature Difference for Scheffler type cooker.

3.4. Parabolic trough type concentrating cookers

The variation in the exergy output as a function of temperature difference for parabolic trough type concentrating cooker of aperture area 0.9 m^2 and focal area of 0.088m^2 is presented in Fig. 7, which depicts the case when the amount of water inside the cooking vessels/pots is 6.3 Kg. The maximum exergy power obtained through curve fitting is 6.92 W and the temperature difference gap corresponding to the half power points is 23.15K. The peak exergy and temperature difference gap product for the two cases is found to be 160.198 WK. The experimental data, for performing calculation and obtaining the thermal parameters, is taken from Ozturk [8]. The curve between the exergy lost v/s temperature difference is plotted in Fig. 8. The heat loss coefficient and quality factor, for 6.3 kg mass of water, are found to be 47.73 W/K m^2 and 0.087, respectively. The specific heat loss coefficient for this cooker is found to be 7.58 W/K m^2 kg.

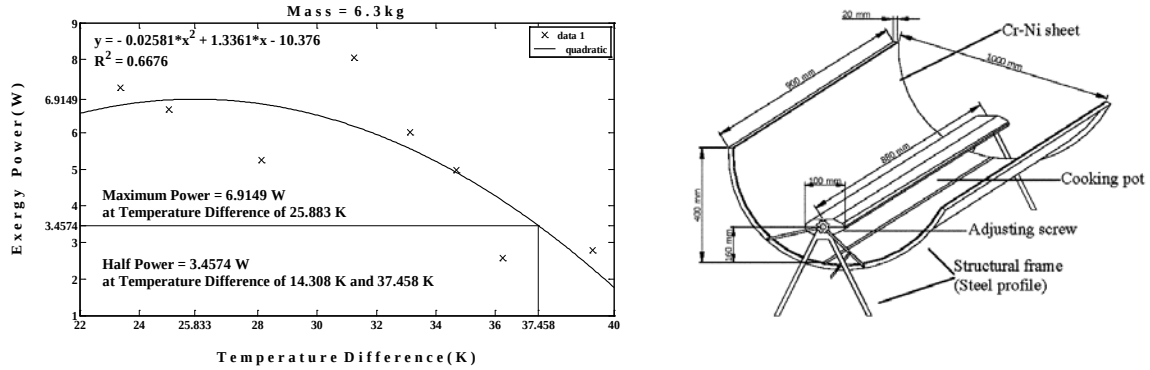

Fig. 7. Variation of Exergy output power with Temperature Difference for parabolic trough cooker with its schematics.

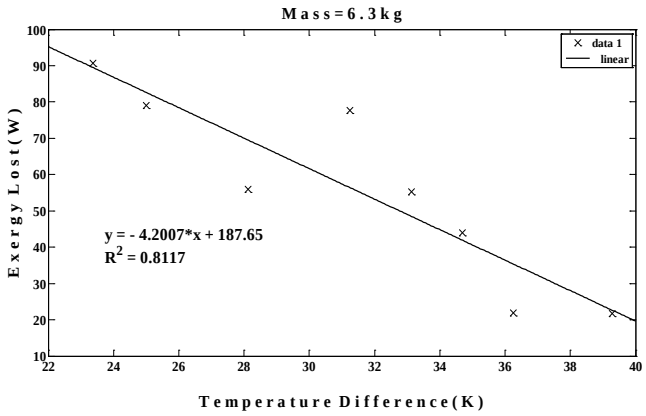

Fig. 8. Variation of Exergy power lost with Temperature Difference for parabolic trough cooker.

The cooker which attains higher exergy at higher temperature difference is the better one. It has been also noticed that the variation in the exergy lost with temperature difference is more linear when temperature of water varies in the range of 60°C to 95°C (see Fig. 2, 4, 6, 8). This range of temperature is also generally used in calculation/determination of F_2 *(second figure of merit)*, which is an important and well known performance indicator for SBC [1, 12]. The amount of heat energy at higher temperature is more valuable than the same amount of heat energy at lower temperature and in energy analysis it is not possible to take into account such qualitative difference. The exergy analysis is a more complete synthesis tool because it

account for the temperatures associated with energy transfers to and from the cooker, as well as the quantities of energy transferred, and consequently provides a measure of how nearly the cooker approaches ideal efficiency.

4. Conclusion

An exergy based analysis is applied to solar cookers of different designs. Variations in exergy output and exergy lost with respect to temperature difference are studied and four thermal performance indicators, viz. peak exergy, quality factor, exergy temperature difference gap product and heat loss coefficient, are proposed. The approach presented through this manuscript is comprehensive, realistic and flexible for it can easily accommodate the effect of variations in solar insolation (peak to valley) which can be greater than 300 W/m^2. The exergy output power, if required, can be converted into standardized exergy power on par with standardized cooking power. To establish a test standard for different types of solar cookers, one may require more comprehensive testing and data analysis. However, the proposed parameters may stimulate the discussion and strengthen the case for exergy based test standards.

Abstract: Photovoltaic thermal (PVT) technology refers to the integration of a PV and a conventional solar thermal collector in a single piece of equipment. In this paper, an integrated photovoltaic thermal solar (IPVTS) water heating system for various configurations has been evaluated for constant collection temperature. Analysis is based on basic energy balance for hybrid flat plate collector in terms of design parameters for a solar water heater installed at Solar Energy Park, IIT Delhi, India and climatic parameters provided by India Meteorological Department Pune, India. It is observed that the daily thermal energy gain of IPVTS system decreases with increasing the constant collection temperature. It is also observed that for collectors partially covered by PV modules, daily thermal energy increases with decrease of collector area covered by PV module. The exergy analysis of IPVTS system has also been carried out.

1. Introduction

Photovoltaic thermal (PVT) technology refers to the integration of a photovoltaic (PV) module and a conventional solar thermal collector in a single piece of equipment. The reason behind the hybrid concept is that more than 80% of the solar radiation falling on PV cells is either reflected or converted to thermal energy. This leads to an increase in the PV cell's

working temperature as much as 40-50^{o} C above the ambient temperature. Because of this temperature increase there can be two undesirable consequences: (i) 0.3% to 0.6 % of efficiency loss per degree C rise in PV cell temperature and (ii) a permanent damage in the structure of PV module if the thermal stress remains for a long period of time. In applications of PVT system, the production of electricity is the main priority, and therefore, it is necessary to operate the PV modules at low temperature in order to keep the PV cell electrical efficiency at a sufficient level. The temperature of the PV module in the hybrid PVT system can be reduced by cooling the base of PV module by allowing water/air to flow below it (Prakash [1], Tripanagnostopoulos et al. [2], Zondag et al. [3], Jones and Underwood [4], Chow [5], and Infield et al. [6]). Thermal energy available from PV module can be used for many applications namely water and air heating for domestic, agricultural sectors and buildings for thermal heating/cooling.

In this paper, the performance of the N collectors connected in series is evaluated by considering the three different cases, namely: Case A: All the collectors are fully covered by glass and connected in series. Case B: All collectors are partially covered by PV modules and connected in series and Case C: All the collectors are fully covered by PV module (glass to glass) and connected in series.

2. Methodology

For the present study conventional tube-in-plate-type collector of area of 2m^2 is considered. The design parameters of photovoltaic thermal (PVT) collectors are shown in Table 1. The glazing surface of the collector is either glass or PV module depending upon the requirement of the user. To increase the absorption of solar radiation the absorber plate of collector is blackened by black paint.

Energy balance equations:

In order to write the energy balance equation of PVT solar water collectors connected in series, the following assumptions have been made:

- One dimensional heat conduction is good approximation for the present study.
- The specific heat of water remains constant. It does not change with rise in temperature of water.
- The system is in quasi-steady state.
- The ohmic losses in the solar cell and PV module are negligible.

Energy balance for solar cells of PV module (glass-glass),

$$\alpha_c \tau_g \beta_c I(t) W dx = \left[U_{tc,a} \left(T_c - T_a \right) + h_{c,p} \left(T_c - T_p \right) \right] W dx + \eta_c \beta_c I(t) \cdot W dx \tag{1}$$

From Eq.(1) the expression fro cell temperature is

$$T_c = \frac{(\alpha\tau)_{1,eff} I(t) + U_{tc,a} T_a + h_{c,p} T_p}{U_{tc,a} + h_{c,p}} \tag{2}$$

Energy balance for blackened absorber plate below the PV module,

$$\alpha_p (1-\beta_c) \tau_g^2 I(t) W dx + h_{c,p} \left(T_c - T_p \right) W dx = h_{p,f} \left(T_p - T_f \right) W dx \tag{3}$$

From Eq. (3), the expression for plate temperature is

$$T_p = \frac{(\alpha\tau)_{2,eff} I(t) + PF_1 (\alpha\tau)_{1,eff} I(t) + U_{L1} T_a + h_{p,f} T_f}{U_{L1} + h_{p,f}} \tag{4}$$

Energy balance for water flowing through an absorber pipe below the PV module,

$$\dot{m}_f C_f \frac{dT_f}{dx} dx = F' h_{p,f} \left(T_p - T_f\right) W dx \tag{5}$$

In the present study three different configurations of PVT solar water collectors have been considered

Case A: All collectors are fully covered by glass and connected is series:

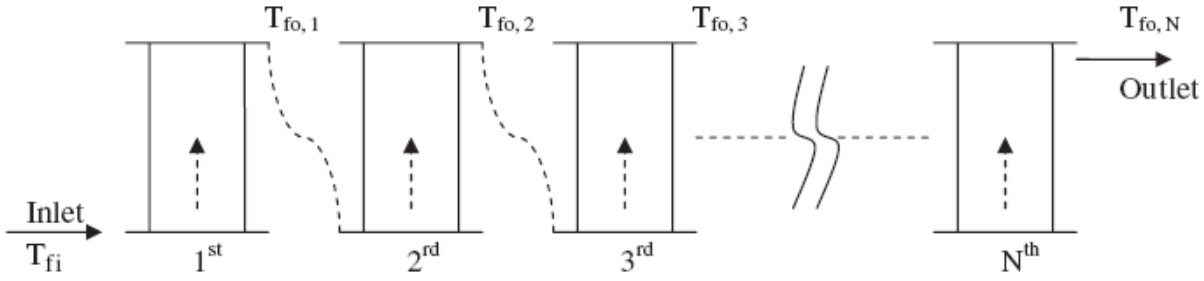

Fig. 1. Collectors fully covered by glass and connection in series.

Following Duffie and Beckman [7] and Tiwari [8] the mass flow rate for N collectors connected in series can be obtained as:

$$\dot{m}_f = \frac{F' N A_c U_{L,c}}{C_f \left[\log\left\{ T_{fi} - \left(\frac{(\alpha\tau)_{c,eff} I(t)}{U_{L,c}} + T_a \right) \right\} - \log\left\{ T_{foN} - \left(\frac{(\alpha\tau)_{c,eff} I(t)}{U_{L,c}} + T_a \right) \right\} \right]} \tag{6}$$

Case B: The collectors are partially covered by PV modules and connected in series

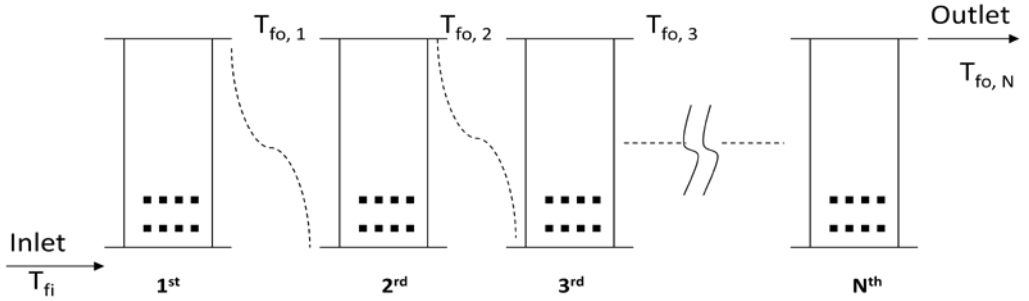

Fig. 2. Collectors partially covered by PV module and connected in series.

Following Dubey and Tiwari [9] the outlet water from N such collectors connected in series can be given as:

$$T_{foN} = \frac{\left(A F_R (\alpha\tau)\right)_1}{\dot{m}_f C_f} \left(\frac{1 - K_K{}^N}{1 - K_K} \right) I(t) + \frac{\left(A F_R U_L\right)_1}{\dot{m}_f C_f} \left(\frac{1 - K_K{}^N}{1 - K_K} \right) T_a + T_{fi} K_K{}^N \tag{7}$$

where,

$$K_K = \left[1 - \frac{\left(A F_R U_L\right)_1}{\dot{m}_f C_f}\right]$$

$$\left(A F_R(\alpha\tau)\right)_1 = \left[A_m F_{R\,m} P F_2(\alpha\tau)_{m,eff}\left(1 - \frac{A_c F_{Rc} U_{L,c}}{\dot{m}_f C_f}\right) + A_c F_{R\,c}(\alpha\tau)_{c,eff}\right]$$

and

$$\left(A F_R U_L\right)_1 = \left[A_m F_{Rm} U_{L,m}\left(1 - \frac{A_c F_{Rc} U_{L,c}}{\dot{m}_f C_f}\right) + A_c F_{Rc} U_{L,c}\right]$$

Case C: All the collectors are fully covered by glass to glass type PV module and connected in series

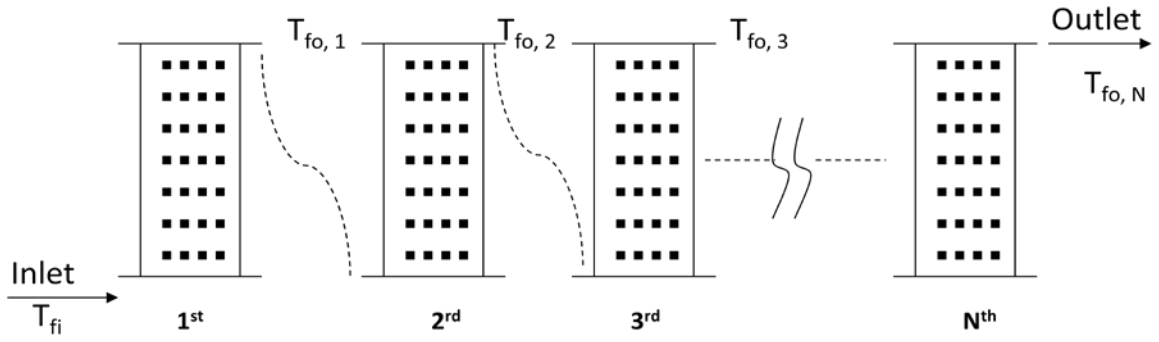

Fig.3. Collectors fully covered by PV modules and connected in series.

Following Dubey and Tiwari [9] Mass flow rate for N collectors partially covered with PV modules connected in series can be obtained as,

$$\dot{m}_f = \frac{N F' A_m U_{L,m}}{C_f\left[\log\left\{T_{fi} - \left(\frac{PF_2(\alpha\tau)_{m,eff} I(t)}{U_{L,m}} + T_a\right)\right\} - \log\left\{T_{foN} - \left(\frac{PF_2(\alpha\tau)_{m,eff} I(t)}{U_{L,m}} + T_a\right)\right\}\right]} \quad (8)$$

The rate of useful thermal energy obtained from N identical collectors connected in series can be given as

$$\dot{Q}_u = \dot{m}_f C_f\left(T_{foN} - T_a\right) \quad (9)$$

Electrical Efficiency of solar cell depends on solar cell temperature and can be given by Evans [10] and Schott [11]

$$\eta_c = \eta_o\left[1 - \beta_o\left(\overline{T_c} - T_o\right)\right] \quad (11)$$

Table 1. Design parameters of photovoltaic thermal (PV/T) collector

Parameters	Values	Parameters	Values

K	204 W/m^oC		
$\dot{m}$	0.06 kg.sec		

3. Result and Discussions

The variation of solar intensity and ambient temperature for a typical day in the summer month (January) is shown in Figure 4.The values of design parameters of flat plate collector are given in Table 1. Here, the results of the three cases, case A (fully covered by glass) and case B (partially covered by PV modules) and case C (fully covered by PV modules) are discussed in detail. Equations 6, 7 a nd 8 have been computed using MATLAB software for evaluating the mass flow rate at different outlet water temperatures for a typical day during the month of January for a given design and climatic parameters (Table 1). Figures 5a and 5b represent the hourly variation of mass flow rate for case A and case B respectively at various constant outlet temperatures. The result shows that for constant collection temperatures 30-60^{o}C the mass flow rate of water in tubes decreases from 0.1 - 0.01 kg/s in case A, 0.08-0.01 kg/s in case B. Figure 5c gives the hourly variation of mass flow rate for case C. Figure shows that in this case one cannot get the outlet water temperature more than 40^{o}C in January month and the mass flow rate decreases from 0.04 to 0.01 kg/s for case C.

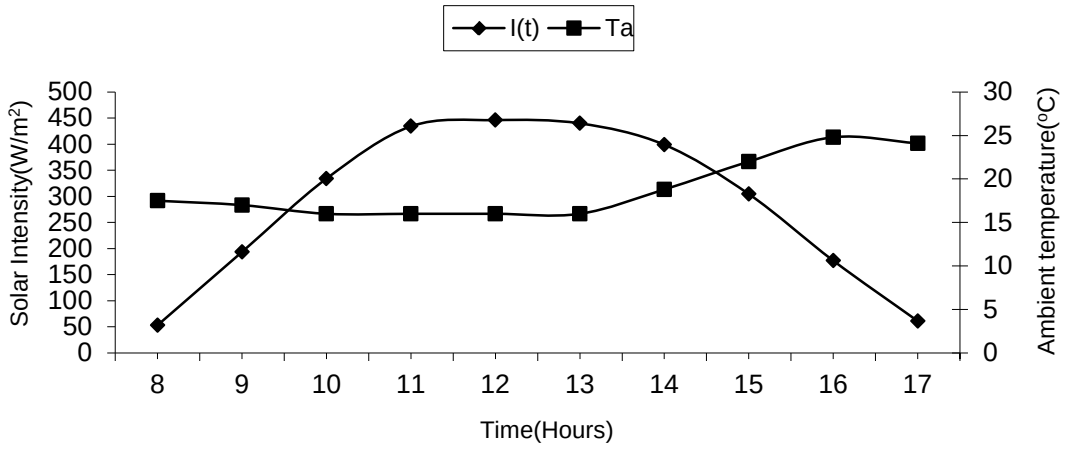

Fig. 4. Hourly variation of solar intensity and ambient temperature of a typical day in the month of January.

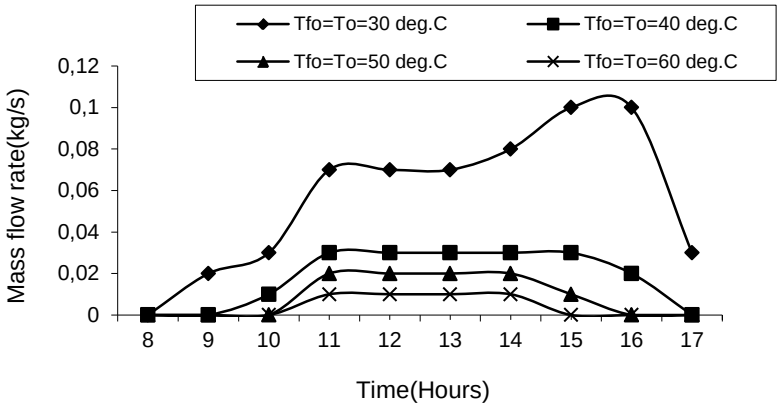

Fig. 5a. Hourly variation of mass flow rate at different outlet temperature for case A.

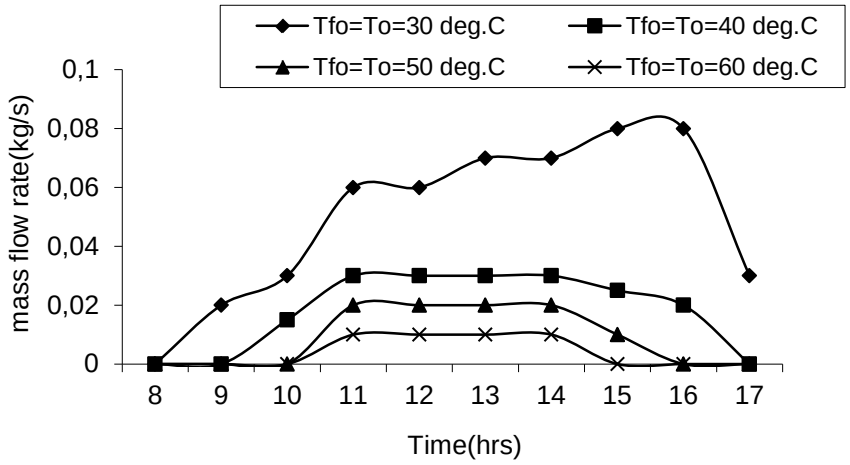

Fig. 5b. Hourly variation of mass flow rate at different outlet temperature for case B.

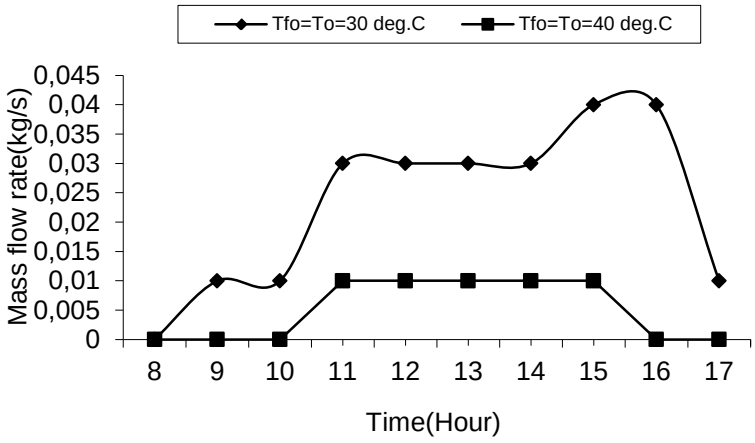

Fig. 5c. Hourly variation of mass flow rate at different outlet temperature for case C.

Fig. 6a and 6b represent the hourly variation of thermal energy gain and electrical energy gain respectively for various configurations of PVT collectors. The figures show that as the

collector area covered by PV modules increases the thermal energy gain decreases whereas the electrical energy gain increases as the collector area covered by PV modules increases.

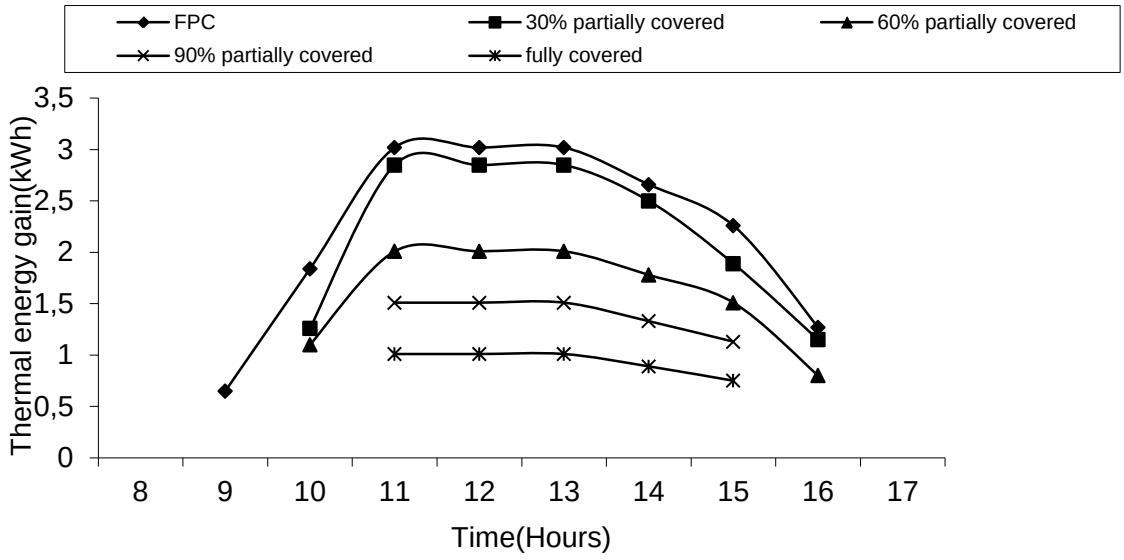

Fig. 6a. Hourly variation of thermal energy gain for different configuration.

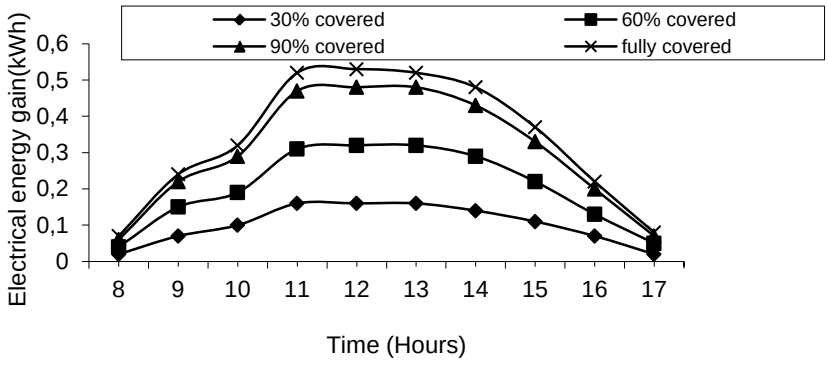

Fig. 6b. Hourly variation of electrical energy gain for different configurations.

4. Conclusion

The maximum thermal energy gain is obtained when collectors fully covered by glass cover; however maximum electrical energy gain is obtained when collectors are fully covered by PV modules.

Abstract: Solar domestic hot water (SDHW) can be used to reduce energy bills and greenhouse gas emissions associated with heating domestic water. However, one of the most significant barriers to further deployment of solar thermal applications is the space and weight required for storage of the energy collected. Phase change materials (PCMs) are advantageous for daily energy storage with SDHW due to their high storage density and isothermal operation during phase transitions, and would overcome these obstacles.

The aim of this paper is to outline the initial steps in the development of a SDHW energy storage system using PCMs, with emphasis on the numerical and experimental studies used to access the phase change and thermal behaviour of the selected PCM. Lauric acid was selected as the PCM based on the melting temperature range which was targeted by studying solar data from an existing solar hot water system in Halifax, Nova Scotia, Canada. Due to the low thermal conductivity of PCMs, additional work is required to develop and validate a design to enhance heat transfer to the storage material using fins. The selected design will be built and installed in an existing large scale solar thermal system on an apartment building in Halifax. The system will be instrumented in order to acquire continuous data (temperatures, flow rates, pressures, etc.) to fully characterize the system.

Keywords: *Latent heat storage, Solar domestic hot water, Phase change materials, Heat transfer enhancement*

1. Introduction

Solar thermal energy for domestic hot water heating is one of the most cost effective and efficient areas of alternative energy exploitation [1]. The use of phase change materials (PCMs) in latent heat energy storage systems (LHESS) can reduce the volume and weight of storage due to their high storage density, and overcome major obstacles in the further deployment of solar thermal energy [1]. LHESS have high energy densities compared with sensible heat storage systems [2], and have been shown to store up to 14 times more heat per unit volume than sensible heat storage materials [3]. Fig. 1 shows a simple schematic of a SDHW system with PCM energy storage.

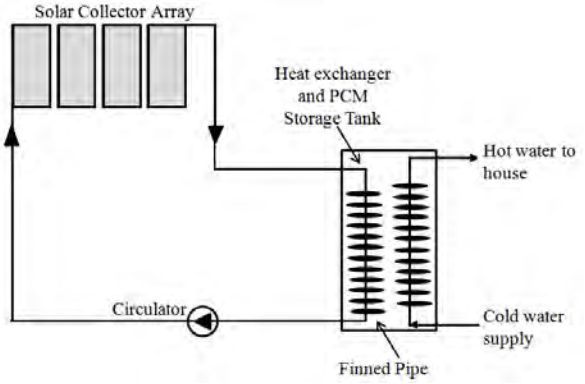

Fig. 1. Schematic of a LHESS for SDHW.

Energy storage using PCMs in combination with solar collectors has been studied mathematically [4] and experimentally [5] and shown to be advantageous. However, missing from previous works is a working prototype of a SDHW system for a large scale application [6].

This paper presents a phase change heat transfer study performed using a PCM, lauric acid, in a small-scale experimental LHESS using fins to enhance the overall heat transfer process. A numerical model was also created and its results are compared and validated with experimental results. Results of this study are to be used in the design of a SDHW system, with the numerical model to be used further in design optimization, mainly for fin configurations, of the LHESS. The resulting LHESS design will be built and installed in an existing large scale solar thermal system on an apartment building in Halifax by Scotian Windfield Inc.

2. Phase Change Material Selection

The PCM is selected based on its phase change temperature range and the operating temperatures of the SDHW system. A melting temperature range of 42 to 48°C and solidification temperature range of 35 to 40°C were targeted by studying the solar data from an existing SDHW system in Halifax, Canada. Several PCMs were considered based on their appropriate melting temperatures, low toxicities, and cost. The most promising materials were tested using a differential scanning calorimeter (DSC) to study their melting and solidification temperature ranges. Salt hydrates (e.g. Glauber's salt and sodium acetate) tested in the DSC showed significant supercooling, which is a common and undesirable phenomenon for these materials [7].

The DSC curve for lauric acid (dodecanoic acid; $CH_3(CH_2)_{10}COOH$; crude [< 80% pure], Fisher Scientific), presented in Fig. 2, shows a melting temperature range of 43.3 to 45.7 °C and solidification temperature range of 38.8 to 35 °C. The DSC curve for this lower purity sample compared well with literature curves for pure lauric acid [8]. Other fatty acids that were tested had either incompatible phase transition regions or toxicities and cost that were undesirable.

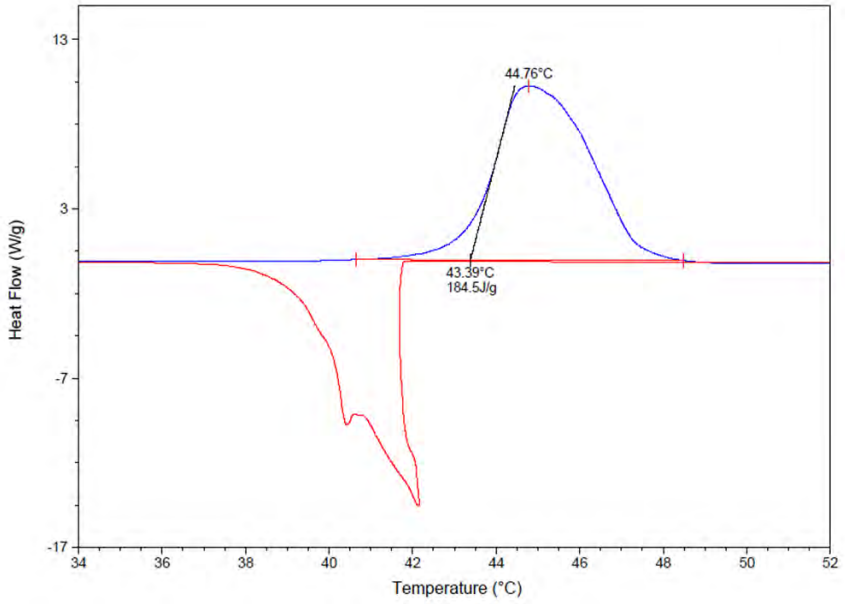

Fig. 2. DSC Curve for Lauric Acid (80% purity) measured at 10 K/min.

Lauric acid was selected based on its melting temperature range, high heat of fusion, minimal supercooling and safety. The material properties are displayed in Table 1.

Table 1. Thermal and Physical Properties of Lauric Acid [8,9].

Molecular Weight	200.31 (kg/kmol)
Density of Powder at 20°C / Liquid at 45°C [§]	869 / 873 (kg/m^3)
Fusion Temperature	42 (˚C)
Latent Heat of Fusion	182 (kJ/kg)
Heat Capacities Solid/Liquid [†]	2.4/2.0 (kJ/kg·K)
Thermal Conductivities Solid/Liquid [†]	0.150[*]/0.148 (W/m·K)
Viscosity [†]	0.008 (Pa·s)

[*] Value obtained from present experiments.
[†] Nominal properties calculated near the melting point.
[§] Density used in the numerical model presented = 880 kg/m^3.

To insure stable properties after many melting/solidification cycles, lauric acid was thermally cycled from 37 to 63 °C. After 800 cycles, there were no obvious signs of degradation. Lauric acid is also safe to use in conjunction with a SDHW system because it is a food grade substance and only a mild irritant [9].

3. Experimental Setup

The experimental setup used to study the melting and solidification behavior of lauric acid in a cylindrical container with horizontal copper fins is shown schematically in Fig. 3a. A Solidworks 3D rendering of the container is shown in Fig. 3b. Eight type T probe thermocouples are connected to a National Instruments 16-channel thermocouple module (NI9213) CompactDAQ data acquisition system. Temperatures are recorded using LabView. Thermocouples are located inside the lauric acid (T2 to T7) as well as on the inlet and outlet (T1 and T8), as seen in Fig. 3a. A pulse counter flowmeter from Omega is connected to a counter/pulse generation module (NI9435) on the DAQ system and read by LabView. The container is made of ¼-inch acrylic plastic and is un-insulated to allow visual study of the system.

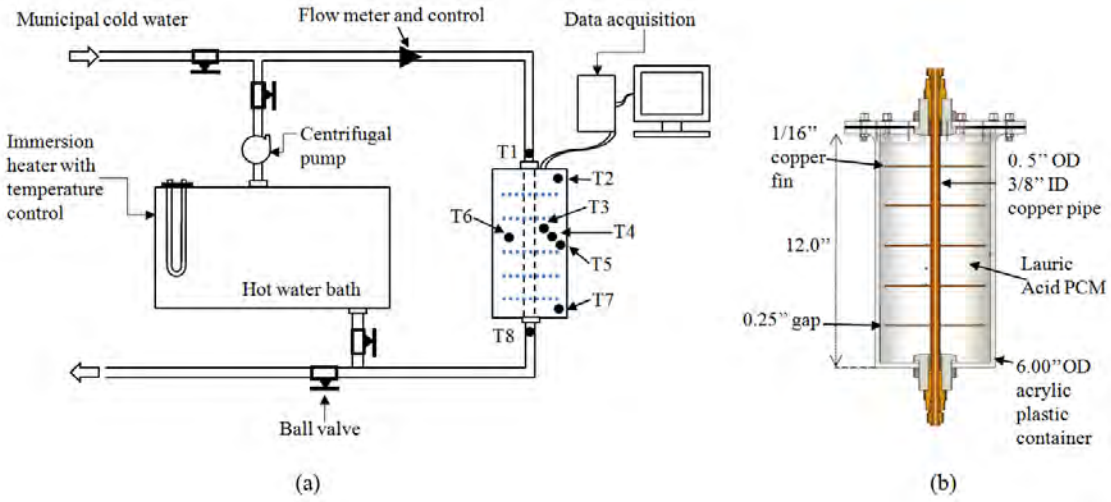

Fig. 3. (a) Schematic of the experimental setup and (b) PCM container.

The conditions under which the experiments were performed are summarized in Table 2.

Table 2. Experimental parameters.

Hot Water Inlet Velocity	1.5 (m/s)
Cold Water Inlet Velocity	3.5 (m/s)
Hot Inlet Temperature	55 ± 1 (^{o}C)
Cold Inlet Temperature	12 (^{o}C)

At the beginning of the experiment, lauric acid was solid in the container at room temperature. Hot water from the constant temperature water bath was pumped through the finned copper pipe, eventually melting the lauric acid. T he charging portion of the experiment was completed when the system reached steady state. At this point, cold water from the municipal water supply was pumped through the system to solidify the lauric acid and recover the stored thermal energy. The experiment concluded when the lauric acid was at room temperature. The results obtained with this setup were compared to results of numerical simulations.

4. Numerical Study

COMSOL Multiphysics (version 4.0a) was used to build a 2D axisymmetric numerical model of the experiment using the *Heat Transfer in Solids* physics to model the copper and lauric acid, and the *Laminar Flow* and *Heat Transfer in Liquids* physics to model the flowing water. The thermophysical properties of water and copper used in the model are those given by COMSOL. For lauric acid, the thermophysical properties used are those presented in Table 1. In this first numerical study, natural convection in the lauric acid was neglected to reduce computing time. An extremely fine mesh was used, with a maximum element size of 2.58×10^{-9} m^2. The following boundary and initial conditions were used:

i. Initial temperature of 295 K;
ii. All outside walls have radiation heat losses to the surroundings and natural convection losses are accounted for on the side wall;
iii. No-slip condition on the inner pipe wall;
iv. Inlet temperature and water velocity as in Table 2;
v. No viscous stress and convective flux at the pipe outlet.

Groulx and Ogoh's method of numerically modeling the melting process was used [10]. The simulated time for melting was 11.5 hou rs, and 10 hour s for cooling. Simulations took approximately 8 hours to run.

In the experimental setup, two thermocouples (T4 and T6) were placed symmetrically between horizontal fins at the same height but spaced 180^{o} apart in order to confirm symmetry in the experiment. In the numerical model, a reference point was added to extract information at this location, as shown in Fig 5.

5. Results and Discussion

5.1. Charging Process (Melting)

Figure 4 presents the temperatures measured experimentally by thermocouples T1 to T8 during the charging process. Refer to Fig. 3 for thermocouple positions.

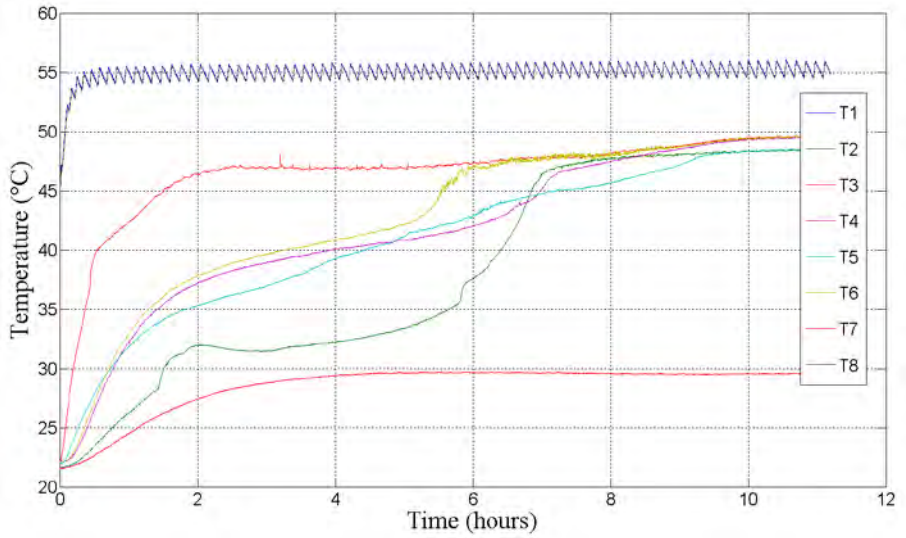

Fig. 4. Experimental temperatures during charging.

The inlet temperature (T1) fluctuates during the charging process due to the emersion heater on/off fluctuations, the outlet temperature (T8) logically follows the same trend. The temperature increases more rapidly close to the pipe and fins (T3), where it takes a longer time for the lauric acid to heat up and melt in regions farther from the pipe, T4 and T6, followed by T5. The region in the upper corner of the container experiences a fast increase in temperature (T2) after 6 hours, mainly due to the onset of natural convection in this region. The lauric acid does not reach the melting temperature in the bottom corner (T7).

Figure 5 shows the numerically obtained temperatures in the system during charging. The black contour line represents the melting interface.

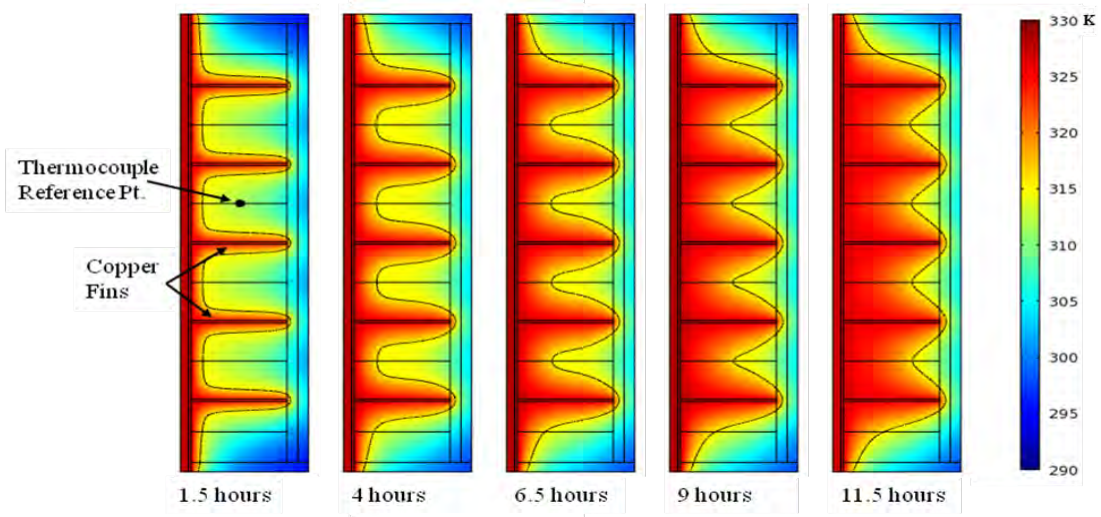

Fig. 5. Numerical temperature plots during charging after 1.5, 4, 6.5, 9 and 11.5 hours.

In Fig. 5, it can be observed that after 1.5 hours the melting process started near the pipe and fin surfaces first, with fairly small temperature increases everywhere else. The heat transfer has been enhanced by adding fins, which is clearly evident by looking at the overall temperature increases far from the pipe. After 11.5 hours of charging, solid lauric acid was still present around the inside wall of the container and in the corners. Experimentally, after 11.5 hours, solid lauric acid was only found in the bottom corners. This difference is thought

to be due to the effect of natural convection in the system, which increases the overall rate of heat transfer.

The experimentally measured (green and blue lines) and numerically calculated (red line) temperatures during the charging process are presented in Fig. 6.

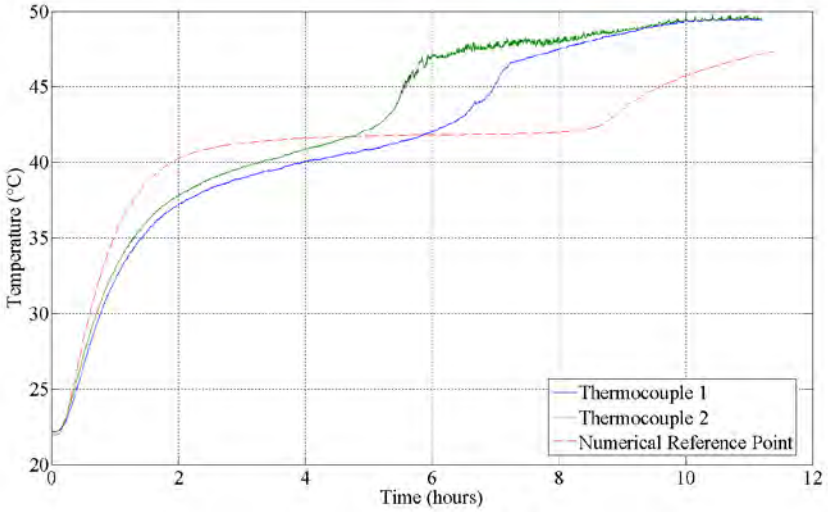

Fig. 6. Numerical validation of melting process in PCM container.

Thermocouples T4 and T6 showed slightly offset temperatures due to asymmetry in the fin assembly which caused one side of the container to heat up faster than the other. Melting occurred between 3 and 8.5 hours in the numerical model. The melting point was reached experimentally after 5 and 6 hours, with fairly constant temperature increases leading to this point; this is consistent with the formation of a mushy region around the thermocouple probes. Complete melting of the lauric acid numerically took longer, possibly due to the lack of natural convection in the model. Experimental results showed a sudden temperature increase in the liquid lauric acid just after melting; this rate of temperature increase in the liquid lauric acid was predicted well by the model.

The numerical model predicted higher effective heat transfer rates initially, leading to a faster temperature increase in the first 2 hours of charging; this is thought to be due to the ideal contact conduction between pipe, fins and lauric acid in the model. In the experimental setup, contact resistances between pipe and fins, as well as between copper surfaces and the solid lauric acid, may have resulted in decreased heat conduction rates at startup.

5.2. Discharging Process (Solidification)

Because of the higher flow rate of cold water used during the discharging process, solidification happened over a shorter period of time than melting: 3.5 hours compared to 11. Figure 7 shows the temperatures in the system during discharging, obtained numerically. The white contour line represents the solidification interface. Solidification of the lauric acid in the numerical model took 4 hours, as seen in Fig. 7.

Figure 8 shows the experimental (blue and green lines) and numerical (red line) cool down temperatures during discharging.

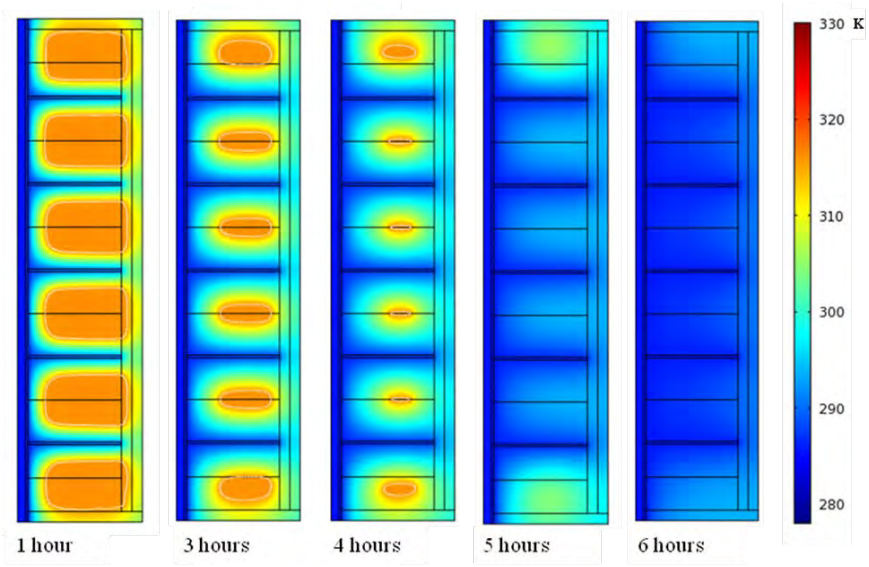

Fig. 7. Numerical temperature plots during discharging after 1, 3, 4, 5 and 6 hours.

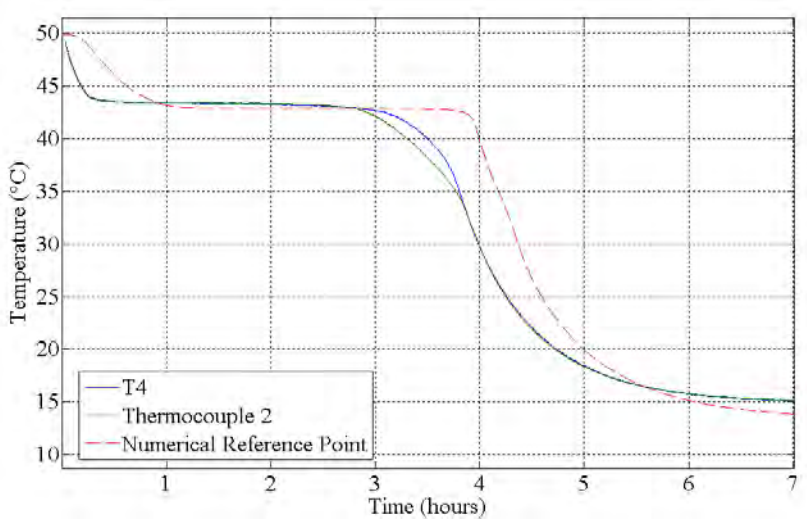

Fig. 8. Numerical validation of solidification process in PCM container.

Of importance to note, the lauric acid solidified at a temperature of 43°C, different from the predicted DSC measurements, which normally have a certain degree of supercooling. Nucleation happened in the first 15 minutes of cooling during the experiment, due to the presence of the thermocouple probes; this cannot be predicted numerically. However, the model does predict a solidification plateau similar to the one observed experimentally, and only slightly over predicts the time required for solidification at that point in the system.

Throughout the experiment, an insignificant amount of volume change from the solid to liquid phase was observed. Lauric acid did react weakly with copper, taking a bluish color in the liquid state; however this mild reaction does not lead to corrosion in any significant form [11].

6. Conclusion

The melting and solidification behavior of lauric acid inside a cylindrical container with a horizontal finned pipe was examined experimentally and numerically. Results for the charging experiment, when compared to the numerical simulations, clearly showed that a mushy region appeared in the system. The presence of natural convection in the liquid melt played a significant role in speeding up the heat transfer and melting process. During

discharging, the numerical results predicted fairly well the cooling and solidifying behavior observed in the experimental measurements; demonstrating that the effect of natural convection during solidification is for the most part negligible.

Abstract: One of the most expensive components of a solar thermal system is the storage tank. Retrofitting conventional domestic hot water heaters when installing a new solar hot water system can decrease the total investment cost. In this study, retrofitting of existing water heaters using forced circulation flow was investigated. A comparison with a standard solar thermal system is also presented. Four simulation models of different system configurations were created and tested for the climate in Lund, Sweden. The results from the simulations indicate that the best configuration consists on connecting the collectors to the existing heater throughout an external heat exchanger and adding a small heater storage in series. For this retrofitted system, preliminary results show that an annual solar fraction of 53% is achieved. In addition, a conventional solar thermal system using a standard solar tank achieves a comparable performance for the same storage volume and collector area. Hence, it is worth to further investigate and test in practice this retrofitting. Furthermore, using the same system configuration, solar collectors can also be combined with new standard domestic hot water tanks at new installations, accessing a world-wide developed and spread industry.

t *Time during stagnation periods……(h)*

1. Introduction

Only in Sweden there exist more than half a million electrically heated single family houses that use conventional water heaters for domestic hot water production [1]. Since the solar tank is one of the most expensive components in a solar thermal system, retrofitting existing domestic water heaters when installing a new system can decrease its total investment cost. Previous research approached similar retrofitting using natural convection systems [2]. Thermosyphon systems became popular in several parts of the world such as Eastern Asia and Australia mainly due to its simplicity and reliability [3]. The thermosyphon driving force depends on the pressure difference and frictional losses between the heat exchanger side-arm and the tank. Hence, the generated flow will be complex function of the state of charge of the tank, the temperature profile along the heat exchanger and pipes, the height difference between the top of the heat exchanger and the top of the tank and the pressure drop in the heat exchanger, piping and connections [4].

Such dependence on the heat exchanger pressure drop and tank characteristics limits how the retrofit is carried out and which storage tanks can be used. Moreover, Liu and Davidson (1995) [5] showed that, when properly designed, forced circulation systems can generally achieve higher performances compared to natural convection driven systems.

In this research forced circulation was used to connect solar collectors to conventional domestic water heaters. This was carried out by means of two pumps, one in the tank loop and the other in the solar collector loop. Four different system configurations were simulated in TRNSYS [6]. Since forced circulation is used, almost any kind of storage tank can be retrofitted when installing a new solar thermal system. For a better understanding of the research contribution to the field and to increase the paper readability, the main objectives of the study are stated bellow:

- To compare the performance of different alternatives on r etrofitting conventional domestic water heaters when installing a solar thermal system;
- To compare the performance of the retrofitted system with the performance of a standard solar thermal system.

2. Methodology

Four different simulation models of the retrofitted system were created in TRNSYS software [6] in order to estimate the configuration achieving the highest performance. A comparison with a conventional flat plate system was also performed. The retrofitted system models range from simple connections to more advanced configurations. However, the complexity was never raised up to a level that would be technically difficult to build such a system in practice. Also, it was avoided to design configurations that would predictably cause such a rise on the investment cost that would be hardly paid back by the increase in energy savings. Some of the systems' details are not revealed due to patent pending. Each system model is made up of a solar collector array, storage tank/s, auxiliary heater, heat exchanger between the collector and the tank loops, circulation pump/s, and radiation processor.

The main boundary of this investigation was to use the most common type of existing heater in single family houses in Sweden. This information is very important for the system design but also very hard to attain. To the best of our knowledge, there is no official data concerning the most common tank size in such houses. According to the Swedish domestic water heater manufacturers, installers and researchers in the field, the most common Swedish single family house tank size is 200-300 litres, depending on the family size. In any case, the tank volume tends to be proportional to the family size. Thus, the trend is that higher loads also correspond to higher available storage volumes and the system design strategy does not change. On the other hand, the average domestic hot water load in single family houses is documented. Preliminary results showed that retrofitting a 300 litre tank for such a domestic hot water load would achieve a higher annual solar fraction than using a 200 l itre tank. Hence, to work on the safe side, it was decided to retrofit a 200 litre tank. If such a system achieves satisfactory performances the same should happen if a 300 litre tank is retrofitted instead.

An auxiliary heater power of 3 kW was used in all models since this is also the most common. The auxiliary heater keeps the top volume of the storage at 60˚C. This is a recommendation of the Swedish building regulations to avoid legionella problems [7]. The same document legislate that it is mandatory that the hot water temperature available at the tap is not less than 50°C. As a design guideline it is recommended that the domestic hot water system can be able to deliver two times 140 litres of 40°C water in one hour [7]. If the temperature setting is increased, all the different simulated systems reach approximately this peak on consumption. In practice, the thermostat is set to 60°C which ensures that ordinary loads are fulfilled. In case of extraordinary large draw-offs, the user has the possibility to steer the set point temperature. This is also normally the case for stand-alone conventional heaters.

The domestic hot water load profile consists on seven different draw-offs during the day. It is a simplification of the hourly profile described by [8] but scaled down to the latest data on the Swedish average hot water consumption of 42 litres/person/day [9]. Simulation results show that using a detailed hour profile would have a minimum impact on the results and would only increase the simulation total time. The measured average cold water temperature in the taps was 8.5°C. The consumption variation during the year was also introduced [10]. The daily and yearly domestic hot water profiles used in the models are shown in Figure 1. The average number of inhabitants in Swedish single-family houses is three [11]. Hence, the domestic hot water annual consumption in these houses was estimated to be 2050 kWh/year.

Since long stagnation periods affect the system's long-term reliability and can cause serious permanent damages on its components [12], the criteria used to design the collector array was based on the maximum solar fraction possible to be achieve under a certain overproduction limit. This deterioration factor was set to 5000 °C.h/year and integrates the number of hours which the collector was under stagnation and how much the collector outlet temperature raised over 100 °C during that period. This was calculated in the following way:

$$\Sigma\ (T_{out}-100)\ t \quad (°C.h) \text{ (during stagnation periods)} \qquad (1)$$

Stagnation period was defined by the time period during which both the top of the storage tank and the outlet collector temperature was above 100°C. During this period the pump on the collector loop is stopped. As shown in equation 1, it was assumed that stagnation time and collector outlet temperatures above 100°C have a linear influence on this parameter. 5000°C.h/year was considered to represent a reasonable practical maximum overproduction. This corresponds to, for example, 100 hours at stagnation where the collector outlet temperature was 150°C. Hence, by means of simulation, the maximum collector area that ensures maximum solar fraction under the overproduction limit was determined for each system configuration at a 50° collector tilt from horizontal. This design criteria is further discussed in the "Results and Discussion" chapter.

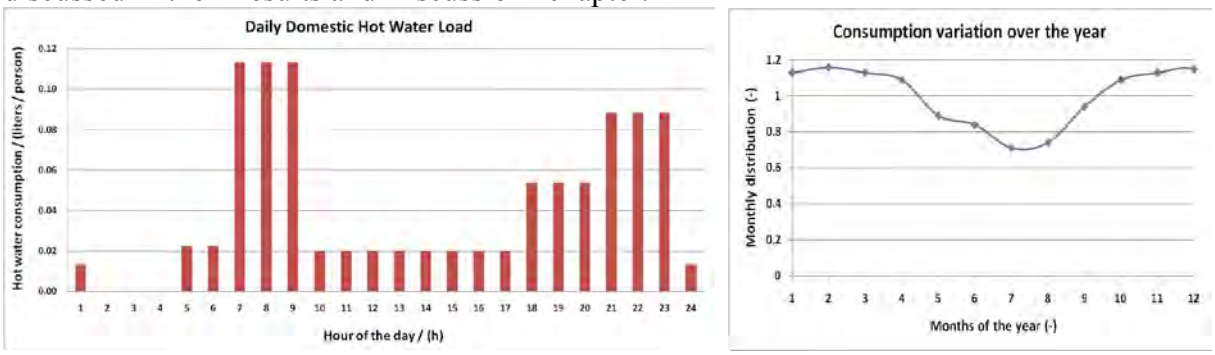

Fig. 1. Daily and yearly domestic hot water profile.

2.1. Standard system

A model of a standard solar thermal system was created and is described by the sketch in Figure 2. The figure illustrates a solar tank with and internal heat exchanger and auxiliary heater. The storage volume is 255 litres in order to match the volume of the retrofitted system that has the best performance (retrofitted system 4, Figure 6). There are three temperature sensors that control the pump, two placed on the tank's surface and the other at the collector outlet.

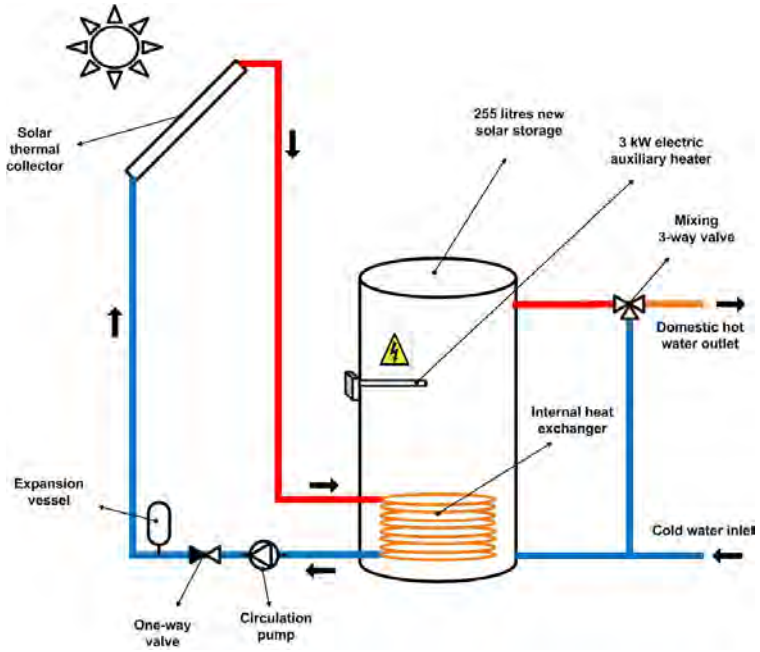

Fig. 2. Sketch of the standard solar thermal system.

2.2. Retrofitted system 1

Figure 3 describes one of the most simple and direct ways of assembling solar collectors to existing tank heaters. The connection is carried out by means of an external side-arm heat exchanger between the collector and the tank loops. Also, two temperature sensors are placed on the tank's surface in order to control both the collector and the tank pumps. As exemplified in Figure 2, solar storages are specially designed for solar thermal applications with, at least, two connections for the domestic hot water and two others for the solar collector loop. On the other hand, conventional tank heaters have only the two connections for domestic hot water (see Figure 3). In order to overcome this technical challenge, the working period of the pump placed on the tank loop must be controlled with the domestic hot water draw-offs so they do not coincide. When no hot water is required, the pump is able to charge the tank. When draw-offs take place, the pump is turned off and the incoming cold water is pressed in the bottom of the tank replacing the outgoing domestic hot water at the top.

2.3. Retrofitted system 2

In this system, a new 3 kW auxiliary water heater is added to the side-arm heat exchanger (Figure 4). Alternatively, if possible, the old auxiliary heater at the bottom of the existing tank can be used. The aim is to achieve stratification in the tank. The heater and the pump on the tank loop are turned on when the temperature in the sensor placed on the top of tank falls below the set point temperature minus the dead band. Consequently, the cold water in the tank bottom flows through the heat exchanger and is heated up in the side-arm heater before entering the top of the tank. The heater is turned off when the temperature on the upper sensor is higher than the set point temperature plus the dead band.

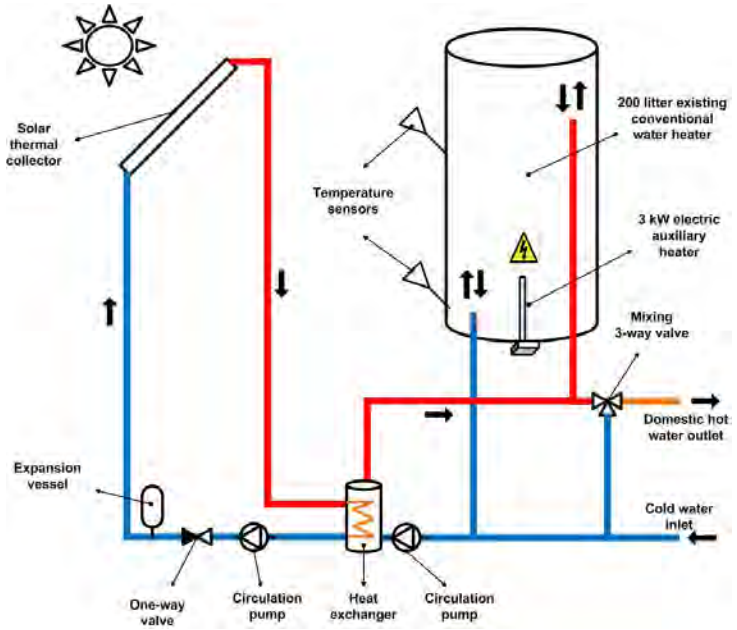

Fig. 3. Retrofitted system 1 - simple retrofitting of existing hot water heaters.

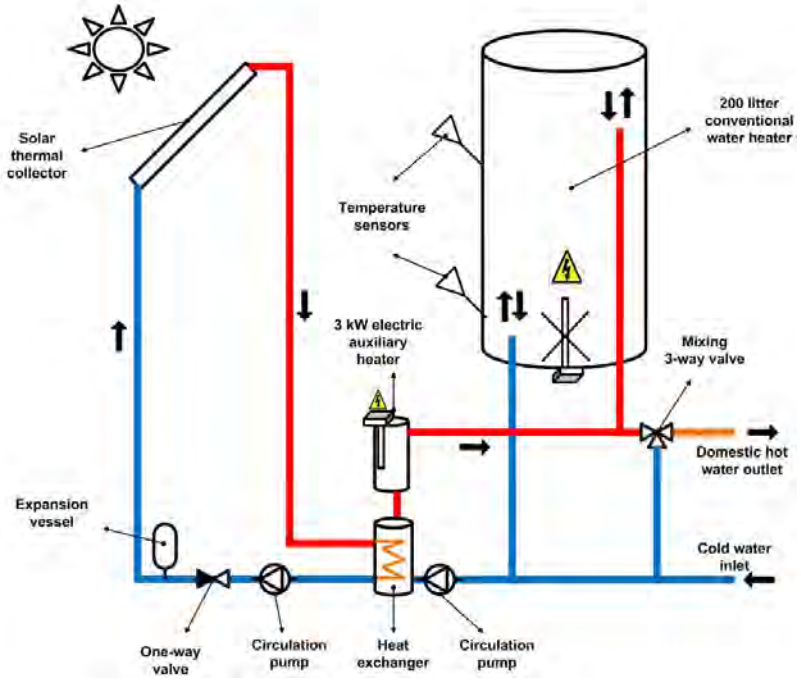

Fig. 4. Retrofitted system 2 - retrofitted system with auxiliary heater on the side-arm.

2.4. Retrofitted system 3

In retrofitted system 3, a small 55 litre auxiliary heater storage was added to the system (Figure 5). This means that the retrofitted storage is exclusively used for solar hot water. The volume of 55 litres was chosen based on design guideline for the domestic hot water load. The 4-way valve was modelled in TRNSYS using type 221 [13]. The valve has three inlets, two from hot sources and one from a cold source. It is programmed in order to use as much water volume as possible from the colder hot source which, in this case, corresponds to the solar storage. Hence, as long as there is available solar hot water in the retrofitted storage at the same temperature or above the domestic hot water load temperature, the water inside the auxiliary heater tank will not be used.

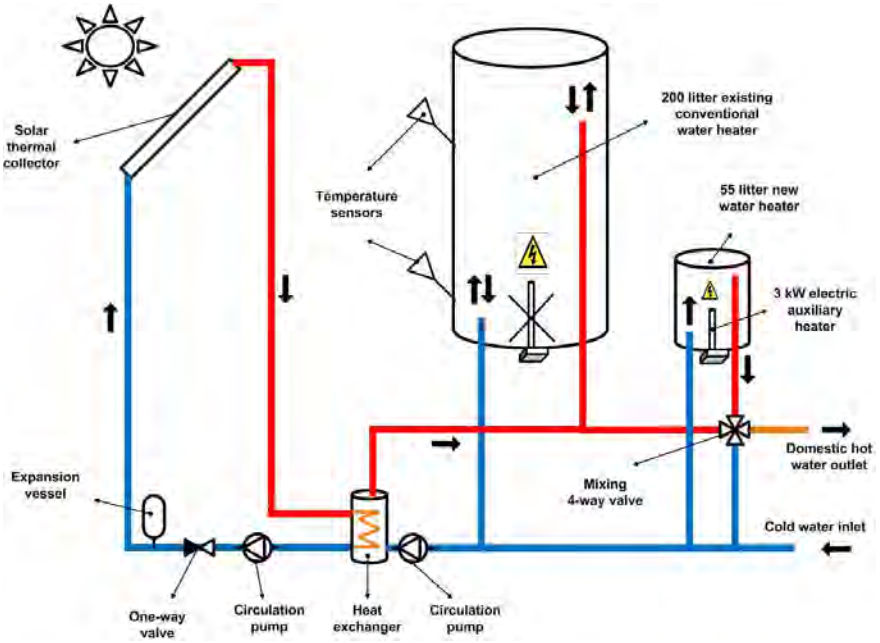

Fig. 5. Retrofitted system 3 - retrofitted system with an additional tank heater connected in parallel.

2.5. Retrofitted system 4

The last retrofitted system consists of connecting the small heater storage to the existing heater in series instead (Figure 6). Thus, when hot water is drawn off by the user, the water at the top of the solar storage is pushed to the bottom of the small heater.

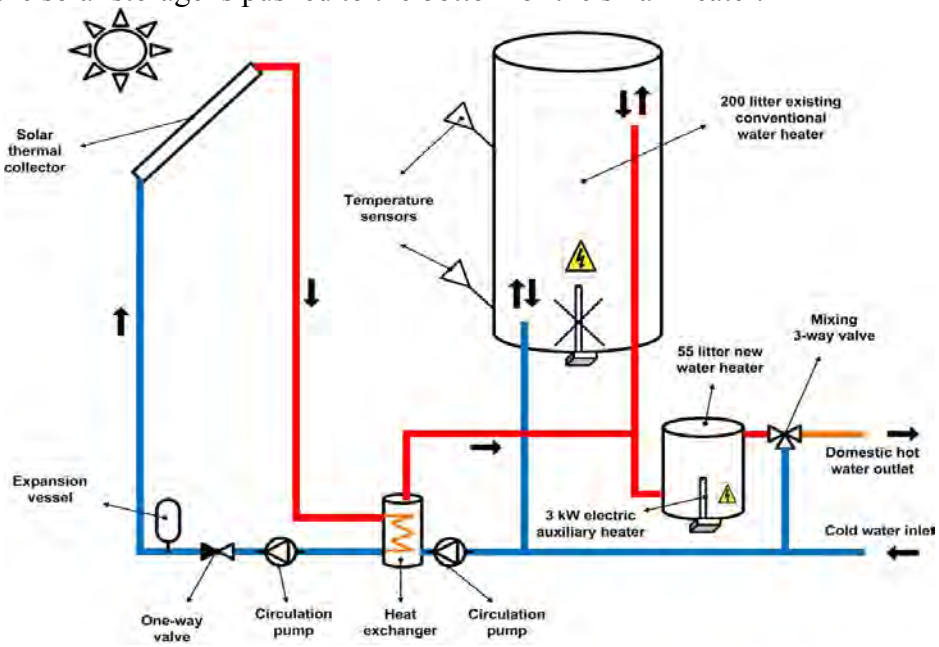

Fig. 6. Retrofitted system 4 - retrofitted system with an additional tank heater connected in series.

3. Results and Discussion

The assumed design criterion limiting the collector area takes into account not only the number of stagnation hours but also the collector outlet temperature. This deterioration factor was set to 5000 °C.h/year. Obviously, this design criterion can be questioned, especially when it comes to the particular chosen number of 5000 °C .h/year. Also, it is uncertain if temperature and time during stagnation periods should have equal weight on t his factor.

Hence, further research is needed to understand how to quantify this factor and what should be its weight on the system design. However, the intention is to take into account a deterioration factor when designing a new solar thermal system. The assumed design guideline should be seen as a first iteration step in that direction. The important analysis at this stage is result comparison between these two different collector systems rather than conclude about the absolute value of the solar fraction results. As both systems were designed in the same way, inaccuracies that occur in one system will occur in the same way in the other one. This makes it significantly more reliable to take conclusions about the systems performances. In a future analysis the system should be design to minimize the costs per produced energy unit.
The simulation results of the annual solar fraction for every system are presented in Table 1.

Table 1. Annual solar fraction of the various retrofitted systems and the standard solar system.

System name	Annual solar fraction (%)
Standard system	52%
Retrofitted system 1	6%
Retrofitted system 2	15%
Retrofitted system 3	42%
Retrofitted system 4	53%

Retrofitted system 1 shows a very low annual solar fraction of 6%. This can be explained by the auxiliary heater placing at the bottom of tank which makes it impossible to establish any tank stratification. In addition, the cold water pushed in the bottom of the tank is directly heated to the set point temperature of 60°C demanding constantly auxiliary energy every time a draw-off takes place. Also, the inlet collector temperature is 60°C practically all year long which decreases the working hours and its efficiency.

In retrofitted system 2 the auxiliary heater is moved to the tank side-arm aiming to increase stratification. The results show that the annual solar fraction increases only to 15%. This is mainly explained by the small stratification increase. In this configuration, the upper volume of the tank is always at least at 60°C while the bottom is fairly cold most of the time. This is because hot water is extracted during the whole day and replaced by cold water at the bottom. Hence, the collector pump works many hours when the collector outlet temperature is higher than the tank bottom but lower than 60°C. Due to the inlets geometry of the retrofitted tank, water heated by the collector is placed at the very top of the tank. Consequently, the tank top temperature will decrease and destroy stratification making the auxiliary heater run during most of the year.

Simulation results of retrofitted system 3 show that the solar fraction increases to 42%. Since it is difficult to achieve stratification with the connections of the retrofitted tank it is more advantageous to place the heater in another tank. This prevents the heater to be turned on almost continuously when the collector is working at temperatures under 60°C. Hence, the retrofitted tank will work at lower temperatures increasing the collector working hours and efficiency. In addition, a new well insulated hot temperature tank provides the extra energy when solar energy is not available. Having the larger tank working at lower temperatures and the smaller tank at higher temperatures, decrease significantly the heat losses. One can say that the system "stratification" is achieved by two tanks with low stratification but working at different average temperatures.
The estimated annual solar fraction for retrofitted system 4 is 53%. The reason why the solar fraction of the series connected system is higher than the parallel connection is not obvious.

The main reason is that, during the summer period when solar hot water is available over 60˚C, the total solar storage volume of the series connected system is increased to 255 litres, since both tanks are connected in series and no auxiliary energy is needed.

4. Conclusions

Four different system configurations on how to retrofit existing domestic hot water heaters were theoretically analysed. The simulation results show that the best configuration for the retrofitting consists on using the existing tank for solar hot water storage and connect it in series with a small auxiliary heater tank. The system annual performance was compared with that of a conventional solar thermal system. Preliminary results show that its annual solar fraction is 53% compared to 52% of a standard solar thermal system with the same storage volume. This means that both system performances are comparable. Hence, it is worth to further investigate and develop this retrofitting in practice. In the future, the model validation and an economical assessment will be performed. If it proves to be cost-effective, this solution can be very interesting since it can be applied not only in retrofitting existing tank heaters but also in combination with new heaters accessing a world-wide industry.

Abstract: Almost all modern solar and wind energy plants can be used only as auxiliary energy sources because of their intermittent character. On the other hand, geothermal systems can produce energy continuously. However, geothermal power plants need expensive wells, and the well will not always give high temperature underground water. It is possible to improve the performance of the plant by combining the different features of these mentioned systems. It is possible to obtain hot water not from drills but by using solar and wind energy installations placed on mobile platforms (travelling energy collectors) that will transport hot water to the power plant, where it will be stored in special tanks. A similar procedure is possible for cold water. To transform thermal energy, stored in the hot water and cold water tanks to electric energy it is possible to use conventional equipment of geothermal power plants. In this paper we give estimations of some parameters of the proposed power generation system based on travelling energy collectors. The estimations show that the power plant based on travelling energy collectors can be considered as a base load source of electric energy.

Keywords: *Solar energy, Wind energy, Travelling energy collector*

1. Introduction

Solar energy and wind energy can be considered as complementary. Solar energy can be captured only during daytime. Wind energy at a height of more than 80 meters is more intensive at night time. In summer it is possible to obtain more solar energy than in winter, and in winter there is more wind energy. So, it is useful to make power plants based on both solar and wind energies.

If we want to create a base load power plant that uses solar and wind energy we also need to store energy for at least some days. The best type of energy storage for such a period is Thermal Energy Storage (TES). Many types of thermal energy storages have been proposed. In this article we will suppose that the TES is based on hot and cold water. Water is the cheapest material and it has high heat capacity.

The proposed solar-wind power plant will work as follows: solar concentrators will prepare hot water for TES, and wind powered refrigerators will produce cold water for TES. Sometimes wind powered heaters can be added to produce an additional amount of hot water. Hot water and cold water from the TES will be used to produce the electric energy with the same equipment that is used for geothermal power plants. The hot water from the TES can also be used for space heating and the cold water can be used for air conditioning purposes.
In principle, the solar concentrators can be placed in a compact area, but the wind power installations must be distributed in a relatively large region because of the turbulences that each installation produces. Moreover, wind speed is higher over the sea surface, and the power plant is to be located on the shore. For these reasons we propose Travelling Energy Collectors (TEC) that will collect solar and wind energy on the sea surface and transport this energy in the form of hot and cold water to the power plant. The distance of transportation (or service radius) will depend on economical considerations and can vary from some kilometers to many tenths of kilometers.

2. Methodology

2.1. Power plant based on travelling energy collectors

The scheme of the power plant based on travelling energy collectors (TEC power plant) is shown in Fig.1.

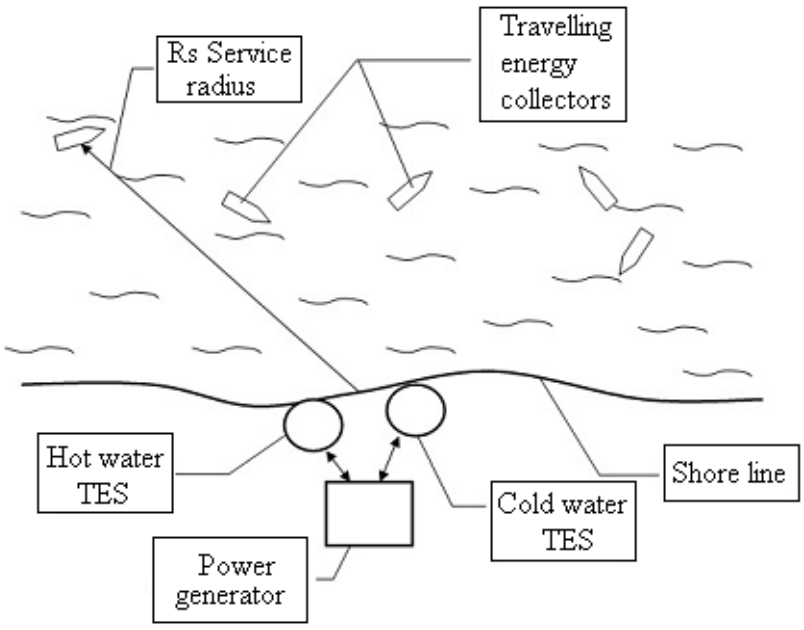

Fig. 1.Power plant based on travelling energy collectors.

It contains a power generator, hot water TES, cold water TES, and a multitude of thermal energy collectors (TECs). The TECs collect the solar and wind energy from the circular segment that has radius R_s, transform these energies to the hot water and cold water, and transport them to the hot water TES and cold water TES. The water from the hot water TES is supplied to the vapor generator that produces energy in the heat engine with the Organic Rankine Cycle (ORC). This type of engine is used for geothermal power plants. The water from the cold water TES is used for heat engine cooling. The Carnot efficiency of the power generator will be:

$$\eta_c = (T_h - T_c)/T_h \qquad (1)$$

where T_h is the temperature of hot water and T_c is the temperature of cold water. The total efficiency of the power generator will be:

$$\eta = \eta_c \cdot \eta_r \qquad (2)$$

where η_r is the relation of power generator efficiency to its Carnot efficiency. For ORC heat engines η_r usually has the values in the range of 0.5 – 0.67 [1]. In this article we will use a value η_r = 0.55.

If the temperature of the hot water is 90° C and the temperature of the cold water is 5° C, the efficiencies of the power generator will be:

$$\eta_c = 0.234, \quad \eta = 0.129 \qquad (3)$$

If we put the hot water TES at a depth of 50 m below the sea surface to obtain overpressure of 5 bar, it will be possible to increase the hot water temperature up to 140° C. The temperature of the cold water can be decreased down to – 20° C, if we use an ice-water mixture of salted water. In this case the power generator efficiencies will be:

$$\eta_c = 0.387, \quad \eta = 0.21 \qquad (4)$$

The efficiency 0.21 is at the level of the highest efficiencies of silicon photovoltaic panels, but in our case the power generator can supply the energy continuously.

2.2. Travelling energy collectors

A travelling energy collector (TEC) will be made as an unmanned sail catamaran. The scheme of the TEC is presented in Fig.2.

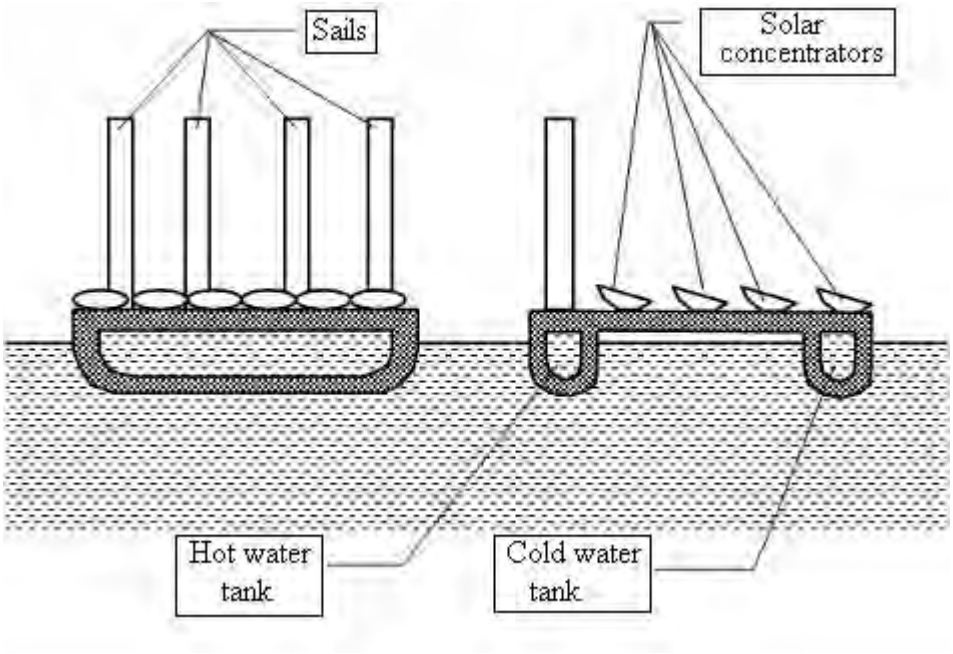

Fig.2. The scheme of the TEC.

The TEC contains sails, solar concentrators, small wind turbines, hot water tank and cold water tank. There are different types of maritime wind collectors. Some of them contain large wind turbines on the ship, others use the sails to move the ship, and submerged water turbine produce the electric energy [2].We propose to use small wind turbines, because large wind turbines have large weight, and the scheme containing the submerged water turbine has low efficiency. Small wind turbines can be placed into the sails (Fig.3).

In this case the film roll and the rope roll will be placed in the leading edge of the sail. When the TEC is working in the mode of wind energy collection, the sail film is wound to the film roll and small wind turbines are open for the wind. If the sail is to be used to move the catamaran, the ropes will be wound to the rope roll. These ropes run around the rear roll and pull the film from the film roll to close the wind turbine space and to form the sail air foil. The TEC will work in solar energy mode in the presence of direct solar radiation; otherwise it will work in wind energy mode, in transport mode, or in discharge mode.

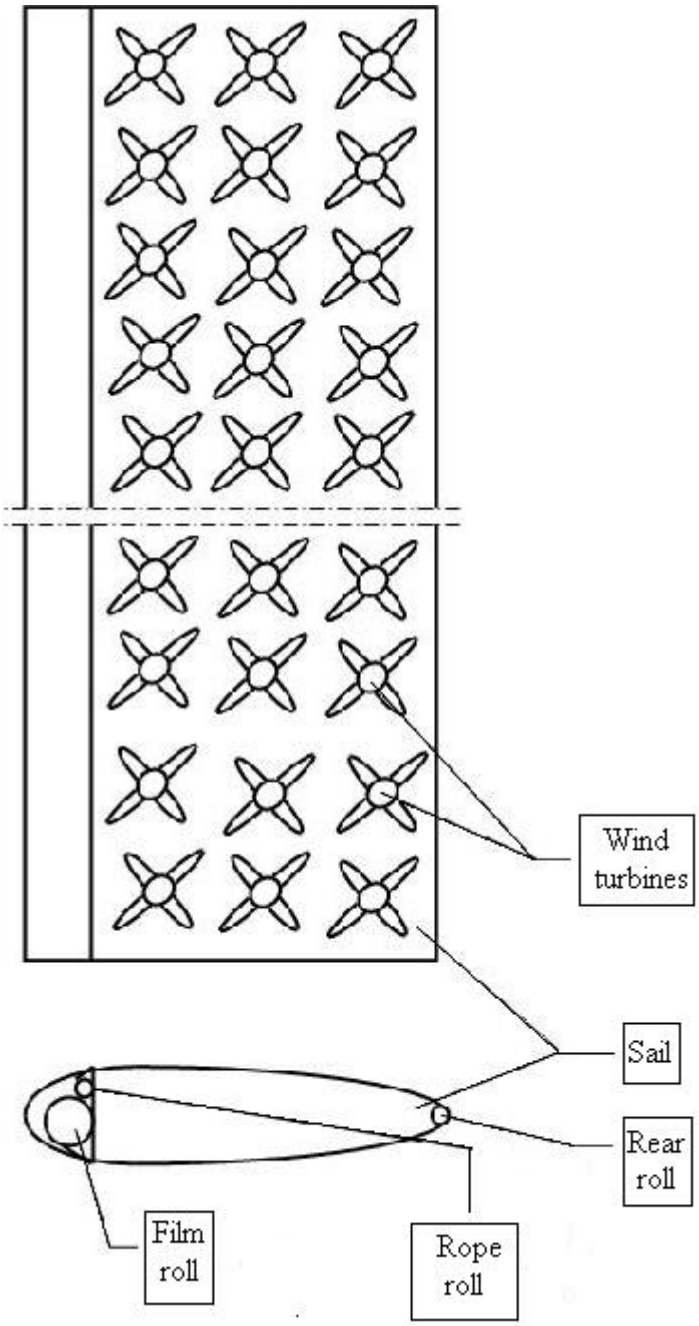

Fig.3. Small wind turbines.

In the solar energy mode the solar collectors will heat the water in the hot water tank. In the wind energy mode the energy from the wind turbines will feed the chiller to cool the ice-water mixture in the cold water tank and increase the amount of ice in the mixture. The approximate proportion of hot water energy to the cold water energy is:

$$E_h / E_c = T_h / T_c , \qquad (5)$$

where E_h is the energy of the hot water stored in the hot water tank, E_c is the energy of the ice-water mixture stored in the cold water tank, T_h is mean temperature of the hot water tank, and T_c is the temperature of the cold water tank.

The hot-water energy can be calculated using the equation:

$$E_h = M_h \cdot C_w \cdot (T_{h1} - T_{h2}), \quad (6)$$

where E_h is the hot water energy, M_h is the hot water mass, C_w is specific heat capacity of the water, T_{h1} is the temperature of the hot water after the heating in the solar concentrators, T_{h2} is the temperature of the hot water before heating in the solar concentrators.
To calculate the cold water energy we will use the following equation:

$$E_c = M_i \cdot q_i, \quad (7)$$

where E_c is the cold water energy, M_i is the mass of the ice in the ice-water mixture, and q_i is the latent heat of ice melting.

3. Solar Concentrators

Low-cost light-weight solar concentrators are needed for travelling energy collectors to heat the water in the hot water tank. At present we are developing these concentrators [3]. Each concentrator will contain a multitude of flat triangular mirrors that approximate a parabolic surface. A prototype of the support frame for the mirrors is shown in Fig.4.

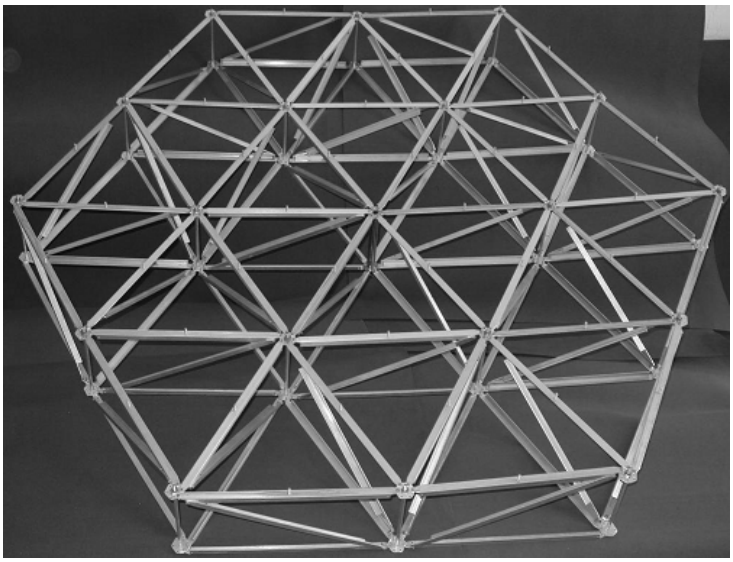

Fig.4. Support frame for the mirrors of solar concentrator.

The cost of mass production of these concentrators can be as low as 50 dollars for square meter of mirror surface [4].

3.1. Solar energy mode

The travelling energy collector will work in the solar energy mode in the presence of direct solar radiation. Let the TEC have a deck area of 1000 m^2. In this case the total area of solar concentrators can be approximately 500 m^2. Let us suppose that 1 m^2 of solar concentrator produces 700 Wt of heating power (concentrator efficiency is 0.7), and direct solar radiation is present during 4 hours per day. In this case the hot water will obtain the energy of

$$E_h = 504 \cdot 10^7 \text{ J/day.} \quad (8)$$

Let the initial temperature of hot water be T_{h2} = 403° K, the final temperature of hot water will be T_{h1} = 423° K. In this paper we will consider a TEC that discharges the hot and cold water each day. Using equation (6) it is possible to calculate the mass of hot water needed to store the heat energy in the hot water tank. In our case we will have:

$$M_h = 60000 \text{ kg} = 60 \text{ ton,} \quad (9)$$

3.2. Wind mode

In the nights and during cloudy days the TEC will work in the wind mode. For this purpose the TEC is to be oriented perpendicular to the wind speed, the sails are to be opened, and small wind turbines will produce the electrical energy for the ice machine. The ice machine will increase the amount of ice in the cold water tank. Using equations (5) and (8) we obtain:

$$E_c = E_h \cdot (T_c / T_h) = 504 \cdot 10^7 \cdot (253/413) = 308 \cdot 10^7 \text{ J/day} \quad (10)$$

Here we suppose that T_c equals – 20° C and T_h equals 140° C.
The power of wind turbines can be evaluated using the equation:

$$P_t = \eta_t \cdot S_t \cdot (\rho \cdot u^3)/2 \quad (11)$$

where η_t is turbine efficiency, S_t is the total area of the small wind turbines, ρ is the air density, and u is the wind speed. In this paper we will assume that η_t = 0.3, S_t = 500 m^2, ρ = 1.25 kg/m^3 and u = 8 m/s. In this case we will have:

$$P_t = 48000 \text{ Wt,} \quad (12)$$

We will suppose that the transport and the discharge modes will take 3 hours per day. The solar mode takes 4 hours per day, so the wind mode will take 17 hours per day. Not all this time will be used for power generation, because the TEC has a drift that must be periodically compensated. For drift compensation the sails are to be closed as for transport mode and the TEC is to be moved against the wind. We will assume that drift compensation will take 30% of the total time in the wind mode. The power generation in the wind mode will take t_g = 11.9 hours per day. The energy generated by the wind turbines will be:

$$E_t = P_t \cdot t_g \cdot 3600 = 206 \cdot 10^7 \text{ J/day,} \quad (13)$$

If coefficient of performance of the ice machine is 1.5, the total cooling energy produced in the form of ice will be E_c = 308 * 10^7 J/day. This is sufficient to obtain the balance of heating and cooling energies in the power plant. To store this amount of energy it is necessary to produce the following mass of ice:

$$M_i = E_c / q_i, \quad (14)$$

where E_c is the cooling energy, q_i is the latent heat of water freezing. Water has the value of q_i = 332 kJ/kg. For our example M_i will be:

$$M_i = 9300 \text{ kg}. \quad (15)$$

We will assume that the mass of the ice-water mixture is:

$$M_{iw} = 40000 \text{ kg} = 40 \text{ ton}, \quad (16)$$

In this case the total weight of hot water and cold water in the tanks will be 100 ton.
Different geographic areas have different relations between the amount of solar and wind energy, thus for each area different parameters of the power plant should be selected. The main parameter is the cold-water tank temperature. Increasing this temperature, it is possible to decrease the amount of wind energy to obtain good balance for example in tropical areas, where the wind energy can be relatively poor.

3.3. Transport and discharge modes

In transport mode the sails move the TEC from the power plant and after collection of energy return it to the power plant. The maximum distance of movement is:

$$R_s = t_{tr} \cdot u_{tr} / 2, \quad (17)$$

where R_s is the service radius of the power plant, t_{tr} is the time of the transportation mode, u_{tr} is the transportation speed. In our example t_{tr} = 2 hours. If the transportation speed is 10 km/h, the service radius will be:

$$R_s = 10 \text{ km}. \quad (18)$$

In the discharge mode the TEC discharges the hot water to the large hot-water tank of the power plant. The temperature of the discharged water is T_{h1}. After this the TEC loads its hot water tank from the large hot-water tank of the power plant with water that has the temperature T_{h2}. In parallel the ice-water mixture that contains M_{i1} kilograms of ice is discharged to the large cold-water tank of the power plant and a new ice-water mixture that contains M_{i2} kilograms of the ice is loaded to the small cold-water tank of the TEC.

3.4. TEC number

One TEC produces the energy of 504 * 10^7 J / day. This corresponds to a mean power P_{TEC} = 58330 Wt. If we want to create a power plant of power P_{pp}, we need the following number N_{TEC}:

$$N_{TEC} = P_{pp} / (P_{TEC} \cdot \eta), \quad (19)$$

where P_{pp} is the output power of the power plant, P_{TEC} is the power of one TEC, η is the efficiency of the power plant. If P_{pp} = 10 MWt, η = 0,21, we need:

$N_{TEC} = 816.$ (20)

This calculation shows that each TEC cannot be driven by an operator. It must be made as an autonomous robot, and its cost is to be as low as possible.

4. Discussion

A power plant for continuous electrical energy supply is proposed. In this power plant the conventional equipment from geothermal power plants is used for electricity generation. Instead of drilling deep wells to obtain hot water we propose the use of moving platforms (TECs) that contain solar concentrators for hot water production and small wind turbines for cold water production. Moving platforms transport the hot and cold water to the power plant located on the sea shore. Approximate calculations show the feasibility of this system.

5. Conclusion

Travelling energy collectors will permit solar and wind energy collection from sea areas near the shore, transform it to heat energy and store in hot water and cold water thermal energy storages. These storages will permit continuous energy production using the equipment of geothermal power plants. The travelling energy collector will be implemented as a catamaran with sails that include a multitude of small wind turbines. The solar concentrators will be placed on the deck of the catamaran. The catamaran will contain a hot water tank and a cold water tank to transport the heat energy to the power plant. It is necessary to make a large number of travelling energy collectors for one power plant. For this reason the catamaran must have an autonomous control system that will allow operation without human interaction.

Abstract: A daylight concentrating and transmission system via plastic fibers based on dual axis sun tracker to lighting indoor has been built and investigated. The sunlight tracking and concentrating platform adopting horizontal coordinate system combined with photosensitive sensor can realize high position resolution. A sunlight concentrating and transmission experiment has been carried out using 6m long PMMA plastic fibers based on that platform. It is found that color temperature of light transmitted by fibers is 600K lower than that of nature light. The spectrum of light transmitted by fibers is similar to that of nature light. This similarity also exists in chromaticity coordinate, color rendering index, dominant wavelength between light transmitted by fibers and nature light. A quantitative determination of flux loss has been carried out and the results show that there is an attenuation about 2db existing on the interface of fiber.

1. Introduction

The daylighting system is an optic-mechanical-electric technology that collects day light outside to transmit into basement and room lacking nature light by fibers in high concentrated level [1-2]. The infrared portion of solar radiation has been separated and eliminated by lens and fibers so that the output flux is a cool light. There are two major benefits from daylighting. The first benefit is the reduction in purchased electricity needed to light the building, and the second benefit is a reduced cooling load due to the high efficiency of light. Another potential benefit of daylighting is the advantageous factors for healthy of natural lighting but this effect is difficult to quantify. The excellent color rendering properties of daylight and its close match to the photopic response of the human eye make it an ergonomic light source that is generally preferred for pleasant working conditions[3-4]. There are two types of daylighting systems including light guide pipe and fibers. The latter is the research hotspot at present due to its smaller and few penetrations on the roof which means saving on the building's heating, cooling, and maintenance bills. T he purpose of this particular study is to evaluate the feasibility and performance of the technology. The day light concentrating and transmission system via fibers consists of a two-axis sun tracker and concentrating collector that gather direct normal solar radiation into the fibers. The key to realize stable flux output is high precision sun tracking which need a trade-off with fabrication cost[6]. And, at the present time, the optical parameters of sunlight transmission system via fibers have not get adequacy quantitative determination. Those problems provide the investigation motivation of this

research work. According to the structure forms, there are two ways of focalization including optical fiber bundle and single fiber. For the former, concentrator with large diameter is used to produce large focal spot, and so it can use optical fiber bundle to receive the concentrated radiation[7-9]. For the latter, the concentrator is lens with small diameter which produces small focal spot only suiting for single fiber. It is critical to obtain high accuracy position tracking in respect that small focus error will cause a large amplitude reduction of out flux due to single fiber's small diameter. Although much research has been devoted into sunlight concentrating and transmission system via fibers, there are still lots of problems and unknown characterizes awaiting solutions, such as quantitative study of the spectrum of output light. In order to try to answer above questions, a dual-axis sun tracking system has been investigated by the combined use of horizontal coordinate system and photosensitive sensor designed specially, based on that corresponding research has been done.

2. Dual axis sun tracking and concentrating system

2.1. Configuration of hardware

The system mainly is composed of support, reducing gears, motor, lens and control module. It must be emphasized that small deviation of focusing spot will lead to significant instability attributed to no light preserved module existing in the daylighting system. To satisfy above strict demand, orbit calculation method and optical sensing method are integrated into control flow. The prototype of the dual axis tracking and concentrating system is shown in Fig 1.

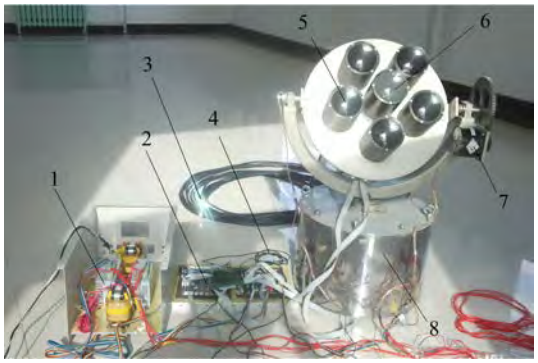

Fig. 1. Double-axis sun tracking system

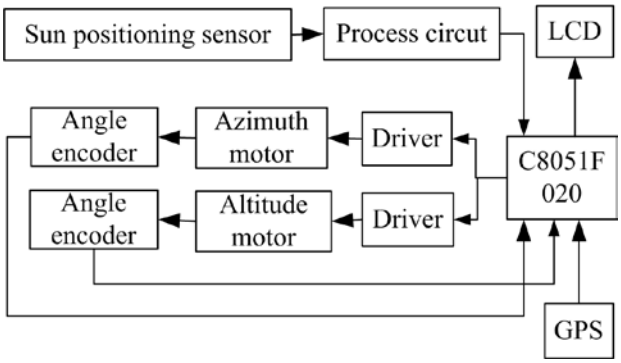

Fig. 2. Control system frame

In fig.1, the components numbered are step motor drivers, control board, plastic fibers, GPS module, lens, sun positioning sensor, altitude motor, substructure for installing azimuth motor successively. In practical, it is too difficult to realize accuracy positioning about 0.1° only depending on orbit calculation due to the varied limits, such as installation error and gravity deformation, et al, although it is possible in theory. The misalignment between geodetic coordinate and device coordinate led by installation error and gravity deformation will result in an inevitable calculation error in sun position[10]. So an optical sun positioning sensor is designed specially to eliminate the error accumulation and initial error, which uses photosensitive elements array to sensing the location of the focusing spot generated by lens. By comprehensive utilization of two methods, it is able to realize stability and high precision profit from orbit calculation method and sun optical positioning sensor respectively. The control system is designed to work automatically. Step motors are used to drive the tracking action and angle encoders are applied to feedback the real angle information of the mechanical components. Global positioning system module is adopted to provide exact time and latitude and longitude which are the parameters to calculate the sun position. With the help of GPS module, the tracking system can figure out the sunrise and sunset time to realize full automatic tracking without manual operation, meaning remarkable reduction of

maintenance. For convenience, a LCD display screen is installed to show real-time working state. Plano convex lenses made of K9 optical glass are adopted to concentrate sunlight which has a transmission coefficient that is no less than 0.9 at visible spectrum range. It is no cooling problem for lenses and fibers because there is nonexistence of hot spots due to their high transparency. Performance parameters of the hardware have been described in tab 1. To facilitate the precision drive, sinusoid subdivision drivers are used to improve step motors to achieve 12800 pulses per cycle, about 0.028°/pulse. In addition, gear pairs are applied to further improve the fine adjustment; however nonlinearity caused by gear clearance emergences isochronously. To ensure stable tracking, it is needed to introduce intelligent algorithm to compensate the nonlinearity. For instance, database is recorded in the program memory to distinguish different situations of nonlinearity. The concentrator is convex lens made of super white glass which transmittance is 0.92. According to the sun's

Table.1 Parameters of double-axis sun tracking and concentrating platform

Name	Unit	Amount	illustration
Torque of azimuth motor	N.m	3.6	Step motor
Torque of altitude motor	N.m	1.2	Step motor
Reduction ratio of azimuth		1:3	Straight gear
Reduction ratio of altitude		1:5	Straight gear
Tracking type			Orbit and optical sensor
Tracking accuracy	°	±0.15	
Range of altitude	°	0～90	
Range of azimuth	°	0～360	
Diameter of lens	m	Φ0.1	K9 material
Focal length	mm	180	Adjustable
Concentration ration		900-10000	Adjustable
Transmittance of lens		0.92	Visible band

2.2. Control method

As for the optical sun positioning sensor, it is used to detect detailed deviation and feedback the signal to microcontroller to realize exact tracking. The most important advantage of the optical sun positioning sensor is the ability to eliminate the error accumulation caused by errors from motor or reducing gears. The optical sun positioning sensor is good at dealing with error accumulation but bad at anti-climate impacts while the orbit calculation method is opposite. So it is wise to adopt combined utilization of both methods to obtain good tracking accuracy and anti-interference ability meanwhile. The flow chart of sun tracking process is shown in Fig 3. Because of complexity in practice, the flow chart has more fine regulation actions than that listed out in Fig 3.

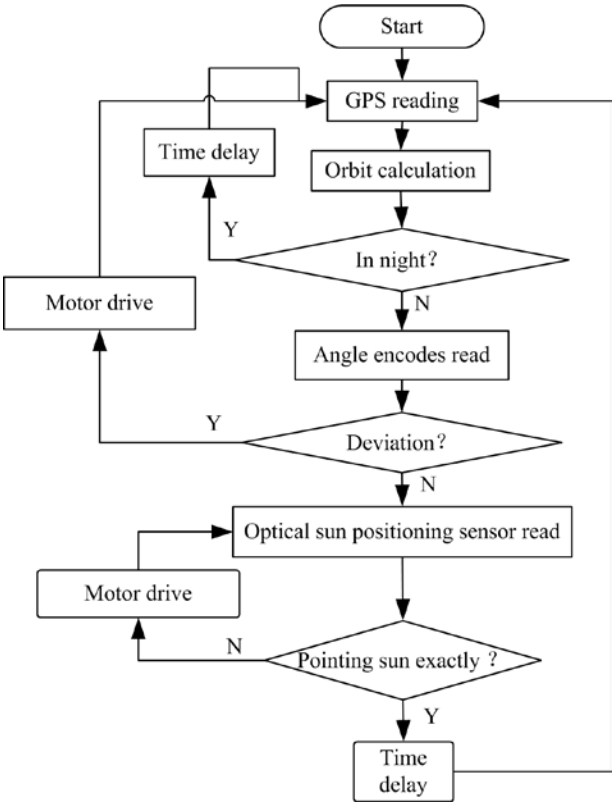

Fig.3. Control flow chart of sun tracking process

3. Plastic fibers

The diameter of fibers used for concentrated sunlight transmission is flexible and two orders of magnitude higher than that of fibers used for distant communication, whose range is 1-6mm generically. The materials of fibers include polymethyl methacrylate(PMMA), polystyrene and special quartz. Light attenuation is severe, about 0.25db/m, only suiting for close distance transmission not longer than 30m. Some parameters of the fibers tested in the work are described in Tab 2. The fiber tested in this research is made of PMMA, and has absorption peaks in 620nm and 705nm which is shown in Fig 4. The advantages of PMMA fibers are flexible and big numerical aperture which is very in favor for light focusing. Unfortunately, the upper limit for work temperature is only $70^{o}C$ which restricts the upper limit of concentration ratio, about 2500 without water cooling. But this upper limit could be extended to 10000 for quartz fiber which is used in solar furnace.

Table.2 Parameters of PMMA fibers

Name	Unit	Amount	illustration
Diameter	mm	2.5	
Length	m	6	
Numerical aperture		0.5	Ranger of angle of incidence is ±30°
Average attenuation	db/m	0.25	380nm～760nm

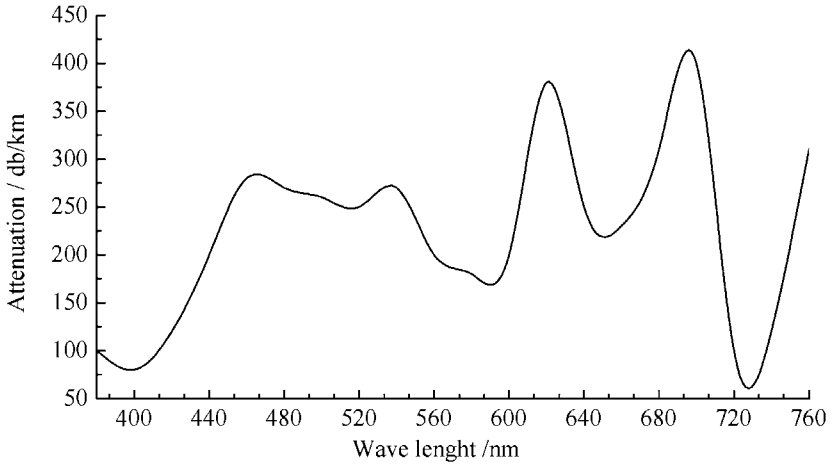

Fig.4. Curve of intrinsic attenuation of PMMA fibers

4. Results

The experimental system consists of the dual axis tracking and concentrating system, fibers, illuminometer and HAAS-2000 spectral radiometer, as in Fig 5. A sunlight concentrating and transmission experiment lasted for 9 hours has been carried out using 6m long PMMA fibers .

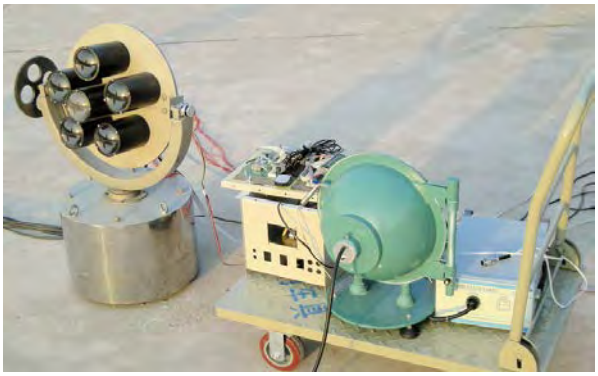

Fig.5 Optic testing system of concentrated sunlight transmission system

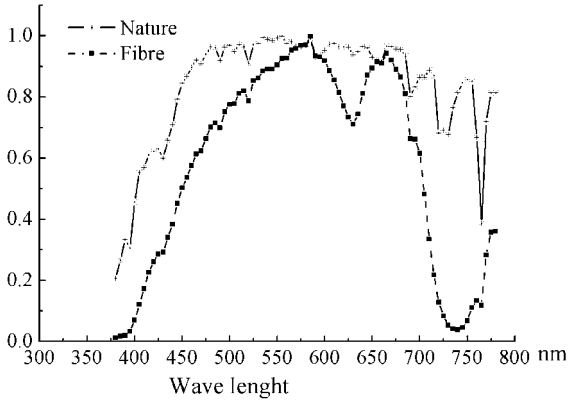

Fig.6 Spectrum comparison of nature light and light transmitted by fibers in visible band

The spectrum of light transmitted by fibers is similar to that of nature light, as shown in Fig 6. Although the deviation between two curves is evidence in 705nm led by absorption peaks of fibers, it influences the visual perception slightly because it is away from green band which is most sensitive for eyes. This similarity also exists in chromaticity coordinate, color rendering

index, dominant wavelength between light transmitted by fibers and nature light, as described in Tab 3.

Table.3 Parameters comparison between nature light and light transmitted by fibers

Parameters	Light out fibers	Daylight	Difference
Color temperature	4444K	5037K	-11.8%
Dominant wave length	571.6nm	569.4nm	+0.4%
Peak wavelength	585nm	538nm	+8.7%
Width of half wave	255.8nm	360.6nm	-29%
Color coordinate X	0.3688	0.3446	+7%
Color coordinate Y	0.3972	0.357	+11.2%
Color rendering index	88.9	99.3	-10.5%
Red light ratio	17.9	18.8	-4.8%

As identified in Tab 3, the flux transmitted through fibers is approximate to nature light, so it can satisfy the need of drawing office, indoor plant cultivation and shady bedroom.
As for the transmission loss, it is consists of three parts which are intrinsic loss, loss on end faces of fibers and loss led by bend. Among them, the intrinsic loss is a constant while loss on face is a large variation, determined by roughness mainly. In fact, the loss on face takes an essential ratio of total loss. So it makes sense to make certain that how much loss on face is. A experiment for determining the value of loss on face is designed, which separates the intrinsic loss from total loss by a series calculations.
For fibers without bend, we have

$$P_{out}(z) = P_{in}(0)e^{-\lambda z}e^{-\gamma}$$

Here $z = 6m$. As for the total η, it can be described as followed

$$\eta = 10\lg\frac{P_{out}(z)}{P_{in}(0)} = -10(\lambda z + \gamma)\lg e$$

Traditionally it is a custom to use decibel in attenuation analysis, so we have

$$\begin{cases}\overline{\lambda} = (10\lg e)\cdot\lambda \\ \overline{\gamma} = (10\lg e)\cdot\gamma\end{cases}$$

It is easy to get following conclusion after a further derivation

$$\begin{cases}\eta = -\overline{\lambda}z - \overline{\gamma} \\ \overline{\gamma} = -\eta - \overline{\lambda}z\end{cases}$$

$\overline{\lambda}$ is a constant known as $0.25\,db/m$ and $P_{out}(z)$ can be measured by integrating sphere and spectroradiometer while $P_{in}(0)$ can be worked out by the following formula

$$P_{in}(0) = I \cdot \pi D^2 / 4$$

Measured data of luminance outdoor and output flux of fibers is shown in Fig 7. Two curves are anastomotic through one day.

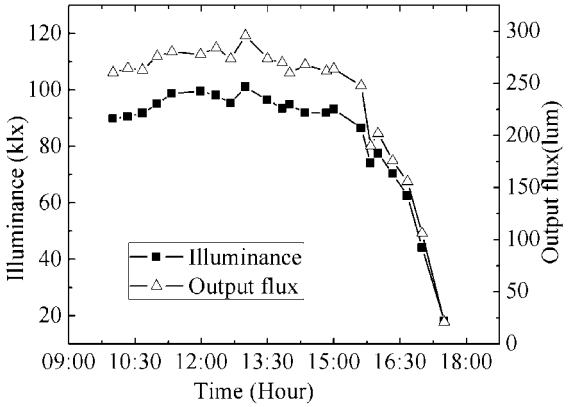

Fig.7 Corresponding relation of illumination outside and output flux of fibers

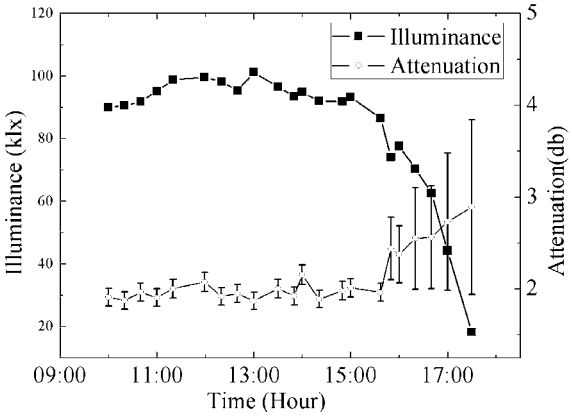

Fig.8 Corresponding relation of illumination outside and attenuation on interface

From measured data recorded in Fig7, the loss on face can be calculated out as shown in Fig 8. The loss on face can be regarded as a constant about 2db approximately which is accord with the optical principle. As to the increasing after 16:00pm, it can be explained that scattering radiation takes more and more proportion in total sunlight and this scattering radiation cannot be focusing onto the fibers, so above formulas in this situation produce large result.

5. Conclusions

Combination of orbit calculation method and sun optical positioning sensor posses accuracy and stability simultaneously in sun tracking which is the key to ensure the output flux of fibers stable. Different from solar thermal and photovoltaic application, there are no measures to storage nature light and so it is fatal when tracking error exceeds the allowable range. It must be pointed out that low speed drive is very beneficial to obtain high precision positioning in sun tracking which affords more time for the microcontroller to analyze the tracking status and implement compensation motions. This strategy makes full use of the feature of sun slow-moving. It is also relatively economic to adopt low power motors owe to the features of this strategy.

The spectrum of light transmitted by fibers is similar to that of nature light which make it favorable for places needing daylighting. Color temperature of the output light transmitted by fibres is about 600K lower than that of nature light which is caused by the selective absorption of plastic fibers. Fortunately, this selective absorption does not cause severe influence to the optical quality of sunlight transmission. The color rendering index still keeps a high value about 88.9 which is far better than those of incandescent lamp, fluorescent lamp and white LED. What's more, the loss on face of fibers cannot be neglected which is about 2db that is meaning 40% loss. The loss on face is relative to the roughness and incident angle. It requires precise measurement and mathematical modeling to establish the quantitative description of concentrated sunlight transmission.

Abstract: An investigation of the accuracy, advantages and disadvantages of using the simpler degree day house load-model Type 12 as a replacement for the more complex multi-zone Type 56 has been made. Results show that Type 12 provides sufficient accuracy for all systems including a storage tank capable of holding at least one day load. A discussion whether Type 12 is an accurate model for other situations is made.

Keywords: *TRNSYS, Renewable energy, Solar Combi, Programming, Type, 56*

1. Introduction

The modeling of solar combisystems in the academic community is often done in a commercially available fortran based simulation environment named TRNSYS [1]. These systems often contain some form of heating system (heat pumps, solar collectors) and some form of load that uses the energy created (building, hot water load). The load is often connected to some form of weather data, deciding the ambient conditions. The interaction between the heat sources and loads form a TRNSYS deck, a series of component models connected to each other to provide information about a system. Here we seek to investigate the impact of the house load model that is chosen. The load structures that will be investigated are the two most common types of buildings used in TRNSYS: the very simple single-zone degree day model with internal gains described by Type 12, and the much more complex multi-zone model Type 56.

Previous work includes Olof Hallström [2], who in his thesis compared Type 12 to a much more complex model developed at Lund University. He found that even though Type 12 was surprisingly accurate for most conditions, especially during low indoor house temperatures, the drawbacks of the type made the choice between Type 12 and Type 56 hard to determine. He identified these drawbacks as the constant heat loss coefficient and the difficulty to include stored solar radiation. It can be noted however, that Type 56 also has a constant heat loss coefficient. Previous simplifications of TRNSYS models have among many others been performed by T. P. McDowell [3], completing a ground source model and by P. T. TSILINGIRIS [4] and his solar heating designs. In both cases a drastically decreased calculation time at low accuracy cost was reached.

Simplifying a deck has the advantage of a decreased calculation time, which can be a major problem in decks taking many hours or even days to complete, especially if a large amount of runs are desired for statistical or optimization purposes. A simpler deck is also highly advantageous for applications directed at the industry, installers and education, such as Climate Well [5] or Winsun Villa [6]. Winsun Villa contains a slightly modified version of Type 12. The conclusions of this publication will be used for the Flexi-Fuel project [7], which has strong connections to the industry and its installers and customers. The objective of the following paper is to determine the accuracy, calculation time and complexity of Type 56 and Type 12 under different conditions.

2. Methodology

2.1. TRNSYS

TRNSYS is a system simulation computational tool developed by Wisconsin University that allows for dynamic simulation of systems using variable time steps. It allows for systems, particularly heating systems, to be created by connecting several components, known as types. These types are mathematical subroutines, i.e. programs, which describe for example a pipe, a house or a heat pump. Apart from the possibility of self-made types, TRNSYS contains a large number of readymade types, and a large number of types are also developed by different institutes and available commercially or for free.

2.1.1. Available load-describing Types

There are several commercially available load models available, but we limit ourselves to observing those Types that are included in the basic TRNSYS package. These are: Type 12, the simplest model, Type 88, a version of Type 12 that also includes some internal gains, (It may be noted that these internal gains are being modeled directly in Type 12 under "misc heat gain", for the investigations performed in this paper.) Type 56 which is a very complex and thorough multi-zone building model, and finally Type 19 a single zone building that is less complex then Type 56, but still requires the input of a large number of parameters. We choose to observe Type 12 and 56 since they are the source of the other models and represent the extremes in simplicity/speed and complexity/accuracy.

2.1.2. TYPE 56

Type 56 describes a building with multiple thermal zones, i.e. rooms. The model uses data from wall and window materials and thicknesses. Each room has a homogenous temperature, and radiation heat between the rooms is based on the room area. Heat addition from solar direct and diffuse radiation is calculated for each room depending on window and heat transfer properties.

2.1.3. TYPE 12

Type 12 is a simple degree-day, single-zone, single capacitance building model with internal gains. The model uses an effective heat capacity for the entire building together with the difference between indoor and outdoor climate to create a heating need. The load is corrected for internal gains. The use of a single heat capacity does not provide any information on solar radiation, which can have significant impact during summer. In this work the solar radiation is added to the internal gain, time step by time step. Duffie and Beckman reasons that since heat capacity effects are difficult to model with a single node when the outdoor temperature is fluctuating around the indoor temperature, Type 12 becomes less reliable for cooling loads. [8]. This has not been investigated here.

2.2. The House

As a reference building the IEA Task 32 building which is based on the IEA Task 26 reference building was used. [9] The reason for this choice is simply that it is a well defined and known building suitable for comparison purposes. Two levels of insulation are chosen to simulate an energy need of 60 or 100 kWh/m²a. The building consists of a two storey house with the specifications described in Table 1, 2 and 3.

Table 1. Building Properties.

A more detailed description on the house's architectural design, internal load and ventilation can be found in [9].

2.2.1. Estimating UA-values

Type 12 uses a single overall UA heat transfer value for the entire house. This value can be estimated by summarizing the U-values from all walls and windows in the building. An effective UA value for the ventilation can be added as this has the same temperature difference as the transmission losses.

$$UA = U_{WALL1} * A_{WALL1} + U_{WALL2} * A_{WALL2} + U_{WALL3} * A_{WALL3} + U_{WALL4} * A_{WALL4} + U_{WINDOWS} * A_{Windows} + \\ + U_{Roof} * A_{Roof} + U_{Floor} * A_{Floor} + V_{house} * n * \frac{1}{3600} * (1 - \eta_{hx}) * \rho_{air} * c_{p\_air} \quad (1)$$

2.2.2. Estimating solar radiation gain

In Type 12, Solar gains through windows can be estimated by adding the window area for each direction and multiply it with a transmission value (In this publication 0.6 has been used for all cases) as described in (2)

$$S = trm(WA_N + WA_E + WA_W + WA_S) \quad (2)$$

Where
trm = transmission constant
WA = Window area in the specified direction

This solar radiation gain value is then inserted into Type 12 through internal gains.

2.2.3 Effective thermal capacitance of the house
An effective thermal capacitance of the type 12 house can be estimated by adding up the thermal capacity for the individual parts of the house. Duffie and Beckman [8] give approximate values of 0.153 MJ/m2/K for a medium house and 0.415 MJ/m2/K for a heavy house and up to 0.810 for a very heavy building. This corresponds in this case (with 140 m2 total floor area) to 21 MJ/K , 58 MJ/K and 113 MJ/K.

3. Measurements

Type 12 is deemed to be the less accurate model, and so when Type 56 and Type 12 are compared, any deviation from each other is considered to be due to an inaccuracy of Type 12.

3.1. The Timescale

Fig 1 shows the output of Type 12 and Type 56, as well as the difference between them. At first glance, the heating load required by Type 12 appears to be very inaccurate for both the well and the less insulated building as we see in the upper part of Fig.1. The whole line depicting the difference between the two types is in the order of 50% for most of the year.

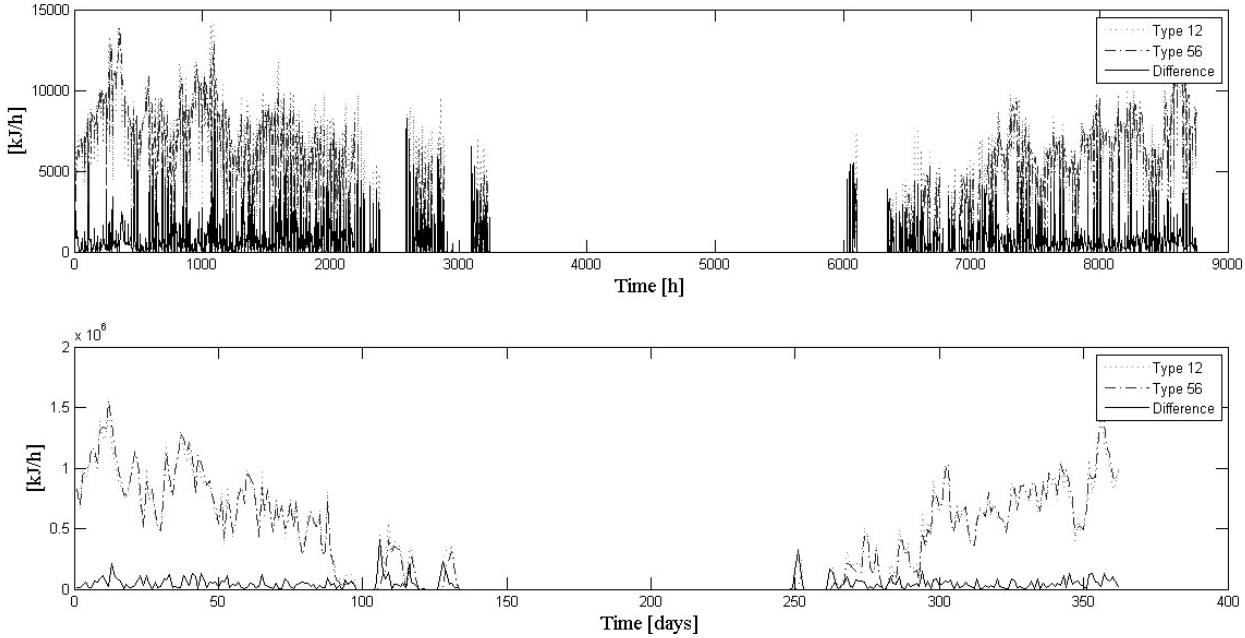

Fig.1 The output from Type12 and 56 with 12min time step (upper diagram) and 12h time step (lower diagram)

Possible heat pumps or solar collectors connected to a system are highly dependent on the temperature of the incoming flow. To gain sufficient accuracy for such heat sources a time step of a few minutes is required. The flow to such sources is often connected to some form of storage, such as a tank, between the load and the heat source. If for example a storage tank has the capacity of storing the energy required for heating a house for one day, a heat demand for one day is sufficient. When we integrate the output of both Type 56 and Type 12 over one day, we see a definite increase in agreement between the models as shown in the lower part of Fig.1.

3.2. The Accuracy of Type 12

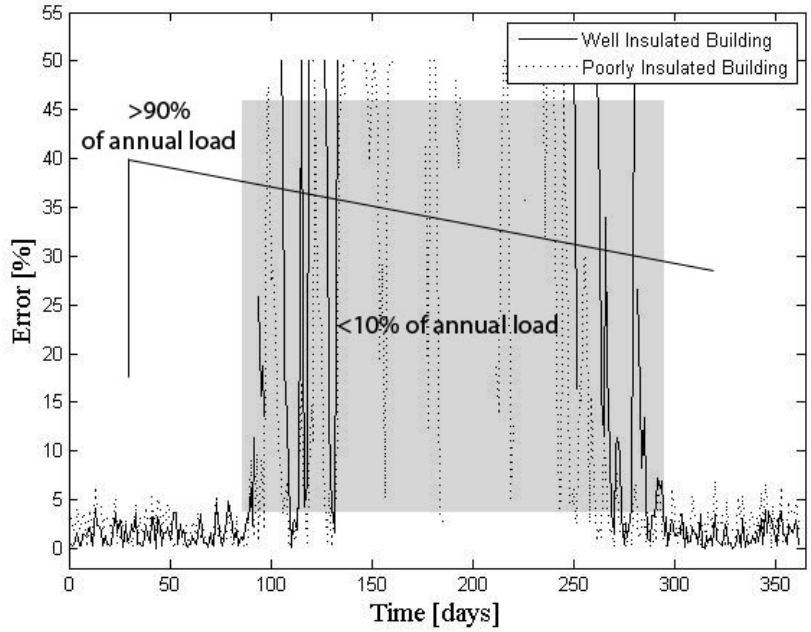

Fig. 2. The Difference in output for Type 12 and 56 for a poorly and a well insulated building

Fig.2 shows the error in percentage over one year. For the colder periods of the year the percentual error keeps below 7% for both levels of insulation. 7% is most likely a smaller error then those arising from building uncertainties such as cracs in the building shell or moisture in the isolation. Even though the error grows large in summertime, less than ten percent of the annual energy requirement occurs during this period. This means that for over 90% of the annual load, Type 12 performs acceptably. The yearly error becomes approximately 8%.

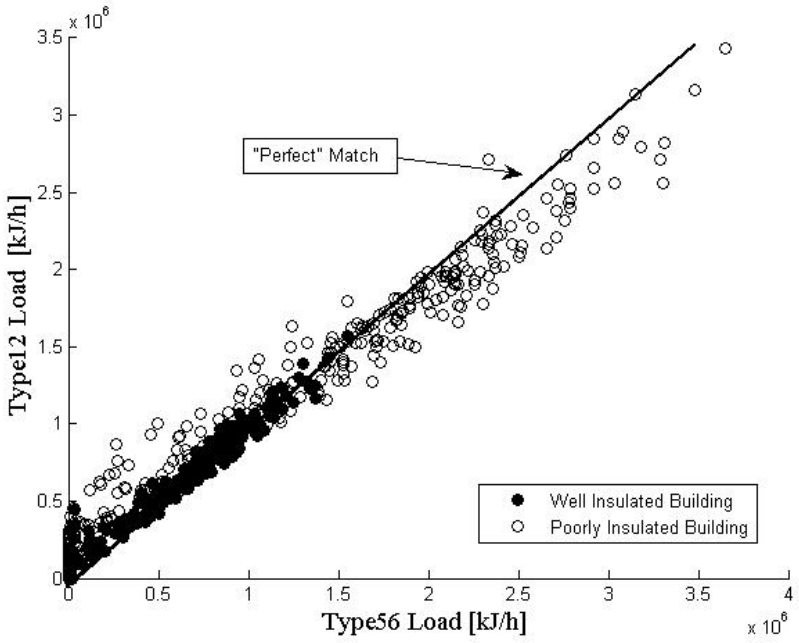

Fig. 2. Type 12 vs. Type 56 for a poorly and a well isolated building

Fig. 3 shows the output from the models plotted against each other. The error in output seems to be evenly distributed at the base of the line. The filled circles showing the well insulated building are closer to the line indicating that the overall UA value was a good guess for this case. At higher values we see a drift downwards, indicating that Type 12 underestimates the energy requirement for cold days, and overestimates it for warm days. This may be due to the fact that Type 12 does not store solar heat in the interior of the building.

3.3. The Phasing of Type 56

The difference in how the models react to outdoor temperatures is described in Fig. 4 and Fig. 5. Fig. 4 shows a zoomed in view of 3 days with the light gray line as outdoor temperature, the highly oscillating line as Type 12 and the less oscillating as Type 56. In this simulation, all windows, internal load and ventilation has been removed to get the crudest model possible. As seen in the image, Type 56 has a slight delay compared to the outdoor temperature, as might be expected by a more complex building model.

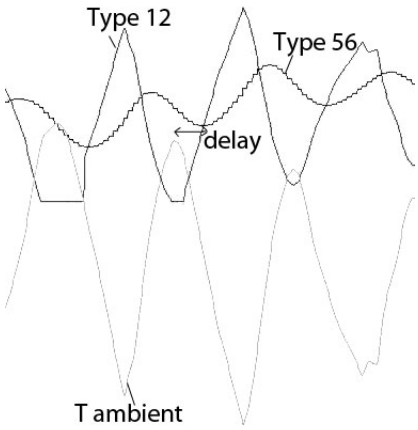

Fig. 4. The Delay of Type 56 when no windows are present

Fig. 5 shows two days but this time windows have been added to both models. Radiation coming through windows provides an instantaneous addition of heat, resulting in a model that responds much faster to outdoor weather. It could be argued that adding radiation through windows and ventilation provides a Type 56 that behaves more like Type 12.

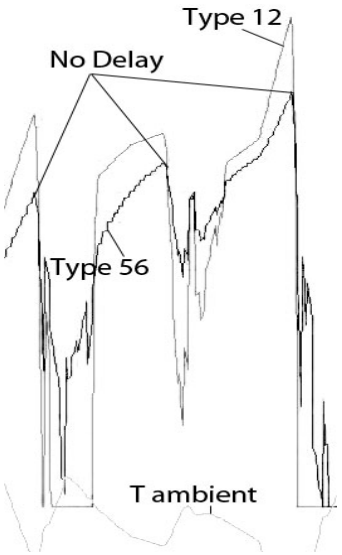

Fig. 5. No Delay of Type 56 when windows are present

3.4. Calculation Speed

Type 12 takes approximately half the simulation time for one year compared to Type 56 (23s against 42s). The time step was then rather long, 12minutes. In a full deck the tank may call the load several times before it converges, 10 times or more is not unusual. Also if a very short time step is used, this difference in calculation speed can have a significant impact on the usability of the deck.

4. Discussion

Considering the results presented above, Type 12 seems to be a good approximation under the right circumstances. It can be recommended for systems including a tank or other form of storage, or for systems that do not require high temporal resolution. The usage of Type 12 can not be recommended in applications consisting of heat sources without any storage. Type 12

only requires one UA parameter, which can be estimated as described above. In practical applications, the complete drawings of a building may not be easily accessible, or as in the case of the Flexi-Fuel project [7], it may prove very disadvantageous for a salesman to ask the client for every constructive layer in the wall before being able to demonstrate his/her products. In a real building the heat load will also be influenced by the wind dependent infiltration rate and quality of insulation work, as well as user behavior concerning choice of room temperature and for example open windows in some rooms periods of the day or night. The simulation model in the flexifuel project is aiming at fast but realistic system simulations and then type 12 may be the best choice.

Abstract: In Iran (and probably in most countries) natural gas is transported through transmission pipeline at high pressures (5-7 Mpa) from production locations to consuming points. At consumption points, or when crossing into a lower pressure pipeline, the pressure of the gas must be reduced. This pressure reduction takes place in CGSs. At CGSs, the pressure is reduced from (5-7 Mpa) to (1.5-2.0 Mpa) (typically 1.7 Mpa) in high-pressure intrastate pipelines. Currently, gas pressure reduction is accomplished by using throttle-valves in all of Iran's CGSs, where the constant-enthalpy expansion takes place and a considerable amount of energy is wasted. The gas must be heated before it enters throttle valves to ensure that it remains above the hydrate-formation zone and dew point, so that no liquid or solid phase condenses at the station exit. The heaters are consuming a considerable amount of natural gas flowing though the CGS as fuel to provide the required heat for preheating the natural gas stream. As the low temperature heat is required for preheating the natural gas in a CGS, this makes a CGS as perfect place to utilize solar energy and to meet low temperature heat demand. As the low temperature heat is required for preheating the natural gas in a CGS, A solar collector array is proposed to be utilized in the CGS in order to displace heating duty of the heater and to reduce amount of fuel consumption. The proposition includes a modified design of an in-use CGS to take advantage of freely available solar heat.
The proposed system has been applied to study the thermal behaviour of a CGS within Iran. The results show that the cost effectiveness of the proposed method with an array of 450 collector modules is resulted in fuel saving with variation between 0 to 20 USD/hr. The annual fuel saving is about 10678 USD and as the capital cost is about 76500 USD, the payback ratio is calculated to be around 9 years. The number of collector modules has been determined based on cost analysis.

1. Introduction

Solar thermal technologies utilise the heat from the sun to offset the heating demand for many applications. The main component of any solar thermal technology is the solar collector. The device absorbs heat form solar radiation and transfers this heat to a circulating fluid (usually water). The heat absorbed by collectors then utilized in many applications. Kalogirou1 presented a survey of the various types of solar thermal collectors and applications. These includes Solar water heating systems, Solar space heating and cooling, Solar refrigeration,

Industrial process heat, Solar desalination systems, Solar thermal power systems, Solar furnaces and Solar chemistry applications[1].

The utilization of solar energy for providing process heat in industrial applications is not common especially for low temperature cases and a few researches have been carried out in this subject. Norton [2] presented the most common applications of industrial process heat. The history of solar industrials and agricultural applications are presented and practical examples are explained. A system for solar process heat for decentralised applications in developing countries is presented by Spate et al. [3] The system is suitable for community kitchen, bakeries and post-harvest treatment.

In Iran (and probably in most countries) natural gas is transported through transmission pipeline at high pressures (5-7)MPa from production locations to consuming points. At consumption points, or when crossing into a lower pressure pipeline, the pressure of the gas must be reduced. This pressure reduction takes place in CGSs. At CGSs, the pressure is reduced from (5-7)MPa to 1.5-2.0 MPa (typically1.7 MPa) in high-pressure intrastate pipelines. Currently, gas pressure reduction is accomplished by using throttle-valves in all of Iran‘s CGSs, where the constant-enthalpy expansion takes place and a considerable amount of energy is wasted (Farzaneh-Gord et al. [4]). The gas must be heated before it enters throttle valves to ensure that it remains above the hydrate-formation zone and dew point, so that no liquid or solid phase condenses at the station exit. Indirect Water Bath Gas Heaters (known as line heater) are employed in the CGS to preheat the natural gas. The heaters are consuming a considerable amount of natural gas flowing though the CGS as fuel to provide the required heat for preheating the natural gas stream. As the low temperature heat is required for preheating the natural gas in a CGS, this makes a CGS as a perfect place to utilize solar energy and to meet low temperature heat demand.

In this study, the objective is to reduce amount of the heater fuel consumption in the CGS by utilizing solar energy. A solar collector array is proposed to be utilized in order to displace heating duty of the line heater. The proposition includes a modified design of an in-use CGS to take advantage of freely available solar heat. The modification has been done in line to minimize the CGS design alteration and availability of the CGS to continue its tasks with or without additional solar system.

2. Methodology

When a natural gas pipeline approaches a city, the high-pressure gas has to be reduced to a distribution level. A city gate station (CGS) is a. Inlet Gas has a high temperature (T_{NG-1}) which is typically related to the ambient temperature (T_{am}). The gas must be heated before it passes through throttle valves to ensure that it remains above the hydrate-formation zone and dew point, so that no liquid or solid phase condenses at the output temperature (T_{NG-3}). The standard preheated gas temperature (T_{NG-2}) is in range of 30-55^{o}C but its value highly depended on inlet pressure and temperature. The heaters are comprised of four basic components, the heater shell, the fire tube, the gas coil and the water expansion section.

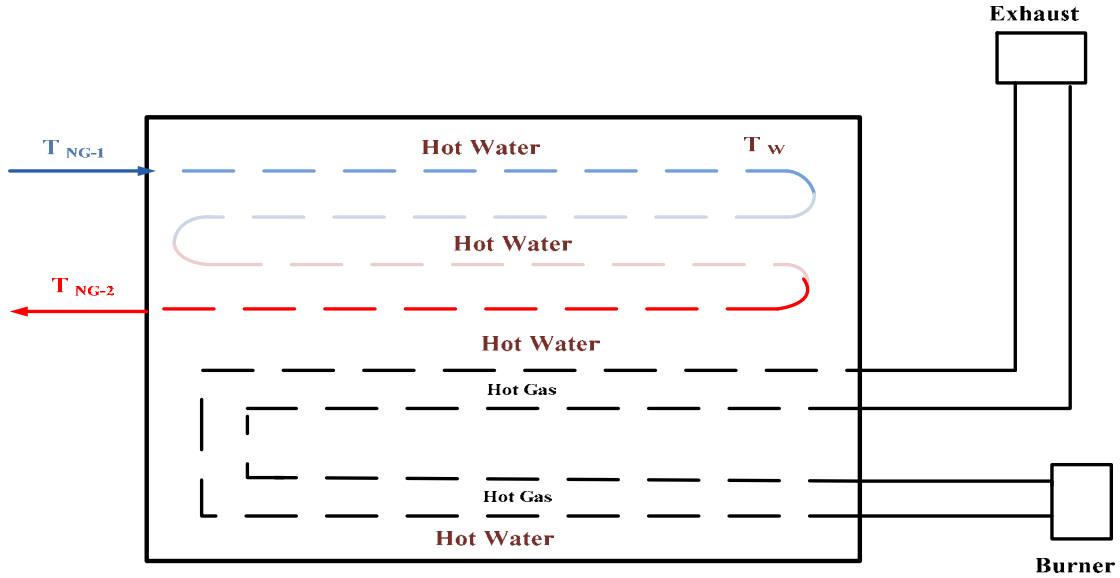

Fig. 1. A schematic diagram of an Indirect Water Bath Gas Heater (Line heater) employed in a CGS for preheating the gas

The heating duty of the heater and the water bath temperature could be estimated by knowing the station inlet and outlet gas temperature and pressure as discussed as follow.

Based on the standard outlet station gas pressure (250 psig or 17 barg) and the natural gas compositions, the hydrate gas temperature (T_{hyd}) could be calculated from thermodynamics models. The outlet station gas stream temperature (T_{NG-3}) is then selected 5 °C above the hydrate temperature [5]. By knowing the outlet station gas stream temperature, the gas temperature at the heater exit could be calculated as below:

$$T_{NG-2} = \overbrace{T_{hyd}}^{T_{NG-3}} + 5 + \Delta T_{tv} \qquad (1)$$

In which, $\Delta T_{tv} (=T_{NG-2} - T_{NG-3})$, is temperature drop due to pressure drop though the throttling valves. The amount of temperature drop is affected by the station inlet pressure and the natural gas compositions. Once, the gas temperature (and pressure) at the heater exit is known, the heater heating duty could be calculated as below:

$$\dot{Q}_{gh} = \dot{m}_{NG}(h_{NG-2} - h_{NG-1}) \qquad (2)$$

As the gas travels a long distance before reaching to the station trough a buried pipeline at depth of 1.2 m, the gas temperature assumed to be equal to the surrounding soil temperature (Edalata and Mansoori,[6]). The soil temperature varies with environment temperature and locations. Najafi-mod et al.11 proposed an empirical correlation for a simple and rational relationship between ambient temperature and soil temperature at different depths. The soil temperature for depth higher than 1 m for Iran could be simplified as follow (Najafi-mod et al.[7]) :

$$T_{NG-1}(^{o}C) = T_{soil} = 0.0084 T_{am}{}^{2} + 0.3182 T_{am} + 11.403 \qquad (3)$$

The heating duty of the heater is provided by burning natural gas as fuel. Considering a value for thermal efficiency, η_h ,of the heater, the fuel mass flow rate, $\dot{m}_f$,could be calculated as below:

$$\dot{m}_f = \dot{Q}_{gh} / (\eta_h LHV) \qquad (4)$$

In which, LHV , is lowering heating value of the fuel (here Natural gas). It should be pointed out that the heater heat lost to ambient is considered through the heater thermal efficiency. The current thermal efficiency of conventional heaters are low and in range of 0.35 to 0.55. In this research, thermal efficiency of the heater is assumed to be 0.45.

As the water bath temperature wouldn't need to be higher than 70°C and the line heater are most needed during winter, in this study an array of flat plate solar collector are proposed to be installed parallel to the heater as shown in Fig.2. The solar flat plat collectors received the water, heated it up and finally returned it to the heater. As it could be realized, a current CGS could be easily modified to take advantages of solar thermal energy as proposed in the Fig.3. The heater is able to continue its normal take with or without solar collectors.

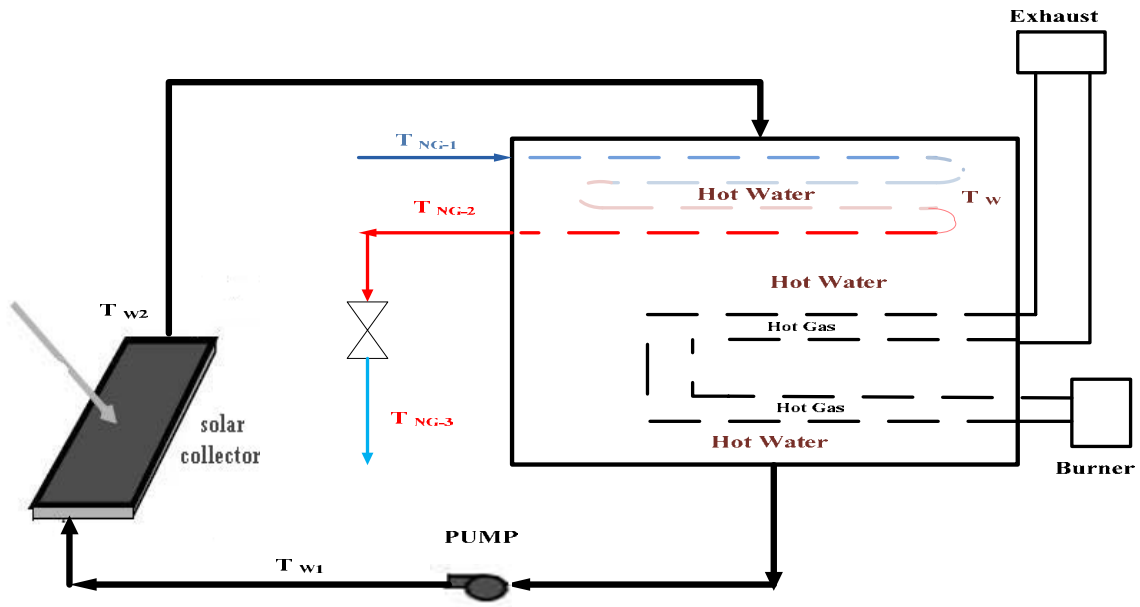

Fig. 2. A schematic diagram of the proposed system to utilize solar energy in the pressure drop stations

The governing equation for a perfectly mixed storage tank could be written as:

$$m_w C_{pw} \frac{dT_w}{dt} = \dot{Q}_{solar} + \underbrace{\dot{m}_f LHV \eta_h}_{\dot{Q}_{heater}} - \dot{Q}_{gh} \qquad (5)$$

In which, m_w C_{pw} , is the system thermal capacity, T_w , is bath temperature and $\dot{Q}_{solar}$ is rate of useful solar energy which is absorbed by the solar collector array and transferred into circulated water. $\dot{Q}_{gh}$ is heating duty of the heater or solar load in the system.

$\dot{Q}_{heater}$ is the rate of thermal energy provided by burning fuel. It should be noted that heat lost from the heater is considered in this term by introducing heater thermal efficiency. There are possibility of two scenarios at this point as a)a heater with automatic controllable $\dot{Q}_{heater}$ b) a heater with fixed $\dot{Q}_{heater}$. It should be pointed out that although all line heaters (within Iran) could be controlled and the rate of $\dot{Q}_{heater}$ could be varied, but these heaters are not equipped with automatic control unit. Here it is assumed that the heaters are equipped with automatic control unit and scenario a (a heater with automatic controllable $\dot{Q}_{heater}$) has been applied. In this scenario, the gas temperature at heater exit is fixed.

Fixed gas outlet temperature could be achieved by controlling rate of $\dot{Q}_{heater}$. $\dot{Q}_{heater}$ could be estimated by making some simple assumptions and applying a "Euler" integration technique. For this, it will be assumed that the values of $\dot{Q}_{gh}$ and $\dot{Q}_{solar}$ are only a function of storage tank temperature at the start of the hour and that (m_w C_{pw}) of the storage is fixed. Therefore, assuming one hour time period (i.e. 3600 seconds), $\dot{Q}_{heater}$ could be estimated by integrating both sides of equation(5). The final equation will be as below:

$$\dot{Q}_{heater} = m_w.C_{pw}(T_{w(i+1)} - T_{w(i)})/3600 + (\dot{Q}_{gh} - \dot{Q}_{solar})_{(i)} \qquad (6)$$

The above equation could be employed to find altered value of the heater fuel mass flow rate as below:

$$\dot{m}_f = (m_w.C_{pw}(T_{w(i+1)} - T_{w(i)})/3600 + (\dot{Q}_{gh} - \dot{Q}_{solar})_{(i)})/LHV\eta_h \qquad (7)$$

Equation (6) or (7) could be rearranged to estimate the hourly variation in water bath temperature as below:

$$T_{w(i+1)} = T_{w(i)} + \frac{(\dot{Q}_{solar} + \dot{Q}_{heater} - \dot{Q}_{gh})_{(i)} \times 3600}{m_w \cdot C_{pw}} \qquad (8)$$

3. Results

The heating duty should be supplied by heater either completely by fuel energy or by combination of solar and fuel energy. As discussed previously, the heater burns natural gas as fuel to preheat the gas. The rate of burning fuel would be useful for studying feasibility of the proposed solar system. Fig 3 shows the averagely daily rate of fuel (natural gas) burned in the heater for months of 2009.

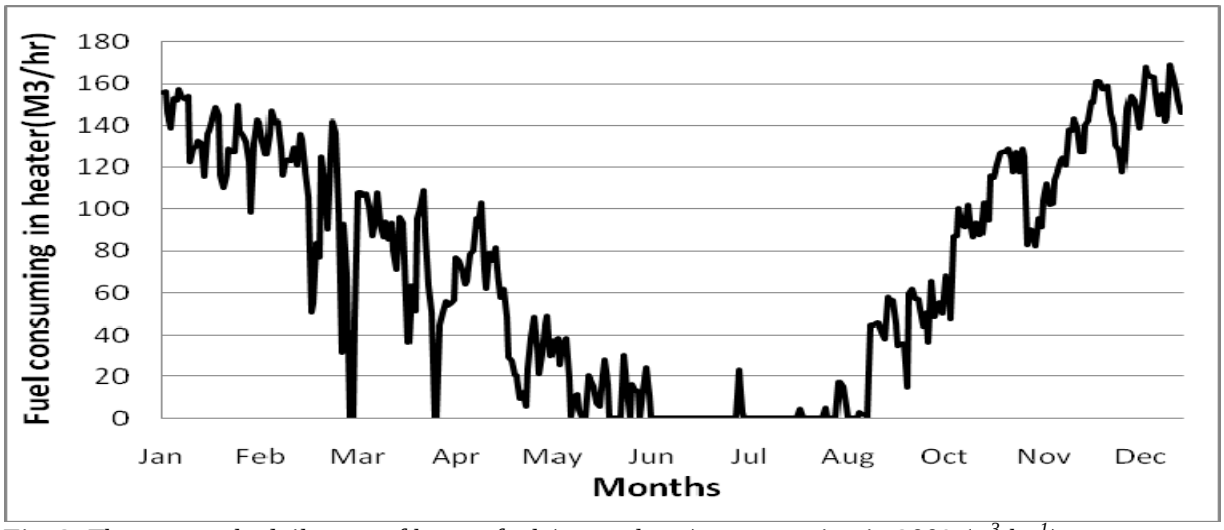

Fig. 3. The averagely daily rate of heater fuel (natural gas) consumption in 2009 ($m^3.hr^{-1}$)

As discussed previously, some part of required preheat energy in the heater is proposed to be replaced by energy gained in solar collector array. The average monthly of absorbed solar energy that gained in Akand Station area shown in Fig 4. It could be realized that the maximum absorbed solar energy is reached in Jun and The lowest value is in October.

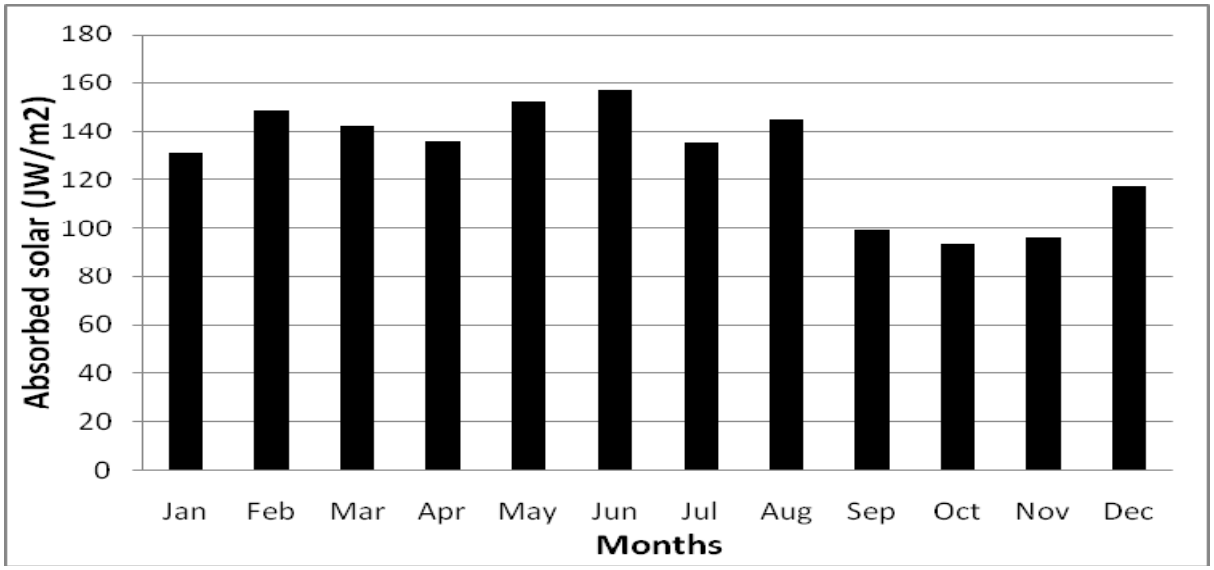

Fig. 4. Average monthly of absorbed solar energy in 2009

The capital cost of the proposed solar system or the array of collector modules could be actually calculated by multiplying the number of collector modules and cost of one module. The cost of one flat plate collector module is about 230 USD in Iran. As number of collector modules in the array increases, the capital cost increases but the heater fuel cost decreases. The variation of annual fuel cost of the heater and solar energy system capital cost against number of collectors modules are displayed in Fig.5. Considering the figure, one could select 450 as an optimum value for the number of collector modules.

It should be noted that the fuel cost calculation is based on current natural gas price which is 0.28 USD for each cubic meter.

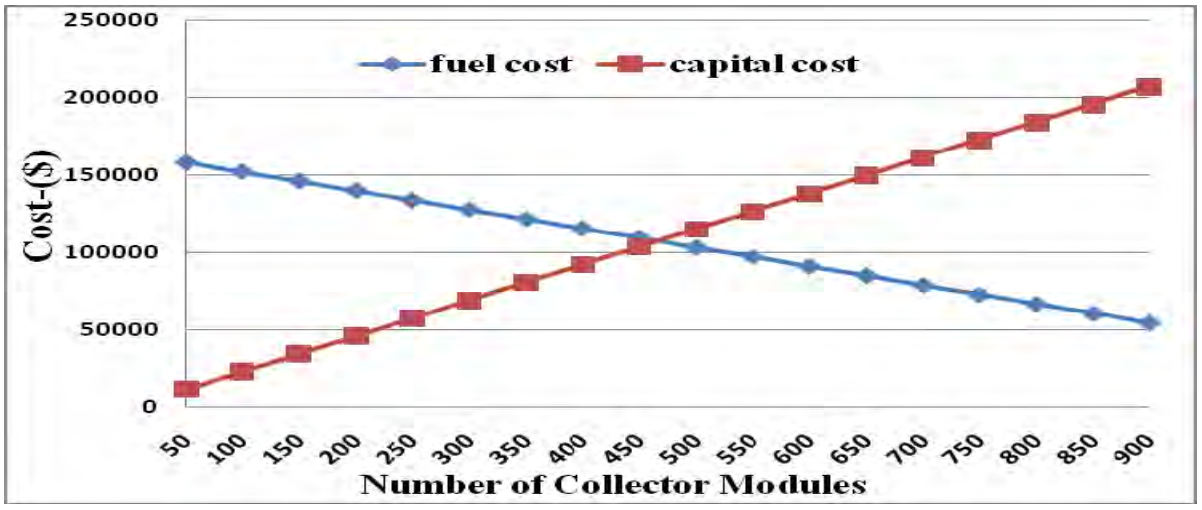

Fig. 5. Variation of solar system capital cost and fuel cost for against number of collector modules

To evaluate the desirability and to investigate the cost effectiveness of the proposed method with an array of 450 collector modules, Fig.6 shows the daily average heater fuel consumption required for preheating gas in 2009 in case of utilizing solar system or without solar system. The distinction between fuel consumptions, shows saving in fuel ($m^3.hr^{-1}$). Annually fuel cost saving can calculate by multiply this amount in 0.28 USD.

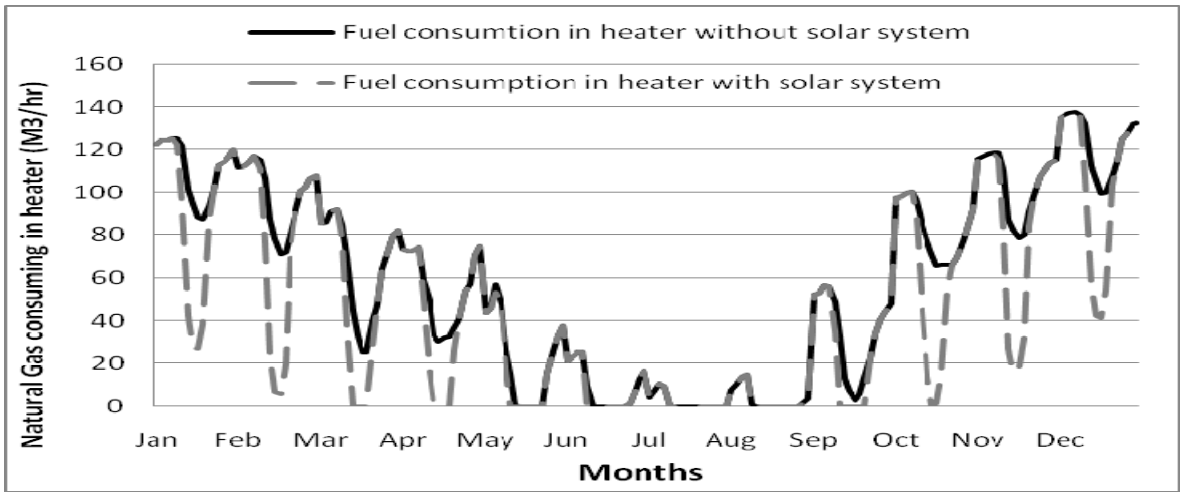

Fig. 6. The heater fuel (natural gas) consumption required for preheating gas in 2009

The annual fuel saving is about 10678 USD and as the capital cost is about 76500 USD, the payback ratio could be calculated as below:

$$Payback\ Ratio = (Capital\ \cos t)/(Benefit) = 9.2\ years \qquad (9)$$

4. Discussion

The natural gas pressure must be reduced to distribution pressure when reaches its end users. The gas must be heated before it enters throttle valves to ensure that it remains above the hydrate-formation zone and dew point, so that no liquid or solid phase condenses at the station exit when pressure and temperature reduced. Currently in all Iran's CGSs, the gas is preheated through a bath type heat exchangers (known as line heater) which burns a portion of the gas for providing heating duty to warm up the natural gas. As the low temperature heat is required for preheating the natural gas in a CGS, A solar collector array is proposed to be

utilized in the CGS in order to displace heating duty of the heater and to reduce amount of fuel consumption. The proposition includes a modified design of an in-use CGS to take advantage of freely available solar heat. The proposed system has been applied to study the thermal behaviour of a CGS within Iran (Akand City Gate Station). The results show that the cost effectiveness of the proposed method with an array of 450 collector modules is resulted in fuel saving with variation between 0 to 20 USD.hr^{-1}. The annual fuel saving is about 10678 USD and as the capital cost is about 76500 USD, the payback ratio is calculated to be around 9 years. The number of collector modules has been determined based on cost analysis.

Abstract: In this paper, the energy balance equations for the different components of hybrid photovoltaic thermal (HPVT) biogas plant have been written for quasi - steady state conditions to develop a thermal model. An analytical expression for slurry temperature has been obtained as a function of design and climatic parameters namely mass of the slurry, mass flow rate of fluid in collector, number of collectors, solar intensity, ambient temperature etc. Numerical computations have been carried out for climatic conditions of Srinagar, India. Based on mathematical computations it has been observed that the optimum slurry temperature (~ 37^{o}C) is achieved for a given set of design parameters of biogas plant and hybrid collectors (M_S =2000, $\dot{m}_f$ = 0.05kg/s, L = 25m). It has been observed that number of hybrid PVT collector has significant effect on slurry temperature.

1. Introduction

Biogas is the gas emitted from cow dung in its anaerobic decomposition. Biogas provides fuel for cooking, thus saves the forests and also women from fetching and carrying heavy loads of fuel wood. Biogas is also used for lighting and space heating purpose in rural villages. Thus improves the quality of life. Finally, anaerobic digestion also yields bio-slurry and bio-dregs rich in nutrients, minerals and biologically active compounds. This forms the excellent organic fertilizer for crops and fodder for pig and fish. Production of biogas is maximum when slurry temperature is between 32 to 37 ^{o}C.

In order to increase the slurry temperature in harsh cold climatic condition, the researchers have proposed the following techniques:

(i) Erection of canopy green house over the biogas plant [1-6].
(ii) Integration of solar water heater/ solar still with dome [7-10].
(iii) Hot water charging the slurry before fedding into digester [11].
(iv) Integration of flat plate collector to digester through heat exchanger inside slurry, generally referred as active heating [12-15].

In their study, either floating or fixed dome type biogas plant has been considered. On the basis of their finding, it has been concluded that active heating of slurry in digester is more effective in comparison with other heating methods [12-15]. The temperature of slurry can be increased upto optimum level (~ 37^{o}C) by optimizing the area of flat plate collector for a given capacity of the slurry. It is further important to mention that only forced mode of operation for thermal heating is viable. Neto et al. [16] have suggested biogas/photovoltaic hybrid power system for decentralized energy supply of rural areas. Also, Dubey and Tiwari [17] have presented a hybrid photovoltaic flat plate collector (hybrid PV water collector) for forced mode to produce electrical as well as thermal energy. If such hybrid PV water is integrated to slurry through heat exchanger as shown in Figure 1a, then one can achieve the following:

(i) Increase in slurry temperature for higher yield in harsh cold climatic condition.
(ii) Hot water for domestic use.
(iii) Electricity production for lighting.

In this case the proposed system can be proved to be more economical than single application in rural area in decentralised manner.

2. Design of hybrid photovoltaic thermal (HPVT)-biogas Plant:

There are two types of biogas plat namely floating gasholder type and fixed dome type. In this paper floating gas holder type biogas plant has been considered.

2.1. Hybrid floating type biogas plant:

Hybrid photolytic thermal (HPVT)-biogas plant has been shown in the Fig. 1. It consists of (i) a floating type biogas plant; (ii) partially PV covered solar collectors connected in series and (iii) a coil type heat exchanger. Heat exchanger is connected with partially PV covered solar collectors connected in series and is immersed in the slurry as shown in the Fig. 1a. The hot fluid (water) at outlet of hybrid collectors is allowed to flow through heat exchanger and then transferring the heat from heat exchanger to slurry and hence the slurry gets heated.

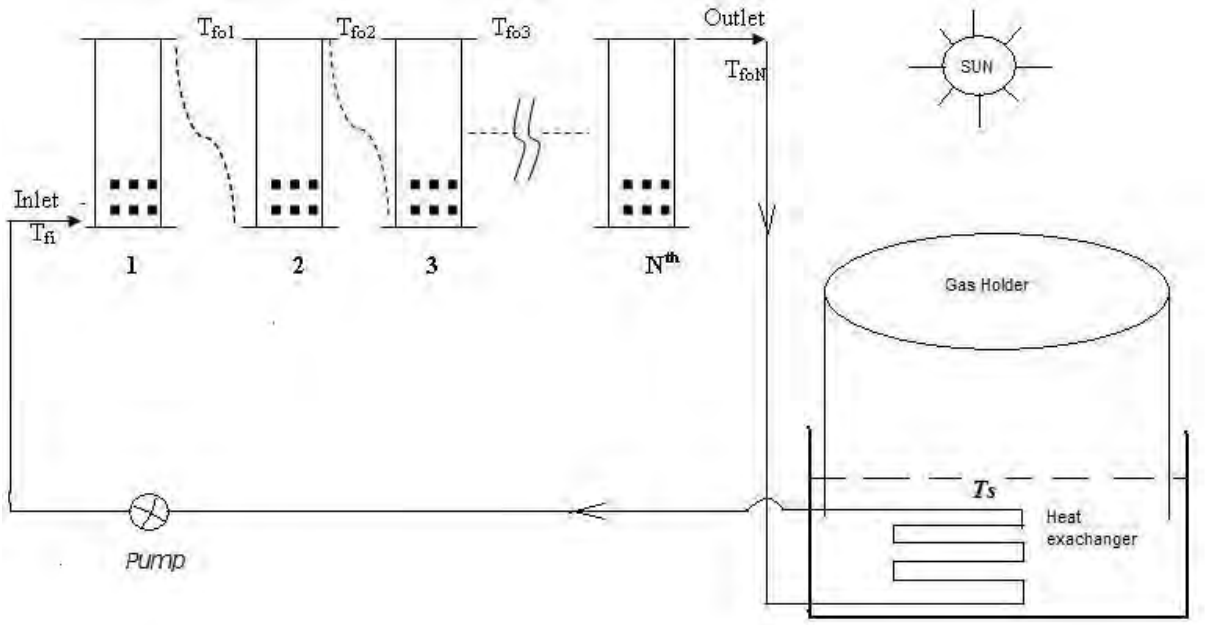

Fig.1 A conventional biogas plant integrated with hybrid PVT solar water collector.

3. Problem Identification

In this paper an attempt has been made to optimize the number of partially covered collectors, size of the heat exchanger and mass flow rate of the water in the heat exchanger for a given size of the biogas plant under a given climatic condition.

4. Thermal Modelling

4.1. Assumptions

In order to write the energy balance equation of hybrid photovoltaic thermal biogas plant, the following assumptions have been made:

- The biogas plant is of floating dome type
- Each component of the system is in quasi – steady state condition
- There is no stratification along the depth of the slurry and the gas column
- Thermal capacity digester and dome of the biogas plant has been neglected

4.2. Energy Balance Equations

The energy balance equations during sunshine hours have been formulated as follows.

For gas holder:

$$\alpha'\left[A_h I(t) + I(t)_v \frac{A_v}{2}\right] = h_1 A_t (T_p - T_g) + h_{rps} A_h (T_p - T_a) + A'_v h_c (T_p - T_s) + h_2(t) A_t (T_p - T_a) \quad (1)$$

For biogas: $$h_1 A_t (T_p - T_g) = h_3 A_h (T_g - T_s) \quad (2)$$

For slurry:

$$M_s C_s \frac{dT_s}{dt} = h_3 A_h (T_g - T_s) + A_h h_{rps} (T_p - T_s) + A'_v h_c (T_p - T_s) - h_4 A_h (T_s - T_\infty) - h_{sa} A'_h (T_s - T_a) - A'_h \dot{Q}_{es} + \dot{Q}_u \quad (3)$$

where,

$$\dot{Q}_{es} = h_{ew} (T_s - T_a) \quad (4)$$

and,

$$h_{ew} = \frac{0.016 h_{sa} \left\{ P(\overline{T}_s) - \gamma P(\overline{T}_a) \right\}}{(\overline{T}_s - \overline{T}_a)}.$$

Now, the rate of heat transfer from flowing fluid in the heat exchanger to the slurry can be written as

$$\dot{Q}_u = U 2\pi r_1 L \left(\overline{T}_w - T_s \right) = \dot{m}_f c_f \left(1 - \exp\left(-\frac{2\pi r_1 U}{\dot{m}_f c_f} L \right) \right) (T_{foN} - T_s) \quad (5)$$

Following Dubey and Tiwari [4], for N identical collectors partially covered by PV modules connected in series, the outlet fluid temperature at the end of N[th] collector can be given as,

$$T_{foN} = \frac{(AF_R(\alpha\tau))_1}{\dot{m}_f C_f} \left(\frac{1 - K_K{}^N}{1 - K_K} \right) I(t) + \frac{(AF_R U_L)_1}{\dot{m}_f C_f} \left(\frac{1 - K_K{}^N}{1 - K_K} \right) T_a + T_f i \, K_K{}^N \quad (6)$$

With the help of Eqs (4) & (5) , Eq (3) can be solved for the slurry temperature

4.3. Electrical output:

The electrical output generated by proposed hybrid photovoltaic thermal biogas can be evaluated by the following expression

$$E_{daily} = \sum_{i=1}^{n} \eta_m \times I_i \times A_m \times N \quad (7)$$

where,

$\eta_m = \eta_{mo} \left[1 - \beta \left(\overline{T}_f - T_a \right) \right]$, $\overline{T}_f = \frac{T_{fON} + T_{fi}}{2}$, η_{mo} =0.12 and β =0.0045 .

4.4. Thermal output:

The rate of thermal energy available from the proposed hybrid photovoltaic thermal biogas plant can be obtained as:

$$\dot{q}_u = \dot{m}_f \dot{c}_f \left(T_{fON} - T_{fi} \right)$$

The daily thermal energy is given by

$$Q_u = \sum_{i=1}^{n} \dot{q}_{ui}; \quad \text{n is sunshine hour.} \tag{8}$$

The daily exergy is given by

$$Ex_{daily} = Q_u \left[1 - \frac{\bar{T}_a + 273}{\bar{T}_{fON} + 273} \right] \tag{9}$$

For a set of design and climatic parameters, outlet temperature of n^{th} collector and Slurry temperature has been calculated using MATLAB software.

5. Results and discussions

Hourly variation of solar intensity on the horizontal and vertical walls of the dome has been calculated by using Liu and Jordan formula with the help MATLAB software. Fig. 2 shows the variation of solar intensity and ambient air temperature with time. Fig 3 gives the variation of outlet temperature from N^{th} collector and slurry temperature during 24 hours period of day and night. Figure shows that there is increase in slurry temperature (T_s) with time of the day as more thermal energy is available from hybrid PVT collectors. It attains maximum temperature (T_{smax}) of about 30^{o}C at 4 pm due to heat capacity of the slurry. This temperature can be further increased by decreasing the mass of the slurry. Further, it is to be noted that the outlet fluid temperature is achieved upto about 80-90^{o}C at noon time as expected. Fig.4 shows the variation of peak slurry temperature (T_{smax}) with mass flow rate. The peak slurry temperature (T_{smax}) increases rapidly with increase of mass flow rate of the fluid due to fast transfer of heat into the slurry. It is observed that there is not much variation in peak slurry temperature (T_{smax}) after mass flow rate 0.05kg/s and hence one can conclude that the optimum mass flow rate is 0.05 kg/s for design parameters given in Table 1 and climatic parameters shown in Fig. 2. Fig.5 shows the variation of peak slurry temperature (T_{smax}) with the mass of the slurry (M_s). This figure shows that peak slurry temperature (T_{smax}) decreases with increase of the mass of the slurry (M_s). It is observed that for the given design and climatic parameters , the optimum mass of the slurry is 2000kg. The variation of peak slurry temperature (T_{smax}) with number of PV/T collectors N is shown in Fig.6. This figure shows that peak slurry temperature (T_{smax}) also increases with increase of number of collectors due to increase of thermal energy provided by PVT collectors to the slurry. It is observed that there is not much variation in peak slurry temperature (T_{smax}) after 50 numbers of collectors and hence the optimum number of collectors for a design and climatic parameters under consideration is about 50.

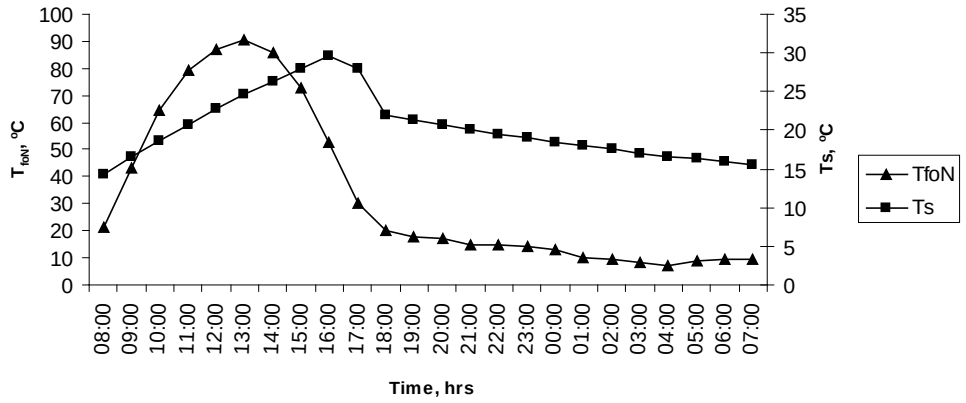

Fig.3. Variation of outlet water temperature (T_{foN}) and slurry temperature (T_s) with time (M_S=2500, $\dot{m}_f$ = 0.02kg/s, L = 25m, N=40)

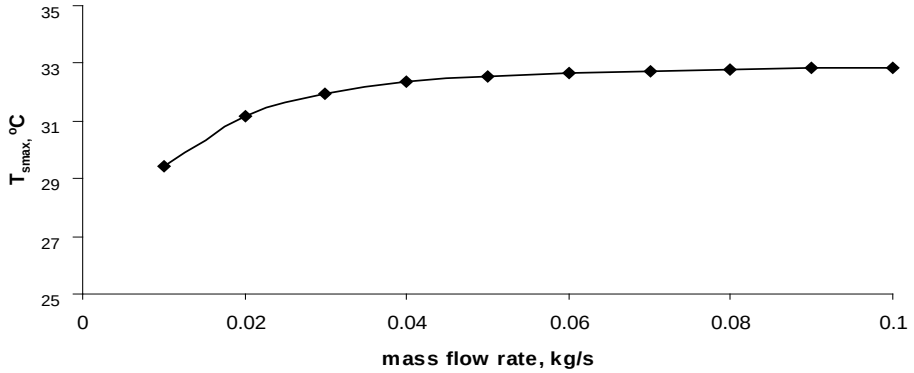

Fig.4. Variation of maximum slurry temperature with mass flow rate of the slurry.

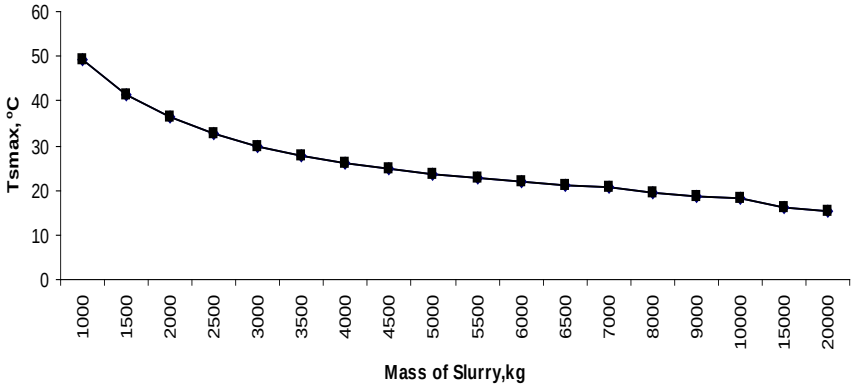

Fig.5: Variation of maximum slurry temperature with mass of slurry for N=40 and mass flow rate=0.02 kg/s.

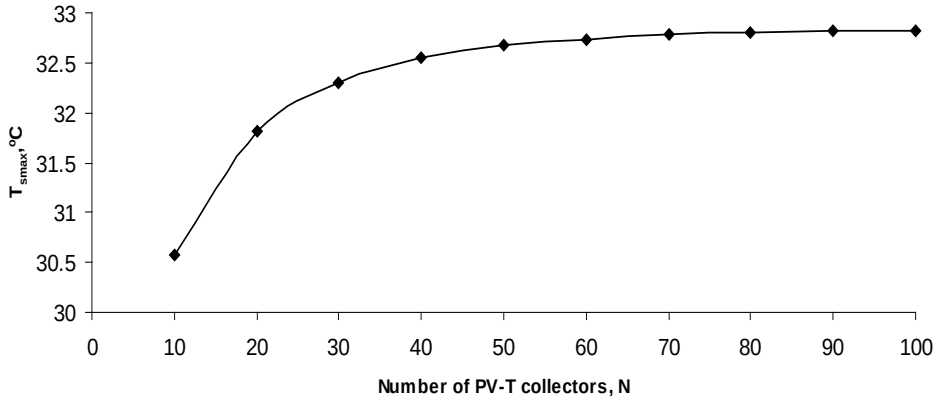

Fig.6. Variation of maximum slurry temperature with number of PV-T water collectors.

6. Conclusions

On the basis of present studies, one can conclude that:

(i) The design parameter of PVT integrated biogas plant can be optimised for a given capacity by using the present thermal model.

(ii) The present system is most suitable and self sustainable for cold climatic condition where ambient air temperature is much less than the optimum operating temperature (~37^{o}C) of the biogas plant.

Abstract: Several solar-gas hybrid power plants based on the parabolic trough system are under construction in the MENA region and in Spain. The thermodynamic cycle of these plants is divided into topping cycle and bottoming cycle according to their temperature range. Since the solar collectors supply heat at a medium temperature level, up to 400°C, the existing technology uses a steam bottoming cycle (steam turbine). The present study aimed at investigating the thermodynamic feasibility of using air bottoming cycle (gas turbine) instead of the steam bottoming cycle. A thermodynamic scheme of solar air bottoming cycle was proposed. The case study considered an existing small size capacity gas turbine (<50 MW) as a topping cycle. The thermodynamic performance of the proposed solar air bottoming cycle was compared to two reference cases, without solar energy, a steam bottoming cycle and a conventional air bottoming cycle.

1. Introduction

Algeria, located in the Middle East and North Africa (MENA) region, is counted among the best insolated areas. Over the country land, estimated at 2.4 millions Km^2, the Sahara represents 86%. It is exposed yearly to a direct sun irradiation higher than 2000 kWh/m^2 gain from 3500 hours of sunshine. These solar potential and land resources are optimal for the implementation of concentrating solar power plants (CSPPs) [1]. In 2009 the power generating capacity in Algeria was over 9 GW, 98% of this capacity is provided by gas-fired plants, guaranteed in 46% by gas turbine power plants [2]. In according to the Algerian energy policy fixing the share of renewable energy to 5% by 2010, augmented afterwards to 8% by 2020 [2], and since Algeria's natural gas resources are among the largest in the world, solar-gas hybrid power plant (SGHPP) is more suitable than solar-only power plant. The former technology allows for guaranteed power delivery to the grid without the thermal storage needed for compensating the solar energy intermittency day/night [3].

Currently, a 150 MW plant is expected to start run very soon in Algeria with about 25 MW from solar field. Similar power stations are under construction in other MENA region countries [4], Egypt [5], Morocco, whereas in Iran [6, 7] and Jordan [8] SGHPPs are under

consideration. The technology is based on the integrating of parabolic trough systems into combined cycles (CC) with gas topping cycle (GTC) and steam bottoming cycle (SBC). The parabolic trough systems represent the most mature solar thermal power technology, from both commercial and technical viewpoints, for mid-to-large scale grid connected power plants [9, 10]. The parabolic trough collectors can supply to the SBC a hot heat transfer fluid at medium temperature level of about 400 °C [11].

In recent years, intensive research works have been directed toward developing advanced bottoming thermodynamic cycles [12, 13]. The examined thermodynamic schemes were based on the combination of air cooling, intercooling, gas to gas recuperation and reheating [14-20]. For large-scale power generation, greater than 50 MW, it is proven that SBC is the most effective thermodynamic scheme than any other bottoming cycle [21-23]. However, for small-scale power gas turbines, generating less than 50 MW, suffering from limited efficiency, ABC can be competitive, thanks to size and economic constraints rendering unfavorable the use of SBC.
The present paper presents a conceptual analysis of SGHPP based on ABC. Air, instead of steam, is used in the bottoming cycle to recover both partially the energy supplied by the solar field and the energy from the gas turbine topping cycle exhaust. This plant will be dispensing with all the equipments related to steam power plant (high-pressure steam generator, steam turbine, condenser, pumps, water treatment plant, cooling towers, etc.). Hence, it is expected that the SGHPP based on ABC to be compact and less complex. In comparison to the steam turbine plant the gas turbine plant has some advantages: low capital investment cost and operating and maintenance cost, compact size, short delivery, high flexibility and reliability, fast starting and loading. In addition, gas turbines, free of water requirement, are more suitable to be implemented in high solar irradiation regions, limited in water resources.

A solar-air bottoming cycle (S-ABC) is proposed, analyzed and compared to two reference bottoming cycles (without solar energy), conventional air bottoming cycle (C-ABC) and steam bottoming cycle (SBC). The comparison is based on three main parameters, net output power, energy efficiency and exergy efficiency. For all scenarios, the same topping cycle was considered, an existing small size power turbine gas.

The thermodynamic simulations were performed by the flow-sheet program, “Cycle-Tempo”. This software is a freeware advanced tool for the analysis and optimization of energy systems, developed at the Delft University of Technology [24].

2. Thermodynamic simulations and evaluations

2.1. Thermodynamic bottoming cycles

In the evaluation, for the three considered bottoming cycles the same gas turbine topping cycle was used. The GE M&I LM5000-PC(1) gas turbine model was chosen [24], it is a simple open cycle composed of a compressor (AC), a gas turbine (GT), a generator (G); all linked by a shaft, and a combustion system (CS). The cycle generates 34.450 MW, at ISO conditions (1.013 bars, 15°C, RH 60%, and CH4 as fuel), with exhaust temperature and mass flow, respectively, 432.22 °C and 124.738 Kg/s. The energy and exergy efficiencies are respectively, 36.57% and 34.86%.

2.1.1. Solar-air bottoming cycle

The schematic flow diagram of the cycle is shown in Fig. 1. To limiting the number of heat exchangers incorporated in the cycle, just one intercooler (IC) was applied between two

compressors, (AC1) and (AC2). The intercooler cooled the air exiting the first compressor (AC1) down to 40°C. After exiting the second compressor (AC2) the air was heated to 370°C in the solar heat exchanger (SHX). Afterwards, after expanding in the first gas turbine (GT1) the air penetrated into the recuperator (GR) for recovering some energy from the topping cycle flue gas before expanding in the second turbine (GT2). The effectiveness of the solar heat exchanger was set at 90%, whereas the air recuperator had the effectiveness of 85%. It assumed that the hot heat transfer fluid, coming from the solar collector, entered into the solar heat exchanger with about 395°C and then leaved with about 295°C. For the two compressors, the optimum pressure ration was 3.16 and 2.41, respectively. Both compressors and the turbine had an isentropic efficiency of 90%. The relevant air mass flow was estimated at 143 kg/s.

Heat delivered to the air in the solar heat exchanger is:

$$\dot{Q}_a = \dot{m}_a \Delta h, \qquad (1)$$

where $\dot{m}_a$ is the mass flow rate of air, and Δh is the specific enthalpy gain of the air across the SHX. The solar irradiation input to the solar collector is calculated as:

$$\dot{Q}_s = \frac{\dot{Q}_a}{\eta_{sf}}, \qquad (2)$$

where η_{sf} denotes the efficiency of the global conversion of solar irradiation to heat. This includes both the optical efficiency of the solar collector and the thermal efficiency characterizing the heat transportation from the solar collector to the SHX. The value of η_{sf} is chosen to be 0.75, appropriate for the LS3 collector technology [25, 26].

The exergy input through the solar irradiation is determined by the formula [27, 28]:

$$\dot{E}x_s = \left[1 - \frac{4T_0}{3T_s}\left(1 - 0.28\ln(f)\right)\right]\dot{Q}_s, \qquad (3)$$

the symbols T_0 and T_s are, respectively, the ambient temperature and the temperature of the Sun (5777 K), and f is the dilution factor (1.3×10^{-5}).
The energy and exergy efficiencies of the cycle are defined, respectively, as follows:

$$\eta_e = \frac{P_{el}}{LHV\dot{m}_f + \dot{Q}_s}, \text{ and} \qquad (4)$$

$$\eta_{ex} = \frac{P_{el}}{E\dot{x}_f + E\dot{x}_s}, \qquad (5)$$

where P_{el} is the total net power delivered by the cycle, and LHV, $\dot{E}x_f$ and $\dot{m}_s$ are, respectively, the lower heating value, the exergy rate and the mass flow rate of fuel.

2.1.2. Conventional air bottoming cycle

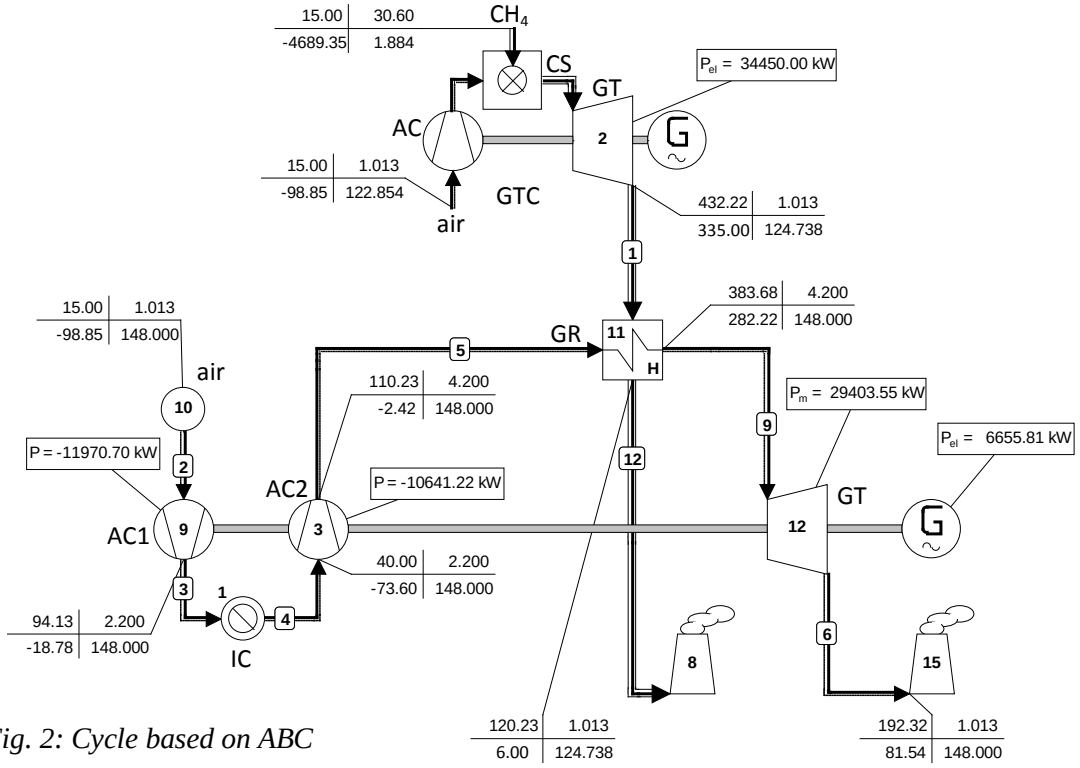

Fig. 2: Cycle based on ABC

As shown in Fig. 2, the air bottoming cycle without solar energy was examined. The C-ABC had the same characteristics as the S-ABC, except that the optimum pressure ration was 2.17 and 1.91, respectively. Also the air mass flow was fixed at148 kg/s.

2.1.3. Steam bottoming cycle

Since the gas turbine topping cycle is of small size (<50 MW), a single-pressure HRSG was chosen. The HRSG was composed of an economizer (EC), an evaporator (EV), a superheater (SH) and a drum (DR). It had the pinch temperature of 20 °C and the approach temperature of 14°C. The superheater had the effectiveness of 87%. The superheated steam entered into the turbine (ST) at 404°C and 19 bars. The isentropic efficiency of the turbine was 85%. The pressure in the condenser (CD) was fixed at 0.074 bars, corresponding to saturation temperature of 40°C. Also, the deaerator (DE) pressure was set at 1.2 bars. More details about the cycle are presented in Fig. 3.

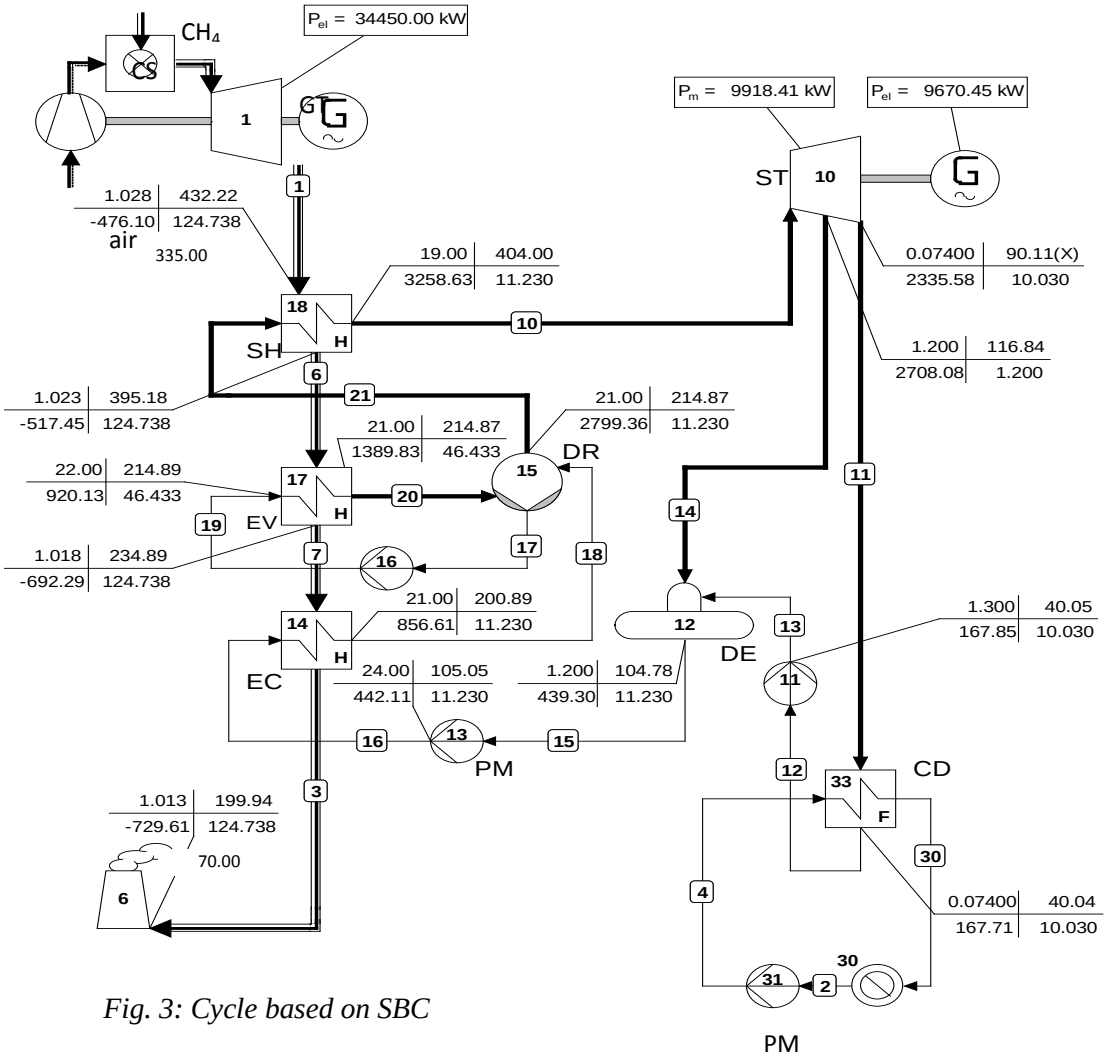

Fig. 3: Cycle based on SBC

3. Results and discussion

Main thermodynamic data related to the cycle performance, for the three examined bottoming cycles, are presented in Table 1. The S-ABC and SBC have nearly the same net output power; contributing to generate 44686 kW for the former and 44120 kW for the last, overtaking by far the C-ABC which delivers 41106 kW. However, the S-ABS is the less efficient cycle, with reference to the topping cycle, it augmented the cycle power by 28.07%, but it decreased the cycle efficiency from 36.56% to 31.87%. In contrary, the SBC is the more efficient cycle; with an energy efficiency of 46.78%, increasing then the topping cycle energy by 10.21 points. With energy efficiency of 41.60% the cycle based on the C-ABS improved the power generation by 19.32%. In term of exergy efficiency, relatively to the simple gas topping cycle the SBC and the C-ABC increase the cycle exergy efficiency from 34.36% (topping cycle), respectively, to 44.66% and 41.60%, the S-ABC decreased it slightly to 33.82%. Note that the cycle exergy efficiency associated to the S-ABC is greater than the energy efficiency.

The comparison between all the examined thermodynamic schemes depend on the relatively high number of thermodynamic parameters and combinations which can modify the performance of the cycle, i.e. turbines and compressors isentropic efficiency, heat exchangers effectiveness, pinch and approach temperature, condenser pressure, etc. The performance of the S-ABC can be improved by more cooling the air down in the intercooler, to less than 40°C, but this level of temperature is typical for cooling by dry air, adequate in regions poor in water resources. Further, at least one intercooler can be added, also an air to air recuperator

can be incorporated to recover some energy of the exhaust air bottoming cycle (143 kg/s at 231 °C). Eventually, the complexity degree of the cycle presents a constraint for any possible modification.

Even, if the S-ABC and the SBC have a comparable performance, potentially the S-ABC can offers 143 k/s of relatively hot air, 230°C, which can be adequate for heat processes requiring pure air.

Table 1. Performances of the three bottoming cycles, S-ABC, C-ABC and SBC.

	S-ABC	C-ABC	SBC
Net output power (kW)	44686	41106	44120
Energy efficiency (%)	31.87	43.63	46.78
Exergy efficiency (%)	33.82	41.60	44.66

4. Conclusion

A case study of solar-gas hybrid power plant has been analysed thermodynamically. The topping cycle of the plant was chosen to be of small size capacity gas turbine (35 MW). An air-bottoming cycle has been proposed instead the well recognized steam topping cycle. Its thermodynamic scheme was based on the combination of intercooling, reheating and gas to gas recuperation. The performance evaluation of the examined cycle was based on the comparison to two reference cases (without solar energy), steam bottoming cycle and conventional air bottoming cycle, in terms of net output power and energy and exergy efficiencies. It was found that the solar-air bottoming cycle and the steam bottoming cycle (without solar energy) had comparable net out powers; whereas the conventional air bottoming cycle (without solar energy) had the smaller capacity generation. However, the steam bottoming cycle is the most efficient cycle, followed by the conventional air-bottoming cycle and afterward by far the solar-air bottoming cycle. The difference in efficiency between the solar-air bottoming cycle and the steam bottoming cycle is due to the definition of energy and exergy efficiency related to the solar cycle. Since the solar heat is provided from the solar irradiation which is free and never depleted, it is may be more practical to don't consider the solar heat energy/exergy as an additional input energy/exergy in the calculation of the energy/exergy efficiency concerning the S-ABC. In that case, the S-ABC becomes the more efficient cycle, with cycle energy and exergy efficiency, respectively, 47.43% and 45.50%.

Abstract: A 110-MW parabolic trough power plant operating in California was modeled to observe the effect of molten salt thermal energy storage capacity on plant performance, cost, and profitability. A plant with no storage (PT-NG) was modeled to match the hourly and annual electricity output of a comparable plant with storage (PT-TES). The solar field area for the PT-TES plant was selected to minimize the unsubsidized levelized cost of electricity (LCOE). For each storage capacity modeled here (1-12 hours), PT-NG resulted in a larger solar field area and higher O&M costs than the respective PT-TES option. PT-TES generally had higher capital costs than PT-NG, and the PT-NG levelized cost of electricity (LCOE) varied from 6% higher compared with smaller TES capacities to 6% less compared with larger TES capacities. The profitability of PT-NG compared to PT-TES followed a similar trend to the LCOE with larger margins of difference in select scenarios. These results were achieved with 3-22% of the net electric output from natural gas in the PT-NG plant. The 30% investment tax credit (ITC), currently in place for solar energy in the United States, lowered the capital costs and LCOE for each configuration. Electricity pricing through a power purchase agreement (PPA) of $200/MWh was more profitable than hourly real-time electricity pricing, which resulted in a net annual loss for all configurations. Both the PPA and ITC were required to achieve a positive annual profit, and the maximum annual profit achieved was $US 11 million per year with 0 hours of storage.

Keywords: *concentrated solar power, thermal storage*

Nomenclature

Q	thermal energy	MJ	
M	mass	kg	
T	temperature	^oC	
K	piping thermal losses	J/m^2	
T_o	ambient temperature	^oC	
L	length of pipe in solar field	m	
l_{gap}	length of gap between solar collector assemblies (SCA)	m	
w_{sca}	SCA width	m	
l_{br}	length of space between SCA rows	m	
A_{SCA}	SCA aperture area	m^2	
l_{sca}	SCA length	m	
n_{sca}	number of SCAs per row		
θ	incidence angle	^{o}	
η_{opt}	SCA optical efficiency		
IAM	incidence angle modifier		
F_s	mirror soiling factor		
d_o	outer diameter of solar field pipe	m	
m	mass flow rate	kg/s	
Δh	enthalpy change	J/s	
t	hour of TES storage capacity	hrs	
h_i	enthalpy at inlet	J/s	
h_e	enthalpy at exit	J/s	
η	efficiency or effectiveness		
h_{es}	enthalpy of isentropic state at exit	J/s	
w	work per unit mass	J/kg•s	
W	power	J/s	
Cp	specific heat	J/kg	
r	density	kg/m^3	
CF	plant capacity factor	%	
$W_{tdesign}$	design turbine output	MJ	
D_{htr}	natural gas-fired heater heat duty	MJ/hr	
k	loan interest rate	%	
j	loan lifetime	years	
C	cost	$US2009	
i	discount rate	%	
n	plant lifetime	years	
F_{debt}	debt portion of capital cost	%	
F_{equity}	equity portion of capital cost	%	
NPV	net present value	$	
LAC	levelized annual capital cost	$/yr	
C_{OM}	annual operation and maintenance cost	$/yr	
p	price of electricity	$/MWh	

1. Introduction

Solar energy is an attractive renewable energy source because the sun's energy is plentiful and carbon-free. Cost and intermittency issues have prevented widespread deployment of

solar power plants, but these issues may be partially mitigated with the addition of thermal energy storage (TES). Molten salt TES can be used in lieu of a natural gas boiler to provide backup energy for a parabolic trough concentrated solar thermal power (PT) plant during cloudy periods and nighttime. TES can enable a PT plant to provide reliable peak or baseload electricity without sacrificing carbon neutrality by relying on a natural gas backup system. However, the additional equipment associated with a TES system can add substantially to the already high capital cost of PT. An investor will only accept the additional cost of these components if the potential exists for an economic benefit that exceeds the extra cost. This study examines the economic implications of TES through an engineering-economic model. The model calculates the levelized cost of electricity and expected annual profit of a PT plant with varying TES capacities and compares these results to a similar PT plant with natural gas backup.

2. Methodology

An engineering-economic model was developed to simulate the hourly and annual performance and cost of a PT plant. A visual representation of the engineering portion of this model is presented in Figure 1. Typical meteorological year (TMY3) direct normal radiation (DNR) and ambient temperature data for Daggett, California [1] were used as inputs to a series of component-based mass and energy balances to simulate the thermodynamic operation of the system. Two separate and distinct engineering models were created: 1) PT-TES, which models a PT plant that uses a TES system, and 2) PT-NG, which models a plant that uses a natural gas-fired heat transfer fluid (HTF) heater in place of a TES system.

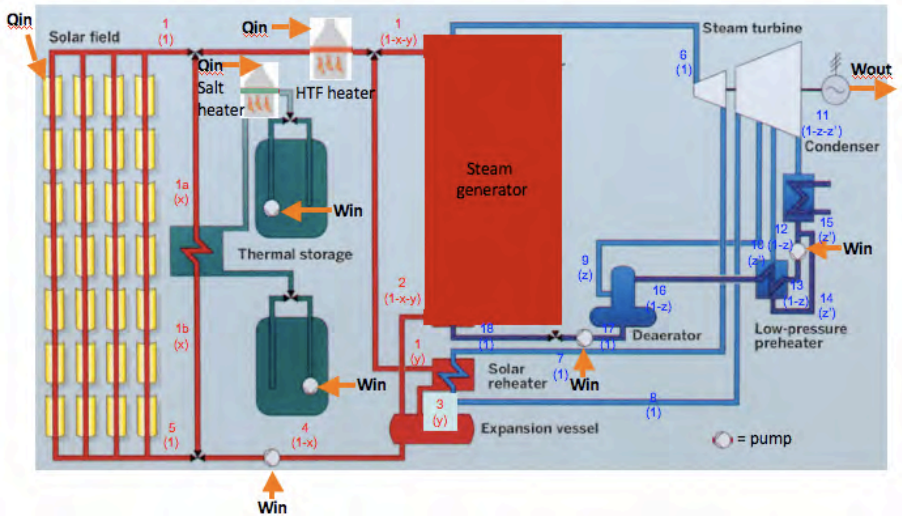

Fig. 1. Parabolic Trough Plant Schematic (adapted from [2]).
Hourly DNR enters the solar field and is concentrated on the heat transfer fluid (HTF) in the receiver tubes (red). The HTF is pumped to the power cycle where energy is transferred to steam (blue) via the steam generator and reheater. The heat from the steam drives the turbines to generate power (Wout) and the cooled HTF returns to the solar field. When the TES system is charging, some HTF flows to the heat exchanger to transfer energy to molten salt. Hot salt is stored in one tank and cold salt in the other. When the ambient temperature threatens to freeze the salt, the salt heater is activated to maintain the temperature above freezing. The HTF heater is used to maintain the HTF temperature above freezing when altering the HTF mass flow rate fails to prevent freezing. The HTF heater is used as an alternative to the TES system in the PT-NG plant. The heat energy input to the two heaters from natural gas combustion is represented as Qin. Five pumps are used in the system, and the work required to operate them is shown as Win. Red numbers refer to HTF states, blue numbers refer to steam states, and numbers in parentheses represent mass flow fractions.

The PT-TES model incorporates seven distinct operation modes, which are presented in Table 1. The hourly simulation selects operation modes based on whether all criteria are satisfied, following the hierarchy shown in Table 1. For example, if Day_TESC fails, the simulation will attempt to run Day_SOLAR. If Day_SOLAR fails, the simulation will attempt Day_TESD, and so on. The PT-NG model only uses Day_SOLAR, Night_SD, and Night_FP, and incorporates an additional mode similar to Day_TESD that uses the HTF heater in place of the TES system. The PT-NG model uses as inputs the T_1, W_{net}, and W_{sold} results from the PT-TES model (see equations 30 and 31), and the solar field area for PT-NG is selected to minimize the difference between W_{sold} from each model, in order to simulate two different power plants that generate comparable amounts of hourly and annual electricity.

Table 1. Plant operation modes.

Mode ID	Description	Criteria
Day_TESC	Only the solar field delivers thermal energy to the power cycle; excess solar energy "charges" the TES system	$Q_{SF} > \min$ $M_{salt} < \max$
Day_SOLAR	Only the solar field delivers thermal energy to the power cycle; the TES system is idle	$0 < Q_{SF} \leq \min$ $M_{salt} \leq \min$
Day_TESD	The solar field and the TES system deliver thermal energy to the power cycle	$0 < Q_{SF} < \min$ $M_{salt} > \min$
Night_TESD	Only the TES system delivers thermal energy to the power cycle; HTF circulates through the solar field at a minimum mass flow rate to stay warm	$Q_{SF} \leq 0$ $M_{salt} > \min$
Night_SD	The power cycle is idle; HTF circulates through the solar field at a minimum mass flow rate to stay warm	$Q_{SF} \leq 0$ $M_{salt} \leq \min$
Night_TESFP	The power cycle is idle; HTF circulates through the solar field at a minimum mass flow rate, and the TES system protects the HTF from freezing	$Q_{SF} \leq 0$ $M_{salt} > \min$ $T_{HTF} \leq \min$
Night_FP	The power cycle is idle; HTF circulates through the solar field at a minimum mass flow rate, and the natural gas-fired heater protects the HTF from freezing	$Q_{SF} \leq 0$ $M_{salt} \leq \min$ $T_{HTF} \leq \min$

The hourly simulation uses an iterative process that selects an operation mode based on the net energy captured by the solar field (Q_{SF}), the total mass of salt in the "hot" TES tank (M_{salt}), and the temperature of the HTF. The minimum Q_{SF} for the 110-megawatt (MW) system modeled here is 245 megawatt-hours (MWh). The hourly Q_{SF} value depends on hourly ambient conditions and HTF temperature, as shown in equations 1 through 3. The solar field area (A) is specified at the beginning of each simulation and varied to achieve the lowest levelized cost of electricity (LCOE). Equation 2 is a simplified version of the calculation used to determine the length of pipe in the solar field, which is a required input to equation 3.

$$K = a + b \bullet (T_{HTF} - T_o) + c \bullet (T_{HTF} - T_o)^2 \quad (1)$$

where a, b, and c are empirical thermal loss coefficients [3]

$$L = l_{gap} + 2 \bullet w_{sca} + 2 \bullet l_{br} + (A \div A_{SCA}) \bullet ((l_{sca} \bullet w_{sca} - A_{SCA}) \div w_{sca} + l_{sca} + l_{br} \div (A_{SCA} \bullet n_{sca}) + (2 \bullet w_{sca} + 2 \bullet l_{br}) \div n_{sca} - (2 \bullet A_{SCA} \bullet (w_{sca} + l_{br}))/A) \quad (2)$$

$$Q_{SF} = A \bullet DNR \bullet \cos(\theta) \bullet \eta_{opt} \bullet IAM \bullet F_s - K \bullet \pi \bullet d_o \bullet L \bullet (T_{HTF} - T_o) \quad (3)$$

where l_{gap}=1m, w_{sca}=5.77m, l_{br}=15m, A_{SCA}=817.5m^2, l_{sca}=149m, n_{sca}=4, d_o=0.07m, and η_{opt}=82% [3]

Equation 4 shows how the model calculates the total amount of M_{salt} using the design values presented in [4]. The HTF factor (F_{HTF}) was selected as 1.5 after several iterations of the model indicated that the hourly m_{HTF} rarely exceeded 1.5 times the design value. The number of hours of TES capacity refers to the number of hours the turbine could operate at full rated capacity using only the thermal energy from the storage system. The extra salt factor (F_{salt}) represents the amount of salt that must remain in the TES tanks at all times. In this study, the nominal value for F_{salt} was 1.14 [4].

$$M_{salt} = -((3600 \bullet (m_{HTF} - m_{HTFo}) \bullet F_{HTF} \bullet (\Delta h_{HTF})) \bullet t \bullet F_{salt}) / (\Delta h_{salt}) \quad (4)$$

where m_{HTF} = 1,206 kg/s, m_{HTFo} = 121 kg/s, F_{HTF} = 1.5, F_{salt} = 1.14

The model calculates the design states and mass flow rates of all fluids in the system shown in Figure 1 through a series of component mass and energy balance equations based on the First Law of Thermodynamics, assuming steady-state conditions and zero kinetic or potential energy flows (equations 5-29). The key design inputs to these equations include: T_1 = 393°C, T_3 = 225 °C, T_5 = 293 °C, T_6 = 373 °C, pressure $(p)_4$ = 110 kPa, p_5 = 620 kPa, p_6 = 10,001 kPa, p_7 = 1,900 kPa, p_8 = 1,700 kPa, p_9 = 700 kPa, p_{11} = 8 kPa, p_{12} = 200 kPa, p_{18} = 10,200 kPa, $\eta_{turbine}$ = 85%, η_{pump} = 80%, $\eta_{preheater}$ = 80%, TES heat exchanger effectiveness of heating and cooling = 88%. The hourly simulation also uses equations 5-29 to set the hourly states, beginning with a starting T_5 value of 100 °C.

Heat exchangers (steam generator/ reheater, condenser, LP preheater, TES heat exchanger, salt & HTF heaters):

$$h_i = (\eta \bullet h_{es} - h_e) \div (\eta - 1) \quad (5)$$

$$h_e = h_i + \eta \bullet (h_{es} - h_i) \quad (6)$$

$$h_e = h_i + (m_{steam} \bullet (h_{i\_steam} - h_{e\_steam})) \div m_{HTFadj} \quad (7)$$

$$Q = m \bullet (\Delta h) \bullet 3600 \quad (8)$$

where, η = heat exchanger effectiveness, adj = mass flow rate adjusted with fractions shown in Fig. 1

Turbines:

$$w = \eta \bullet (h_i - h_{es}) \quad (9)$$

$$h_e = h_i - w \quad (10)$$

$$W = w \bullet m_{steam} \quad (11)$$

Rankine cycle pumps:

$$w = (h_i - h_{es}) \div \eta \quad (12)$$

$$h_e = h_i - w \quad (13)$$

$$W = w \bullet m_{steam} \quad (14)$$

Expansion vessel:

$$h_4 = (1-y) \bullet h_2 + y \bullet h_3 \quad (15)$$

Solar field pump:

$$W = m_{HTF} * (r_4^{-1} * (p_4 - p_5) \div \eta) \quad (16)$$

$$h_5 = h_4 - w \quad (17)$$

Mass flow rates and fractions:

$$z = (h_{17} - h_{16}) \div (h_9 - h_{16}) \quad (18)$$

$$z' = (z \bullet (h_{16} - h_{14}) + h_{14} - h_{16}) \div (h_{14} - h_{12}) \quad (19)$$

$m_{steam} = W_e \div (h_6 + h_8 - h_7 - z \bullet h_9 - z' \bullet h_{12} - (1 - z - z') \bullet h_{11})$ (20)
$m_{HTF} = (Q_{SF} \bullet 1000000) \div (h1 - h8)$ (21)
$y = (m_{steam} \bullet (h_7 - h_8)) \div (m_{HTF} \bullet (h_1 - h_3))$ (22)
$x = (h_1 - h_{1a} \bullet m_{HTF}) \div (h_{1b} - h_1)$ (23)
$m_{salt} = -(x \bullet m_{HTF} \bullet (\Delta h_{HTF}) \div (\Delta h_{salt}))$ (24)

Therminol VP-1 (HTF) and nitrate salt properties [5]:
$Cp_{HTF} = 7.888e\text{-}4 \bullet T^2 + 2.496 \bullet T + 1.509e3$ (25)
$Cp_{salt} = 1.72e\text{-}1 \bullet T + 1.443e3$ (26)
$h_{HTF} = 1.377 \bullet T^2 + 1.498e3 \bullet T - 1.834e4$ (27)
$h_{salt} = 8.6e\text{-}2 \bullet T^2 + 1.443e3 \bullet T$ (28)
$r_{HTF} = -7.762e\text{-}4 \bullet T^2 - 6.367e\text{-}1 \bullet T + 1.0740e3$ (29)

The net electricity generated by the system is calculated using equation 30, and then separated into electricity sold and bought (equations 31 and 32) for the cost model. The power losses due to auxiliary equipment such as electronic motors, drives, computers, etc (W_{aux}) are calculated using the series of equations described in [6]. Equation 33 calculates the capacity factor based on electricity sold, while equation 34 calculates capacity factor based on net electricity generated (after subtracting electricity used by pumps during nighttime hours).

$W_{net} = W_{turbines} - W_{pumps} - W_{aux}$ (30)
$W_{sold} = W_{net}$ when $W_{net} > 0$ (31)
$W_{bought} = abs(W_{net})$ when $W_{net} < 0$ (32)
$CF = W_{sold} \div (W_{tdesign} \bullet 8760)$ (33)
$CF_{net} = W_{net} \div (W_{tdesign} \bullet 8760)$ (34)
where W_{aux} refers to power losses through auxiliary loads

The economic model calculates the total capital cost of the plant and the annual operation and maintenance (O&M) costs using a slightly adapted version of the National Renewable Energy Laboratory's (NREL) Solar Advisor Model (SAM) cost model [7], which was developed for a plant with a solar field area of 854,000 m^2. In order to apply this model to a variety of solar field sizes, a scaling factor (the ratio of the solar field area to the reference solar field area) is used for area-dependent O&M cost items. Calculations were added for the capital cost of the HTF and salt heaters as well (equations 35 and 36).

$D_{htr} = (\max (Q_{htr}) \bullet 0.00094781712) \div 1000000$ (35)
$C_{htr} = 13402 \bullet D_{htr} + 367158$ (36)

The levelized cost of electricity (LCOE) is calculated using equations 37-40. An alternative, subsidized levelized annual capital cost (LAC) is also calculated with the current United States federal investment tax credit (ITC) for solar energy investments. This ITC is applied as a cash grant, i.e., a deduction, of 30% of the total plant capital cost.

$C_{loan} = (k \div (1-(1+k)^{-j})) \bullet C_{cap} \bullet F_{debt}$ (37)
$NPV_{loan} = \Sigma (C_{loan} \div ((1+i)^{year}))$ (38)
$LAC = (i \div (1-(1+i)^{-n})) \bullet (NPV_{loan} + C_{cap} \bullet F_{equity})$ (39)
$LCOE = (LAC + C_{OM}) \div W_{sold}$ (40)

The expected annual profit (P) is calculated using equation 41 and hourly historic electricity pricing data from the California Independent System Operator (CAISO) from 2008 [8]. This calculation assumes that the power plant receives the real-time price of electricity from the

CAISO. An alternative P is calculated under the assumption that the plant owner enters into a power purchase agreement (PPA), and this calculation is shown as equation 42.

$$P = \Sigma (W_{sold} \bullet (p - LCOE)) \quad (41)$$

$$P_{PPA} = \Sigma (W_{sold} \bullet (p_{PPA} - LCOE)) \quad (42)$$

3. Results

The solar field area for PT-TES was selected to minimize the LCOE, while the solar field area for PT-NG was selected to minimize the difference between W_{sold} in the two models. Figure 2 shows that the solar field area increased with increasing storage capacities in order to capture enough energy for the TES system. The solar field area for the PT-NG plant increased even more because it was required to meet the hourly solar-generated electricity output of the PT-TES plant without being able to store excess solar energy during high DNR hours. The capacity factor for each plant was almost identical since PT-NG was designed to match PT-TES. The net capacity factor for each system was smaller because it subtracts nighttime pump energy from the annual electricity generation. Overall, capacity factor increased with storage capacity as the plants operated for more annual hours. The PT-NG plant generated 3-22% of its annual electricity with the NG heater.

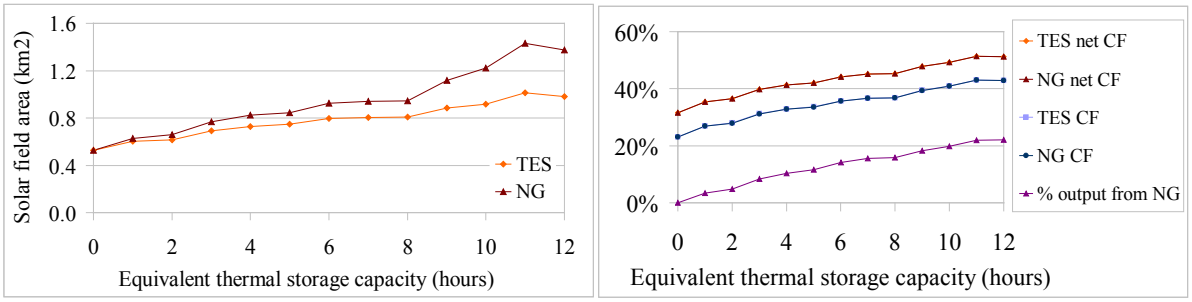

Fig. 2. Solar Field Area (left) and Plant Capacity Factor (right).
The first graph shows the solar field area selected for PT-TES to minimize LCOE and the area selected for PT-NG to match PT-TES electricity output. The second graph shows the corresponding plant capacity factors and the percent of output from natural gas in the PT-NG plant.

Figure 3 shows that the capital costs increased for both plants with increasing equivalent storage capacity, as a larger solar field was required. PT-TES with 1 hr TES had slightly lower capital costs than PT-NG as the latter required a slightly larger solar field. PT-TES with 3-12 hrs TES had higher capital costs than PT-NG as the cost of the TES system outweighed the larger solar field area required by PT-NG. O&M costs increased with storage capacity, as a larger solar field required more workers and maintenance. The O&M costs were higher for PT-NG because of the additional annual fuel purchase.

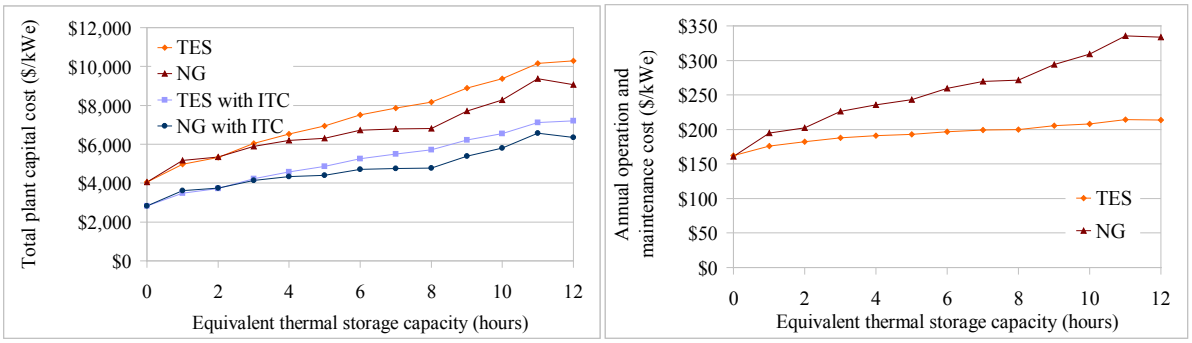

Fig. 3. Total Plant Capital Cost (left) and Annual Operation and Maintenance Cost (right).

The first graph shows the total plant capital cost for each plant with and without the 30% investment tax credit (cash grant). The second graph shows the annual O&M costs for each plant. Assumptions: natural gas = $US 5.92/MMBtu, auxiliary electricity = $US 135.15/MWh.

In Figure 4, the LCOE generally increased with storage capacity, and the LCOE of PT-NG varied +/- 6% from the LCOE of PT -TES. With smaller storage capacities, higher PT-NG O&M costs outweigh higher PT-TES capital costs to result in lower PT-TES LCOE. With higher storage capacities, higher PT-TES capital costs outweigh higher PT-NG O&M costs to result in higher PT-TES LCOE. This second effect was lessened with the ITC as the high PT-TES capital cost decreased, but the high PT-NG O&M cost remained unchanged. Based on these costs, a carbon price of $US 153-$383/tonne CO_2eq would be required for PT to be competitive with coal, depending on plant specifications.

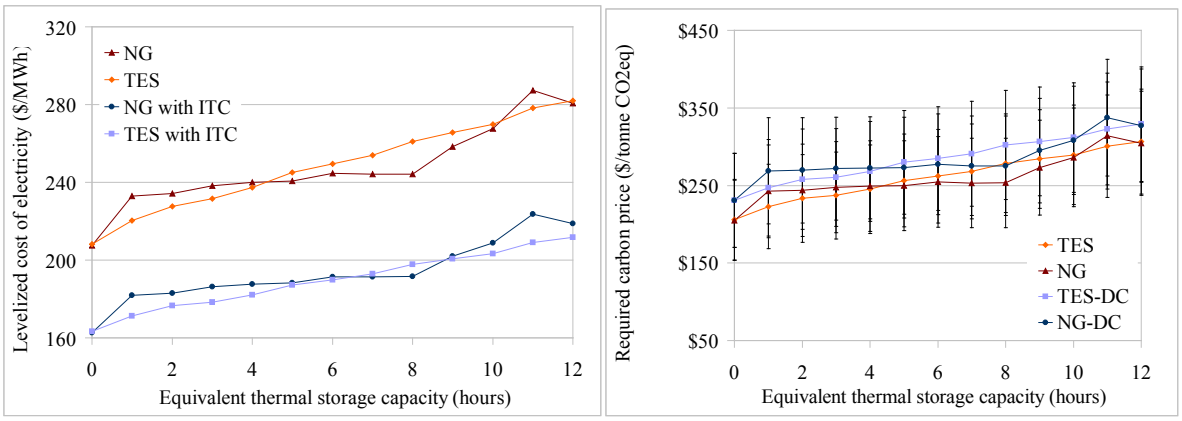

Fig. 4. Levelized Cost of Electricity (left) and Required Carbon Price (right).
The first graph shows the LCOE of each plant with and without the ITC. Assumptions: k=7%, j=20 years, F_{debt}=60%, F_{equity}=40%, i=12%, n=30 years. The second graph shows the carbon price that would be required for these plants to be competitive with coal electricity generation in the United States. Assumptions: coal LCOE=$US 64-74/MWh [9], coal greenhouse gas (GHG) emissions = 0.84-0.88 tonnes/MWh [10], and PT GHG emissions = 0.01-0.185 tonnes/MWh [11]. The bars represent the range of results associated with GHG emission and coal cost bounds.

Figure 5 shows that expected annual profit decreased with increasing storage capacity, and the only scenario that achieved positive annual profit was PPA/ITC with 0-8 hrs TES equivalent, highlighting the importance of guaranteed pricing and financial incentives. Hourly CAISO pricing with no ITC resulted in the largest annual loss, and similar trends were observed across storage capacities as those seen in the LCOE results: PT-TES was more profitable than PT-NG at storage capacities of 1-4 & 11 hr with no ITC, and 1-6 & 9-12 hr with the ITC. At the extremes, the profit of PT-NG with PPA/ITC was 4 times greater than 8 hr PT-TES and three times less than 11 hr PT-TES.

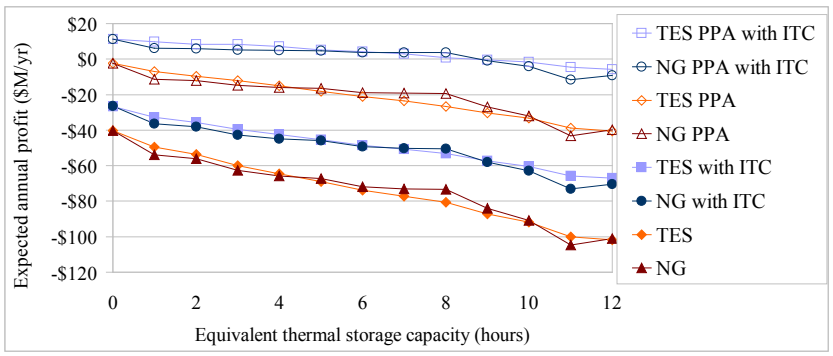

Fig. 5. Expected Annual Profit.
This graph shows the expected annual profit for each plant, using the unsubsidized LCOE, the subsidized LCOE (with ITC), hourly electricity pricing, and power purchase agreement pricing (PPA of $US 200/MWh).

4. Discussion and Conclusions

The results of this analysis are subject to the specific assumptions and calculations outlined above. The uncertainty inherent in these assumptions and the sensitivity of results to changes in nominal values has not yet been explored, but is the subject of future analysis. Nonetheless, the limited scope presented here offers some insights for solar energy policy. Encouraging PT power plants to serve as baseload generators could result in cost increases and profit decreases, whether the additional generation is met by NG or TES. However, a small amount of TES (1-4 hours) is likely to be slightly more profitable and less costly than attempting to achieve similar annual generation with NG backup. If the policy goal is to encourage the deployment of PT power plants as baseload generators, incentives such as the U.S. federal 30% investment tax credit (ITC) or a generous power purchase agreement (PPA) are necessary to reduce the LCOE and result in a positive expected annual profit. The ITC favors TES compared to NG because it reduces the high TES capital cost but does not affect the high NG O&M costs. A price of $US 153 per tonne CO_2eq or higher could make PT competitive with coal electricity generation.

Abstract: The paper defines and describes factors that should be considered when hybrid energy supply systems that incorporate solar systems in particular are planned. In the first point, the author establishes the hierarchy of criteria to apply at subsequent phases of the decision processes carried out when renewable energy systems are to be used. To do this, the authors take the advantage of shortly described case studies: a solar hot water system in an elderly house and an integrated system of steam boilers together with heat recovery from a cooling system in connection with solar heating in a food production plant, etc. Then, the paper indicates the necessity of energy simulations prior to taking up the decisions of localization and to final verification of the project. The example of the simulation method called equivalent thermal network is mentioned in the comparison to the advantages and disadvantages of the other software described. Some forms of promotion are presented, which can be applied to positively stimulate the sustainable development of the use of renewable sources in the European central eastern region on the background of a short comparison.

Keywords: *local availability, hybrid systems, sustainable development*

1. Introduction

Hybrid systems in relation to energy supply are the systems that incorporate different media such as electric current, flowing fluids or solid massive elements to carry out different forms of energy from various sources either renewable or conventional. They are also called integrated systems and can combine a traditional boiler gas fired, a heat pump transferring ground heat or the heat from solar thermal collectors, a usually small photovoltaic system supplying electrical energy for circulation pumps and somehow integrated a passive system such as e.g. solar walls. The particular composition is determined by operational conditions, energy source localization, availability and its form, and by other factors that influence the rational use of energy. The decisions can be taken up after thorough consideration of:

-local climatic conditions,
-social aspects that influence the cycle of energy demand,
-object character,
-technological aspects resulting from selected devices designed for the system,
-economical factors that determine investment capabilities in the frame of the analyzed enterprise and
-the cost of operation of the whole hybrid system.

The paper presents the description of the influence of selected factors on design and decision processes related to appropriate energy supply system and on the realization of objects that use solar energy. There is a vast diversity of social aspects and problems of matching between the demand and solar energy availability in a perspective characteristic for mid-severe climate, characteristic for central - eastern Poland. The procedure of careful analysis describes the most important contracting factors such as:

-high solar gain and low ambient temperature,
-high social acceptation and cost exaggerating investment capabilities in the region,
-standard regulations characteristic for the country and the region and availability of simulation tools, and with special attention
-the applicability of available simulation tools.

2. Methodology

The selection and decisive criteria can be divided in some hierarchy. It is obvious for engineers that the good will of having a system to supply renewable energy cannot be decisive for selection of components for the particular object. It is questionable, however, if the negative will (quite common in some societies) can be decisive for the resignation and if the decision should not be taken by local authority on the basis of justified technical reasons and natural conditions, having in mind the rational use of energy and environment protection. It is a distant goal to reach the situation when such justification is obligatory to potential investors. On this distant way to reach this goal either social mentality must undergo its process of evolution towards higher responsibility for the environment or legislation and standards must be established to rule new attempt to the selection of energy sources. The widely understood education drawing the attention to all mentioned determinants could be very helpful on this way to assume proper hierarchy in the processes of investment, design, realization, maintenance of systems and exploitation of resources to reach the final result established as sustainable development.

Usually, attempting the design process for a particular object, its localization and character is already established, but sometimes, we have a chance to adjust the localization for better exposition to solar radiation or for advantageous distribution of ground collectors and slightly adjust the waveform of load to the cycle of energy availability through some change of habits or technology. The principal idea of hybrid systems is not the most extensive use of all renewable energy sources (res) in one system but the most reasonable integration of those that are convenient for the localization and the object character. Country regions are comparatively flexible in fitting the localization to the needs of effective heating systems and this meets another fact that the systems that are used there are usually outdated and contain low effective boilers fuelled with coal or are expensive such as boilers fuelled with liquid gas or gasoil because of the cost of these fuels. In the first phase of design the availability and economics of resources is considered. The paper is focused on solar energy thermal conversion integrated within hybrid systems because widely understood conversion of solar energy has its special conditions and restrictions worth analyses.

The systems that use direct and dispersed beam require south oriented exposition with possible adjustment to horizontal plane, and thus should be placed on the ground or tilted roofs. They need the coincidence of load waveform and the cycle of availability as much as possible to avoid damage resulting from overheating of elements or heat loss because of extended accumulation. These systems are used:

- for hot water systems: in food industry, for sanitary and living purposes in permanently occupied buildings (SDHW) and to contribute low temperature heating systems, especially
- floor heating systems,
- to heat process water: in fish breeding ponds, to water glasshouse plants and to heat the ground,
- in drying processes of many purposes to contribute technological halls (air collectors and passive solar systems), especially biomass drying for solid biofuels,

Systems that cooperate with heat pumps in heating systems either in central heating or hot water systems require additional supply from electric grid and providing cooling power from the bottom source of so called bottom energetic potential i.e. from the ground, for example. They can have the form of:

- ground water wells, which require proper soil absorption to receive water from absorption wells, proper localization in a distance to each other and good quality of soil to protect durability of drilled objects,

- horizontal and vertical heat exchangers that require big undeveloped land area. One should remember that undeveloped does not mean unused. The terrain with ground collectors underneath can serve as a parking place, sports yard, nice flower bed or grass and only big root trees must be avoided.

Boilers can be fuelled with biofuels but each case must be considered if the particular localization is economically justified in the aspect of transport cost. It is difficult to describe biofuels as one source of energy because they are diversified as much as biomaterials and processes used for their generation. Shortly describing, the generation can also be understood as origin and is the classifying factor for biofuels. The first generation biofuels are produced directly from eatable plants in fermentation and trans-estrification processes and have similar limitations as food raw material. The second generation biofuels are produced from biomass or non eatable seeds having in mind that waste material is its origin. The third generation biofuels use the same material as the second one but after additional treatment, processing and modifications. The fourth generation biofuels are rather a perspective target employing such advanced technologies as in photo bioreactors and the use of intermediary organisms, e.g. algae, during production processes. In Poland, the second generation biofuels will soon have the dominant role over the first one which is positive and desired tendency.

Heat recovery systems from production processes of many types, e.g. from ventilation, from cooling, quite frequent in food industry and rarely from air conditioning as it is not very popular in Poland, or heat recovery from litter in animal farmhouses.

Photovoltaic systems, usually recognized as expensive, become reasonable when traditional connection to grid is more expensive than standards, especially when increased power demand in a farm or a household requires additional investment from regional distribution company which in turn is transferred to a user. They are treated as additional support to supply devices of low demand in complex hybrid systems (e.g. PV panels for circulation pumps in solar domestic hot water – SDHW - systems). Environmental protection aspects can be sometimes decisive if the localization is situated in nature parks. The most famous localization of this type in our country is the mountain shelter in the Valley of Five Polish Tarns. Moreover, it is also practical to install PV panels in periodically occupied small objects such as forest shelters, guest rooms and shepherd's huts but there is a need to provide an energy store system and protection in the period of no use by e.g. spare duty lighting. The potential of photovoltaics is recognized as capable to reach 12% share in total production of energy in Europe by 2020 year. Unfortunately, in Poland, there are no favorable circumstances to promote PV systems [1].

Solar walls in our climate should be completed with TIM (Transparent Insulation Material) modules besides typical massive elements and air gaps because this additional insulation protects the building envelope during fall-winter seasons against thermal losses at low ambient temperatures. It is necessary that the whole insulation of these buildings is of best quality ranging u value between 0.1 and 0.3 at maximum and that the terrain around is properly adapted. Several case studies can be mentioned on the basis of the author's research [5, 7] and the other reference [1]. Particular conclusions can be derived in relation to the application of such passive structures as Trombe-Mitchell's walls in eastern mid-European regions [7]. This typical construction cannot be successfully used for the whole year because:

- insulation even by two glass panels is insufficient for winter and
- solar radiation in summer often exceeds the needs.

In the intermediary season of fall (spring/autumn), solar walls prove their usefulness and thus make possible to reduce heating period and energy demand in total thanks to the solar gain in several weeks within the range of the whole heating period. There is also a very useful solution to the problem of insulation, i.e. transparent panels. Thanks to the capillary structure they let radiation in and prevent from thermal losses because of air trapped within capillary and its material – organic glass - of insulation properties. Moreover, the shading can be realized by means of insulated folded blinds and with the help of leaf trees.

Because of low intensity of heat flux coming from renewable sources such as ground or solar radiation, the renewable systems have comparatively long pipelines and this is one of the reasons of thermal loss from active elements. That is also why designs should strictly reduce collective pipeline length placing collectors as close as possible to the receivers. Moreover, in comparison to traditional heating, the effectiveness of renewable systems depends more on the cycle of load. In particular, the systems that work at loads lower than calculated in the design, have much lower energy effectiveness which influences directly the cost-effectiveness. The research carried out by Chochowski A. and Czekalski D. [1] prove that energy parameters outstand the predicted ones on the basis of static characteristics. Unequal load of the system in subsequent days leads to the reduction of conversion efficiency even of 50%.

3. Results

At first, the exemplary case study of an elderly house for women in a village can be shortly described. The design of this system avoids long pipelines because the boiler room is on the ground floor directly under the roof where collectors are to be installed with proper exposition on south oriented tilted roof. The design process of this hybrid system was carried out when the total modernization of the whole object was considered, including the change of fuel from liquid gas stored in tanks on the backyard to natural gas from local network. The designed solar system was to contribute to the main supply. The designed system consists of the battery of twelve flat plate thermal collectors and nine collectors have been planned on the south tilted roof and the other three on the west roof surface with additional construction for south-west exposition. Optional expansion of the battery into another eight collectors could be possible after removal of gas tanks. The condition of source availability is fulfilled this way. Another criterion for consideration was matching the load waveform to the cycle of heat production. In this aspect there is an ideal phase coincidence either in annual cycle or daily use of hot water and heat production from the solar system. This is possible because of special care that must be carried for the residents, i.e. – because the residents are of advanced age and through this debilitated and less resistant to temperature changes, their bathing in winter must be limited to the necessitate minimum. In summer, when there is a lot of sun radiation there are no such threats as low temperature, cold draughts etc., the balneological care can be more frequently applied. There is also some good coincidence in daily treatment because the baths are taken in the afternoon hours when the house service staff have managed with cleaning and cooking and the water storage tank is full of water heated from collectors at the maximum for the day. In the evening hours, the water storage starts slowly cooling off and the staff except for the person on duty, goes home. Moreover, the residents in elderly houses do not go for holidays as housing estate inhabitants or do not go home in the afternoon as people working in offices. It is only a pity that at so many favourable circumstances, this design has been abandoned.

Czekalski D. [1] points out also some other solutions of good coincidence: a seminary with boarding house, a monastery or a convent with retreat centers, a school with a swimming

pool, etc. Academic centers are especially vulnerable to the pressure of educative aspects of renewable energy applications and they should extremely thoroughly consider the matter of coincidence. The good solution could be a guest room house combined with a sports center containing a swimming pool available for usage during holidays. It seems not justified to supply lecture buildings from solar energy because the largest amount of energy is to be used potentially when the real use drops to zero. Then it is necessary to employ this energy somehow to avoid the destruction of the whole system. Overheated collectors are damaged and hot water stored for too long than a few days is the environment for bacteria growth. This problem has to be solved also for single family houses. In this aspect municipal applications in blocks of flats are advantageous because the part of inhabitants stays at home for the whole year and it is not a problem if this is not the same group when hot water is prepared centrally. The remaining usage is usually sufficient to ensure continuous medium flow through collectors.

Another attempt to the problem of coincidence is the consideration of the integration of an individual system with municipal grids and networks, however at the present state of formal regulations and technical practice, it is an extremely difficult enterprise in our country, available rather to bigger energy producers than just families or single farms. So far, the connection of geothermal source with the heat distribution network and the integration of boilers fuelled by biofuels with gas boilers supplied from gas distribution network or with the heat distribution network has had the best practical experience. In the case of the integration with gas boilers, the network does not receive the energy from the renewable system, only gives the possibility to reduce the amount of supplied fuel. The connection together with the receipt of energy is especially desired in the case of photovoltaic systems and the grid. The two aspect can be covered there: one of autonomous operation of a renewable system and the regular profile of power supply.

The next example of good coincidence could be the idea of integration between the production processes and solar thermal collectors studied for the case of meat production plant. Because of the meat processing, hot water of 80 ^{o}C is used to wash production rooms (intensive use at about 3 p.m.) and water of 60 ^{o}C for hygienic purposes and another processing continuously during two shifts. Hot water is supplied from cooling system recovery and steam boilers that provide also central heating in the object. The hybrid system concept suggests the integration between cooling system heat recovery and solar collectors where load cycle fits the solar daily availability waveform and conventional support from steam gas boilers.

4. Discussion

Some evaluation if the selected modules of a composed hybrid system is possible in advance by means of simulations. The most advanced simulation techniques are useful for designers, who in the case of not standard objects can verify their effectiveness. It is worth mentioning that RES systems are mostly unique because of the local applications, sometimes differing even between neighbor farms or buildings.

The most representative is the following software that is available in European location but with some limitations:
ESOP [4] developed by Viessman – very well prepared software, intended for use by designers but suitable also for local authority representatives. It provides calculation for some typical SDHW systems with the possibility to calculate carbon dioxide emissions and comparisons among different fuels, available in Polish version.

TRNSYS [2] developed by University of Winconsin – advanced software to calculate transient states in the variety of systems, with the reference to geographic and climatic conditions, very useful also for advanced use such as scientific analysis and for designers, however comparatively expensive and Polish version is not available. It is worth mentioning that the university provides some possibilities for free download from internet and even these limited versions are very educative and thus very useful for didactics. The software is grouped in packages for different media and RES and enables cost calculation on the basis of design system and selected devices from USA market.

WUFI [3] developed by Fraunhoffer Institute – software suitable for passive systems such as multi-layer wall structures, available in Polish version also for free download for the purpose of didactics but with limitations, provides some information to know particular producers of the used materials and thus can be useful to calculate the cost of the system.

Moreover, the authors can also mention simulation algorithms based on equivalent thermal network developed in cooperation by Lublin Technical University and the University of Life Science in Warsaw [5, 6]. These algorithms at the current state are suitable for advanced users, perform calculations also for transient states and have not been commercialized yet. The use of these algorithms is undoubtedly more time consuming but the user can decide on all simplifications introduced to the system model and to the calculations. The method enables modeling of energy flow by means of different media and thus is suitable for integrated systems, provides results of calculated energy flux, flows and temperature reached in the system units in time for different days of a year in the form of graphs and matrices. The other algorithms have been developed for solar walls by means of FEM analysis.

What is even more important the ease of simulation analysis can add the value to the planned refurbishments and all purpose modernizations in many municipal sectors in the phase prior to the design instead of time consuming and expensive existing building inventorying in situ. This should be particularly taken into account when numerous objects are to be rebuild in the regions where older technology have been applied so far.

Abstract: Concentrated Solar Power (CSP) is an emerging renewable energy technology that has the potential to provide a major part of European energy needs at competitive cost levels. Swedish industry is strongly involved in CSP-based energy production either in the form of growing providers on the European energy market or as developers and producers of key components for CSP power plants. The growing industrial interest is reflected and accompanied by state of the art research in this field at the Department of Energy Technology at KTH. In the present paper the main challenges and opportunities for CSP R&D are presented and linked to the industrial environment and interests in Sweden. Related to these challenges, an overview of the latest research activities and results at the Department of Energy Technology is given with examples concerning CSP plant operation and optimisation, techno-economic cycle studies and high temperature solar receiver development.

1. Introduction

At first glance, concentrated solar power (CSP) may not seem of great interest to Sweden, which receives only weak solar irradiation with few sunny days in winter when power is needed most. However, seen from the wider perspective of a sustainable energy system, with input from many different energy sources (such as hydro, wind and biomass) across Europe, North Africa and parts of Middle East, CSP could form a dominating part of the solution to future energy shortages and the problem of rising CO_2 emissions [1].

Sweden is today increasingly integrated in the European energy grid and major Swedish providers (e.g. Vattenfall, Fortum, E·ON) are growing on the continental energy market. Furthermore, many Swedish companies (e.g. Siemens Industrial Turbomachinery, ABB) are actively involved in the production of components for CSP plants such as steam turbines, mirrors for the collector fields and many more. As such, Sweden's interest in CSP is due not only to its wider environmental credentials, but also its direct economic importance to the country. There is thus good reason for Swedish energy institutions, authorities, industry and universities to actively take part in development to further strengthen the established position in this field.

2. Concentrated Solar Power Technology

In its most basic form, a CSP plant consists of solar collector field with mirrors that concentrate the solar radiation to one or more receivers where this radiation is converted to high temperature heat [2]. This high temperature heat source can be used to drive conventional power generation

equipment (such as steam cycles, Stirling engines, micro gas-turbines, etc.) to produce electricity. Significant amounts of waste heat are also available which are currently wasted but could be used to drive other processes.

The levelised cost of electricity (LEC) of CSP-based power plants has been shown to be amongst the most competitive of all renewable energy technologies [3], with a significant cost advantage over PV when deployed on a large scale. However, CSP technology has not yet matured to the point of grid-parity with conventional power generation systems, although this is predicted to occur within the next 15 years [4]. Rapid reductions in the LEC of CSP-based systems are expected, as shown in Table 1, whereas the cost of fossil-fuel based power is expected to rise with increased fuel prices and the introduction of CO_2 cap-and-trade schemes.

Table 1. Current and Predicted LEC of Selected Power Generation Technologies [4], [5]

LEC [€cts/kWh$_e$]	Parabolic Trough	Solar Power Tower	Dish Stirling	Solar PV	Coal
Current (2010)	17.2	24.1	28.1	28.4	8.4
Future (2025)	12.8	9.7	14.0	14.8	10.8

Direct solar irradiation is an abundant renewable energy source [1] but is available only at low flux densities: large areas must be used to collect enough energy. Even so, the area necessary to satisfy all of Europe's electricity needs using currently available CSP technology would be only a small fraction of the North African deserts [1]. The most suitable areas for CSP deployment are within the tropics, where irradiation is good, almost all days are cloudless and the land is of desert type with low population [3]. Suitable areas for CSP are shown in Fig. 1.

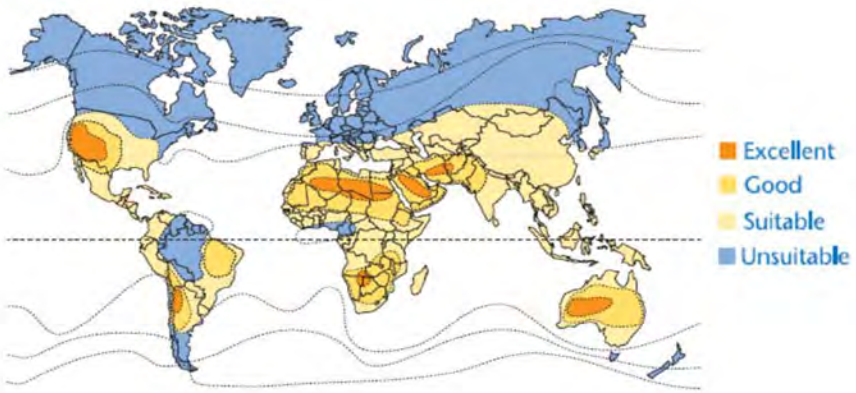

Fig. 1. Distribution of Sites Suitable for Solar Thermal Power Production
Source: German Aerospace Centre (DLR)

In Europe the requirements for economic electricity production with CSP are fulfilled for a number of countries around the Mediterranean Sea but the real "European Sun-belt" is in North Africa. A group of leading European industries have established the DESERTEC foundation [1] for promoting the deployment of CSP-technology in the North-African deserts, with the stated aim of providing 15% of the European electricity requirements [1], as well as meeting local demand. The total investment in CSP plants and transmission lines is expected to be in the region of €400 billion, to be realised by 2050.

2.1 Conventional CSP Technology

The dominating CSP technology: linear parabolic trough mirrors with collectors producing steam for conventional steam turbine plants, as shown to the left of Fig. 2, has been commercial for about 30 years [4]. The power range for these systems has been 30-80 MW_e with solar-electric efficiency around 15-20% [2]. A high number of 50 MW_e plants of that type are presently being put into operation in Spain [5]. Plants in the power range of 400 MW_e are built in the USA and planned for North Africa. Currently almost all steam turbines for solar thermal power plants are delivered from Sweden by Siemens Industrial Turbomachinery.

The technology is well proven and the present development trends are:

- Higher turbine inlet temperatures by developing heat transfer media with the ability to withstand higher temperatures
- Extension of operating time by hybrid operation, energy storage and shorter start-up times
- Efficiency improvements on mirrors and receiver pipes by optimised glass qualities and surface coatings

The cost break down of such a plant shows that the solar field is the most costly part, around 50% and that the thermal conversion unit is only around 24% [4].

2.2 Solar Towers: the Emerging Technology

Solar towers surrounded by heliostats, as shown to the right of Fig. 2, have higher solar concentration factors than parabolic troughs and can thus reach higher temperatures [2]. The size of the heliostat field around a tower has an optimum determined mainly by the height of the tower and the losses from the most distant mirrors. Today the optimal thermal power from a tower seems to be around 100 MW_{th} with a 160 m tower and some 830 heliostats with a 121 m^2 mirror area per unit [5]. Larger systems can be expected considering possible advancement in mirror and receiver efficiencies and control system precision.

Fig. 2. Conventional (left) and Emerging (right) CSP Technology
Source: Solar Millennium/Abengoa Solar

Presently the receivers are placed on top of the tower, which means the heat has to be transported by some means to the power block on the ground down the height of the tower. For small size units (up to around 6 MW_e) the power generation unit could be placed at the top of the tower, close to the receivers. The tower arrangement can be used with steam turbines, providing higher

live steam temperatures than the parabolic trough solar fields. More interesting is that gas-turbines can also be considered for the conversion of heat to electricity. Gas-turbines are cheaper, simpler to install, potentially more efficient and do not need water.

3. Challenges and Opportunities in CSP R&D

CSP remains an emerging technology, with an active R&D community working to improve the viability and effectiveness of the concept. On-going research activities at the Department of Energy Technology (EGI) of the Royal Institute of Technology, Stockholm have highlighted what the authors believe to be some key challenges in the development and deployment of CSP technology at the current time.

3.1 Increasing Economic Competitiveness

Solar thermal power technology cannot yet be considered to be directly competitive with conventional power generation technology (such as those based on the combustion of coal or natural gas) but later most probably with new nuclear power. In the current energy market, deployment of CSP technology is supported by government incentives such as feed-in tariffs and loan guarantees. Increasing the competitiveness of CSP technology is a key challenge in solar R&D and will go hand-in-hand with increased CSP deployment [2]. As such, any reduction in the cost of this technology represents a major opportunity for the industry.

Since the incident solar radiation is free, the cost of the electricity from a CSP plant is dependently solely on the depreciation of the initial investment cost C_{inv} and the annual plant maintenance cost $C_{O\&M}$. The standard definition of levelised electricity cost (LEC) used in solar thermal calculations [4] is based on the net electrical output E_{net} and an annualisation factor α, assuming a rate of interest i, a payback time n in years and an annual insurance rate k_{ins}. The net electrical output is a function of the total collector area A_{col}, the incident solar flux I_o and three efficiency factors ε_{col}, ε_{rec}, and ε_{cyc} for the collector field, solar receiver and power generation cycle respectively.

$$LEC = \frac{\alpha \cdot C_{inv} + C_{O\&M}}{E_{net}} \text{ with } \alpha = \frac{i \cdot (1+i)^n}{(1+i)^n - 1} + k_{ins} \text{ and } E_{net} = A_{col} \int_{year} \varepsilon_{col} \varepsilon_{rec} \varepsilon_{cyc} I_o dt \qquad (1)$$

Any reduction in the LEC will increase the economic competitiveness of the technology and equation (1) brings to light key ways in which reductions can be made:

- The first focus can be placed on reducing the cost of the power plant components (both in term of initial investment C_{inv}, as well as the maintenance $C_{O\&M}$). As the solar field components represent over 50% of the total investment cost, priority should be placed on reducing the cost of these components. Fortunately, these components are still in the early stages of their learning curve and costs are dropping rapidly.
- A second focus can be placed on increasing the net electrical output E_{net} for a given power plant. This can involve optimizing plant design, reducing parasitic consumption as well as improving operational strategy, all of which serve to increase the integrated annual value of ε_{cyc}.

- The final focus can be placed on new power plant concepts. This can involve moving to more efficient thermodynamic cycles (generally requiring higher temperatures), new receiver designs and improved collector field layouts with the aim of increasing the three efficiencies ε_{col}, ε_{rec}, and ε_{cyc} and thus E_{net}. This can result in lower values of LEC for the plant, as long as the increase in E_{net} compensates for any increase in the cost.

3.2 Reducing Water Consumption

The deployment of CSP technology is most effective in areas with high direct normal irradiation (DNI). This fact, coupled with the large land requirements for CSP plants would seem to make desert locations very attractive for deployment [1]. However, the high DNI of desert regions comes with a significant draw-back, in that these regions suffer from a severe scarcity of water resources [6] which will place a limit on the number sites found suitable for deployment of this technology.

The current generation of solar thermal power plants, based on conventional steam-cycles, require water for a number of purposes:

- For the cooling of the condenser, with especially large volumes for evaporative cooling
- To replace that lost from the cycle during steam drum blowdown
- To maintain a high efficiency of the solar field: the mirrors need to be kept clean to ensure a high reflectivity

In order to facilitate the increased deployment of solar thermal power in water-scarce areas it will become necessary to reduce the water footprint of CSP plants, shown for a number of contemporary plants in Table 2. A number of options for achieving this have been highlighted:

- Replacing evaporative or once-through cooling systems in steam-cycle power plants with dry or indirect cooling systems, including options for cold-water storage
- Moving towards higher-temperature solar receivers, allowing the use of gas-turbine cycles, eliminating the use of water as a working fluid as well as the need for cooling
- Moving towards high-efficiency power generation cycles, reducing the size of the collector field per unit electrical output, reducing the water use due to mirror washing

Table 2. Water Consumption of contemporary Rankine CSP Plants [8]

Power Plant Type	Water Consumption [m^3/MWh_e]		
	Evaporative	Hybrid Dry/Wet	Air Cooling
Parabolic Trough	3.0	0.4 – 1.7	0.3
Solar Power Tower	1.9 – 2.8	0.4 – 1.0	0.4

3.3 Increasing Availability/Dispatchability of CSP Plants

The output from a solar thermal power plant is strongly dependent on the available solar flux, which varies due to both the predictable daily evolution of the Sun's position as well as the more unpredictable variations in local weather conditions. This raises two key issues for CSP plants:

- In order to maintain an acceptable lifetime for the power plant components (turbine, steam generators, etc.) the duration of transient operation should be minimized. To improve the dispatchability of CSP plants, it is also of interest to accelerate the start-up of the turbines in order to bring power rapidly onto the grid once solar energy is available
- In order to increase the flexibility and economic viability of a solar power plant in a liberalised electricity market, it is advantageous for the plant to be able to produce power during times of peak demand, which are not necessarily in phase with times when the solar flux is available.

Both these issues require a decoupling of the energy supplied to the power generation cycle from the incident solar radiation. Over a short time period, thermal energy storage can ensure a constant power output to the cycle during solar transients resulting from cloud cover or other meteorological phenomena [2]. Larger storage volumes can also allow dephasing of the electrical output, permitting increased operational flexibility.

At the current time, certain conventional CSP units are built as hybrid plants, using natural gas fired boilers or gas-turbine waste heat recovery boilers for additional steam production when solar radiation is insufficient or absent. With a gas-turbine in the cycle, power production becomes very flexible with the possibility not only to meet peak power demand and to operate at night, but also to reduce the size of the mirror field.

4. Opportunities for CSP R&D in Sweden

Swedish industry is heavily involved in the supply of steam turbines for solar thermal power applications (through Siemens Industrial Turbomachinery) and it can be seen that many of the key opportunities for solar R&D lie in the field of turbomachinery. As all commercial CSP plants are based on the use of steam-cycle technology, improvements in steam-turbine operational strategy present attractive opportunities for R&D. Swedish companies such as ABB are involved in supplying tracking systems and others such as Cleanergy supply Stirling engines for solar dish systems.

The challenges presented in §3 highlight the potential advantages in moving towards gas-turbine-based CSP plants. Use of gas-turbines reduces water consumption and opens the possibility for the use of more flexible hybrid plants as well as higher efficiency combined-cycle systems. Swedish industrial companies are ideally placed to provide gas-turbines in the power ranges suitable for solar thermal applications.

5. Research focuses at the Department of Energy Technology

On-going research activities at EGI are focused on responding to the key challenges identified in §3 as well as supporting Swedish industrial partners in addressing the opportunities created. The following sections present key current projects.

5.1 Solar Steam Turbine Operation

Due to the variable nature of the solar supply and the daily operating cycle of solar power plants, the number of turbine starts per year for solar steam turbines is an order of magnitude higher than for base-load turbines. As a result, the speed with which the turbines can be started assumes a

greater importance in CSP plants and modifications allowing turbines to start faster are examined as part of on-going research.

The speed at which the turbines can reach full load is based on the lowest metal temperature measured before start-up begins. As such, if the steam turbine can be kept hot during idle periods, the duration of the next start-up can be reduced without impacting negatively on the lifetime. A number of modifications that can be made to the turbines to maintain their temperature during idle periods have been evaluated. Heat blankets were shown to be the most effective measure for keeping the turbine casing warm, whereas increasing the gland steam temperature was most effective in maintaining the temperature of the rotor [7]. By applying a combination of these measures the dispatchability of the turbine can be improved significantly: electrical output can be increased by above 9% for both long and short cool-downs, as is shown in Fig. 3.

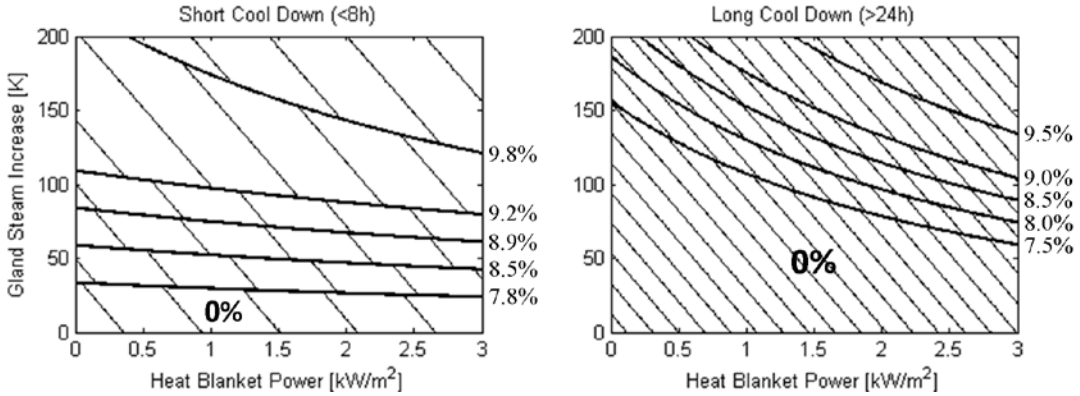

Fig. 3. Impact of applying a combination of heat blankets and gland steam temperature increase on the daily output of the plant on the day following the cool-down period [7]

5.2 Solar Power Plant Thermo-Economics

All operational commercial solar thermal power plants are based on the use of Rankine cycles, which are limited in the efficiencies they can achieve by the relatively low temperatures at the receiver. However, developments in the field of high temperature receivers [8] have opened up the possibility to use more advanced thermodynamic cycles, especially the use of gas-turbines. In order to evaluate the potential of new power plant concepts, thermo-economic models are used to predict investment and levelised electricity costs, as well as other important factors such as annual electricity production, water consumption, exergy efficiency, land use and many more [9]. Coupled with a multi-objective optimisation routine, Pareto-optimal power plant designs can be established and the trade-off between economic and environmental objectives analysed. Polygeneration concepts, mainly using waste heat for production of e.g. clean water, cooling or biogas for local consumption can also be positive factors both for acceptance and economy.

5.3 Solar Receiver Design and Testing for Gas-Turbine Integration

In order to support on-going solar gas-turbine research at EGI, small-scale but high temperature receivers are being design and tested for use with micro gas-turbines. Availability in Sweden of sunlight strong enough for testing is very limited and therefore a small indoor solar lab has been built, shown schematically in Fig 4. An artificial Sun consisting of strong Xenon lamps produces 11 kW of radiation which is directed to a parabolic dish of 1.8 m diameter and used to test small receivers of different innovative designs. Presently two receivers are being investigated:

- A medium temperature receiver in which materials with high thermal conductivity and coatings for good solar absorption are essential for high efficiency
- A generic high temperature volumetric receiver in which different types of heat exchange materials can be tested both for overall heat transfer data and detailed information on solar penetration depth, temperature gradients, pressure drops, etc.

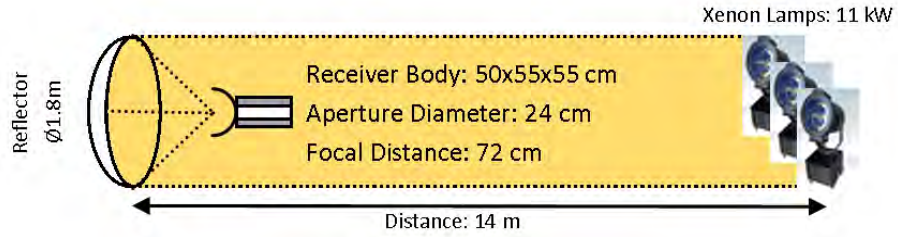

Fig. 4. Basic Layout of EGI's Receiver Test Facility

6. Conclusion

Amongst the plethora of renewable energy technologies on offer, CSP emerges as a promising option for sustainable power generation in the Sun-belt regions of the world. A diverse R&D community supports the refinement of the technology and commercial CSP plants are beginning to appear worldwide. Swedish industry is well-placed in the market, providing almost the entirety of the steam turbines for conventional CSP plants, as well as a number of ancillary components. Within Sweden, the nurturing of active R&D is essential to maintain this dominant position. EGI is actively pursuing key issues on different CSP systems such as techno-economic optimization, polygeneration arrangements, receiver components and their integration with the conversion unit.

Abstract: Enhancement techniques can be applied to flat-plate liquid solar collectors towards more compact and efficient designs. Tube-side enhancement passive techniques can consist of adding additional devices which are incorporated into a smooth round tube (twisted tapes, wire coils), modifying the surface of a smooth tube (corrugated and dimpled tubes) or making special tube geometries (internally finned tubes). For the typical operating flow rates in flat-plate solar collectors, the most suitable technique is inserted devices. Based on previous studies from the authors, wire coils were selected for enhancing heat transfer. This type of inserted device provides better results in laminar, transitional and low turbulence fluid flow regimes.
To test the enhanced solar collector and compare with a standard one, an experimental side-by-side solar collector test bed was designed and constructed. The testing set up was fully designed following the requirements of EN12975-2 and allow us to accomplish performance tests under the same operating conditions (mass flow rate, inlet fluid temperature and weather conditions). In this work the preliminary results obtained are presented and the standardized efficiency curve is shown for both tested solar collectors. A relevant improvement of the efficiency has been reported and quantified through the useful power ratio between enhanced and standard solar collectors.

1. Introduction

In industrial applications, a set of enhancement techniques are widely used to improve the performance of heat exchangers. Enhanced surfaces can be used to increase heat exchange, reduce the size of equipments or save pumping power. Thermal liquid solar collectors are potential candidates for enhanced heat transfer, but not many studies have focused on this aspect. The vast majority of works carried out applying enhancement techniques to improve solar collector performance deal with air collectors, mainly inserting artificial roughness within the exchange surfaces [1, 2, 3].

Regarding liquid solar collectors just a few studies have focused on enhancement techniques. Kumar and Prasad [4] presented a remarkable work inserting twisted tapes in a serpentine solar collector. They investigated the effect of the twisted-tape geometry, different mass flow rates and intensity of solar radiation on thermal performance. The authors observed that heat losses were reduced (due to the lower value of the plate temperature) and consequently an increase on the thermal efficiency was observed.

Recently, Jaisankar et al [5] performed an experimental investigation of heat transfer, friction factor and thermal performance on a tube-on-sheet solar panel with twisted-tape insert devices. They also investigated the effect of the twisted-tape geometry for different Reynolds and intensity of solar radiation. The concluded that when twist ratio is increased, the swirl generation is decreased and both heat transfer and friction factor are minimized. Jaisankar et al also carried out several experimental investigations of heat transfer, friction factor and thermal performance of thermosyphon solar water heater systems fitted with twisted- tape insert devices. [6, 7, 8] The authors found that the heat transfer enhancement in the twisted tape collector was higher than in the standard collector.

Also Hobbi and Siddiqui [9] conducted an indoor experimental study to investigate the impact of several insert devices on the thermal performance of a flat-plate solar collector. They studied different passive heat enhancement devices: twisted strips, coil-spring wires and conical ridges. They observed no appreciable difference in the heat transfer to the collector fluid and concluded that the applied passive methods based on the enhancement of shear-produced turbulence were ineffective in augmenting heat transfer to the collector fluid.

In spite of the fact that many of the previous works within liquid collectors employed twisted tapes as inserted devices, basically due to the existence of well known design correlations [10, 11, 12], the use of other passive tube-side techniques such as wire coils still unexplored. Regarding the aforementioned fact, Webb and Kim [13] also pointed out that the existence of design correlations does not mean, however, that the twisted tape insert is the best insert device. As Garcia mentions [14, 15], wire coils are especially suitable for enhancing heat transfer in laminar, transition and low turbulent flow regimes. In a previous work from the authors, a numerical simulation methodology to study the heat transfer enhancement in a tube-on-sheet solar panel with wire-coil inserts, using TRNSYS as the simulating tool was developed. A parametric study was also performed to relate the fluid and flow characteristics with the heat transfer enhancement by wire-coil inserts. It was shown that the enhanced collector increased useful power in the whole range of mass flow rate when using water as the working fluid [16].

The purpose of the present work is then to characterize a flat-plate solar panel with wire-coil insert devices in terms of heat transfer, friction losses and thermal performance and compare this enhanced collector with a standard collector under the same operating and weather conditions. To test the enhanced solar collector and compare with a standard one, an experimental side-by-side solar collector test bed was designed and constructed. The testing set up was fully designed following the requirements of EN 12975-2 [17]. A relevant improvement of the standardized efficiency curve has been reported. Furthermore, the ratio of useful power and pressure drop between the enhanced and the standard solar collector for different flow rates and operating conditions were computed.

2. Experimental set-up

The experimental setup was designed to carry out simultaneously the thermo-hydraulic characterization of two solar collectors (an enhanced collector with wire-coil inserts and a standard collector) under the same operating (mass flow rate, inlet fluid temperature) and weather conditions. It is located in Cartagena, southeastern Spain (Latitude N'3736, Longitude W'00059). Furthermore, this facility was built in agreement with the requirements of standard EN 12975-2 [17]. A schematic layout of the test bed constructed is shown in Figure 1.

Fig. 1. Experimental set-up

The main components of the experimental setup are the two sheet-and-tube flat-plate solar water heaters with 9 parallel tubes (risers) on the back of the absorber plate, as it is detailed in Fig. 2. T he risers are connected at the top and bottom by headers to homogenize flow distribution and static pressure at inlet and outlet sections. Both collectors have a single glass cover; their technical specifications are summarized in Table 1.

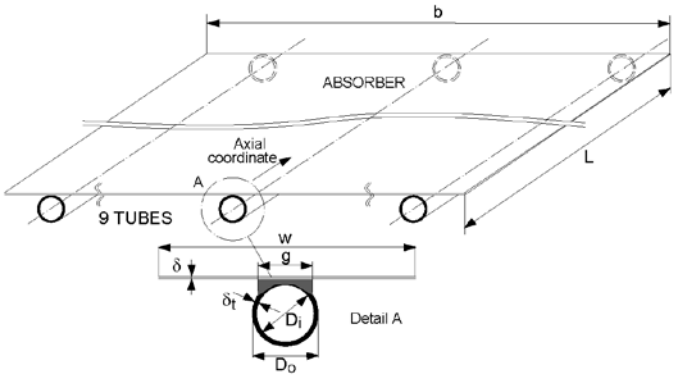

Fig. 2. Sheet-and-tube tested solar collector configuration

Table 1. Main characteristics of the flat-plate solar collectors

Material properties		**Geometrical data**			
k_{abs}	209.3 W/mK (Aluminum)	D_i	0.007 m	N_G	1
k_{tube}	372.1 W/mK (Copper)	w	0.1227 m	N_{tubes}	9
ε_g	0.88 (Glass)	g	0.0035 m	A_C	2.022 m^2
τ_g	0.93 (Glass)	δ_{abs}	0.0005 m	A_{edge}	0.2348 m^2
k_{ins}	0.05 W/mK	δ_{tube}	0.0005 m	L_t	1.83 m

		α_{abs}	0.95 (Miro-Therm)		

One of the solar collectors was modified inserting wire–coils within their risers. A wire coil of dimensionless pitch p/D=1 and wire-diameter e/D=0.0717 was chosen (Fig. 3). This geometry showed good overall thermohydraulic behaviour for the operating conditions in solar collectors according to Garcia [15] work.

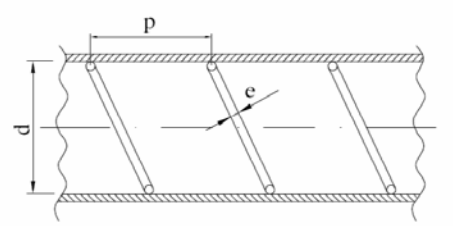

Fig. 3. Sketch of the helical-wire-coil fitted in the raisers of the modified solar collector.

2.1 Instrumentation

The instrumentation was selected and mounted according to the standard EN 12975–2 requirements. Thermorresistance Pt100 class 1/10 DIN A were used to measure the inlet and outlet fluid flow temperatures. To measure the flow rate and the pressure drop through the collectors, electromagnetic flowmeters (Siemens MAG1100 DN 3) and differential pressure transmitters (SMAR) with different configurable ranges were used. Regarding the weather conditions: 3 PSP class I thermoelectric pyranometers were employed to measure the solar irradiance (global irradiance in the aperture plane, global irradiance on the horizontal plane and the other one has a shading band to measure diffuse horizontal solar irradiance). Velocity and wind direction were measured with an ultrasonic anemometer (Windsonic from Gill Instruments Ltd). Ambient temperature, humidity and pressure were also measured. In Table 2 the main characteristics of the selected instrumentation are summarized.

2.2 Uncertainty propagation

We follow the criteria of ISO GUM (Guide to the expression of Uncertainty in Measurement) [18] to derive the equation for thermal efficiency proposed in EN 12975-2 and uncertainty propagation assessment. When the tests are accomplished in steady state, the thermal efficiency can be expressed as Eq. (1).

$$\eta_A = \frac{\dot{Q}_{\text{useful}}}{GA_A} = \frac{Q\rho_{(t)}c_{p(t)}\left(t_{out} - t_{in}\right)}{GA_A} \tag{1}$$

The standard uncertainty of each magnitude is shown in Table 2. The uncertainty of each magnitude is a combination of the uncertainties of Type A evaluation, associated to the standard deviation of the mean of the repeated observations, and of Type B, evaluated from scientific statement based on the calibration available information. According to the uncertainty propagation study carried out, it can be concluded that the initial uncertainties are slightly amplified and the expanded uncertainty at a 95% confidence level are ±0.1% for non-dimensional temperature T^*_m and ±0.9% for thermal efficiency η.

3. Thermal performance calculations according to standard EN 12975-2

The useful power is calculated according to Eq. (2).

$$\dot{Q}_{useful} = Q\rho_{(t)}c_{p(t)}\left(t_{out} - t_{in}\right) \tag{2}$$

where, the fluid density and the specific heat are evaluated at the mean fluid temperature $t_m = t_{in} + \Delta t/2$, and the thermal efficiency can also be expressed according to Eq. (3) as a function of global irradiance intercepted, absorber area and useful power.

$$\eta = \frac{\dot{Q}_{useful}}{GA_A} \tag{3}$$

Table 2 . Instrumentation description and uncertainty.

Magnitude	Sensors	Instrumentation	Uncertainty
Solar Irradiation	3	1st Class Kipp&Zonnen CMP6 Pyranometer Shadow band (Diffuse Irradiation)	±0.,1%
Ambient Temperature	1	Pt100 3w	±0.1ºC
Ambient Pressure	1	Piezorresistive barometer	± 0,4 mbar a 20ºC
Humidity	1	Capacitive sensor	±2%
Wind velocity and direction	1	WindSonic Gill Instrument (Vel. interval 0-60 m/s) (Vel. Direction 0-359º)	± 2% Velocity ± 3% Direction
Inlet and Outlet Fluid Temperature	4	Pt100 4w Class 1/10 DIN A	± 0,03 ºC
Flow Rate	2	Electromagnetic Flowmeter Siemens MAG 1100 Transmitter MAG 6000	± 0,25 %
Differential Pressure	2	Differential pressure transmitter SMAR D0 type (-4 to +4 inch H_20) Standard collector D1 type (0-20 inch H_20) Enhanced collector	± 0,1 % of Span
Absolute pressure	1	Piezorresistive transducer	± 0,5 %

The thermal efficiency η can be correlated with the reduced temperature, $T^*_m=(t_m-t_a)/G$ using linear $\eta = \eta_0 - a_1 T_m^*$ or quadratic regressions $\eta = \eta_0 - a_1 T_m^* - a_2 G T_m^{*2}$, based on absorber or aperture area. The experimental data obtained show a good linear correlation (R^2=0.9874 for the standard solar collector, and R^2=0.9282 for the enhanced solar collector). These linear correlations are simpler and more useful in engineering applications. Additionally, their coefficients are independent of global irradiance.

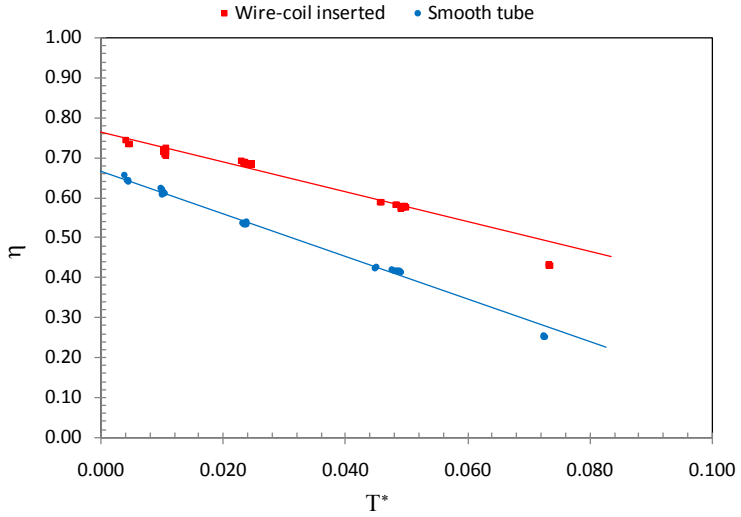

Fig. 4. Thermal efficiency curves for standard and enhanced flat-plate solar collectors (0.04 kg/s)

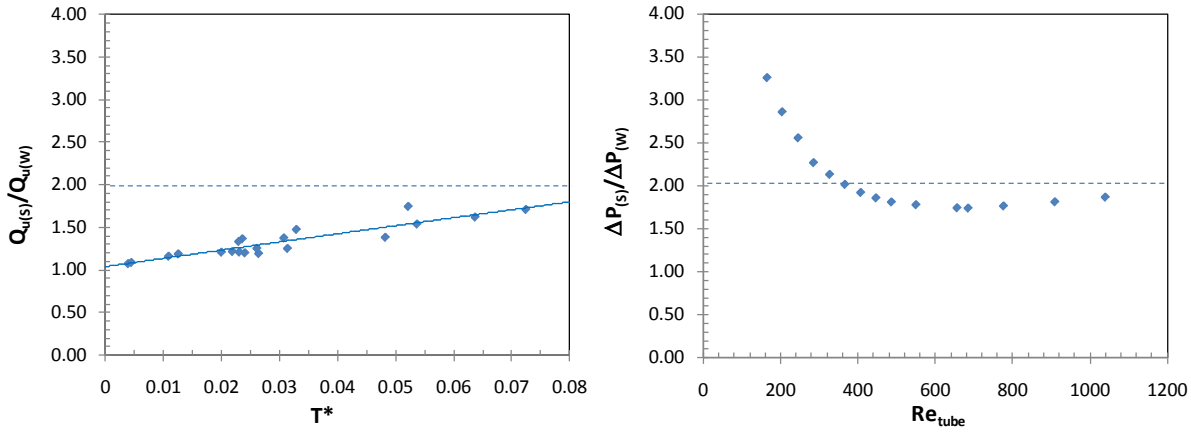
In Fig. 4 the standardized thermal efficiency curves for both standard and enhanced flat-plate solar collectors are shown. It can be observed that a significant improvement in the thermal efficiency of the solar collector with wire-coil inserts is achieved. Note that in the enhanced solar collector the optical efficiency coefficient η_{OA} is about 15% higher and the thermal losses coefficient α_{A1} is lower than in the standard one (Table 4). This effect can be due to the enhancement of heat transfer between the absorber plate and the working fluid which reduces its temperature and as a consequence, the thermal losses decrease. The uncertainty of the regression coefficients have also been assessed according to the methodology proposed by Coleman and Steele [19].

Table 4. Linear correlation coefficients and their uncertainties (95% I.C)

	Standard collector		**Enhanced collector**	
	Coefficient	Uncertainty	Coefficient	Uncertainty
η_{0A}	0.6670	0.44 %	0.7654	3.97 %
a_{1A}	-5.3410	1.71 %	-3.7640	0.52 %



a) *b)*

Fig. 5. Ratios between standard and enhanced solar collectors a) Useful power versus non-dimensional temperature, and b) Loss pressure versus Reynolds number inside raisers

In Fig. 5 a) the useful power ratio between the enhanced and the standard solar collector is showed for different flow rates (0.016÷0.04 kg/s) and operating conditions ($520 \le \mathrm{Re}_{\mathrm{tube}} \le 2340$). It can be observed that there is a linear dependence between the useful power ratio and the non-dimensional temperature. For increasing values of T^* the ratio of useful power is higher. This is due to the fact that the wire-coil insert lowers the absorber temperature reducing the thermal losses. This confirms the results from the previous numerical simulations carried out by the authors. [16] In Fig. 5 b) the pressure loss ratio between both collectors is represented. For Reynolds numbers higher than 500, inside the raisers, the pressure loss ratio remains constant at about 1.8. This increase in pumping power is compensated with an improvement in thermal efficiency, which would be especially suitable for large installations in which several solar collectors are connected in parallel. In this type of configuration an accumulative increase in thermal power is obtained, while the pressure loss remains the same in all the solar collectors, and thus, this configuration would enable optimum operation and would be the best-practice approach.

Nevertheless, in order to establish the optimum operating range within enhanced solar collectors with wire-coil inserts, a heat exchangers performance evaluation criterion has to be employed. A modified criterion (R3m) was proposed by the authors [16]. This criterion stands for the increasing useful power obtained in the enhanced and the standard collector at equivalent operating regimes to satisfy the constraint of equal pumping power. To compute this parameter further efficiency and friction factor tests are being carried out.

4. Conclusions

An experimental side-by-side solar collector test bed was designed and constructed to characterize the thermo-hydraulic behaviour of a standard and an enhanced solar collector under the same testing conditions (operating parameters and radiant conditions). The facility

was built in agreement with the requirements of standard EN 12975 to carry out thermal performance and pressure drop tests.

The thermal efficiency curves of two solar collectors, a standard and an enhanced collector were obtained. The enhanced collector was modified inserting spiral wire coils of dimensionless pitch p/D=1 and wire-diameter e/D=0.0717 within each riser. The thermal efficiency increments depend on the operating flow rates. For a flow rate of 144 l/h (0.04 kg/s) the efficiency optical factor was found to increase by 15%. The collector with wire-coil inserts enhances heat transfer and as a consequence the absorber temperature is reduced. This means a reduction in the thermal losses as well as a decrease of the loss coefficient by 30%. However, an increase in terms of friction losses is observed and thus pumping power rises.
In order to account for the overall enhancement (thermo-hydraulic performance) that wire-coil inserts promote in the solar collector, the ratio of useful power and pressure loss between both solar collectors were computed. For increasing values of T* the ratio of useful power is higher and reaches values up to 1.8. For Reynolds numbers higher than 500, inside the raisers, the pressure loss ratio remains constant at about 1.8. The increase in pumping power is compensated with an improvement in thermal efficiency, which would be especially suitable for collectors connected in parallel. This configuration would enable optimum operation and would be the best-practice approach.

As a final conclusion, according to the present work, wire-coil devices can be successfully inserted within the flow tubes in solar water heaters for enhancing heat transfer rate.

Abstract: Concentrated sunlight has been used to perform useful tasks from ancient time. There are number of varieties of collector trough being used to perform these tasks. Each Varity comes with advantages as well as disadvantages. The aim of this research project is to improve the design of collector trough in terms of efficiency, lessen the heat declination, and eliminate the sun tracker mechanism. Most of the existing solar concentrators use open type trough which cause the rapid heat declination. The design attempted in this paper is to lessen this rapid declination and improve the efficiency by introducing Closed Environment Collector Trough (CECT). The CECT consists of spherical collector trough having a reflective bottom surface, five evenly distributed lenses, 30^o apart from each other, on the upper half of the sphere to eliminate the sun tracker and hexagonal glasses to make the environment closed and impose greenhouse effect on the system. The CECT acts like a heat trap and keeps the heat inside the chamber for a longer period of time which basically lessens the heat declination. The reflective surface and lenses concentrate the sun light directly on the fluid pipe. In this paper novel design has been proposed to improve the overall performance of solar collector troughs.

1. Introduction

Researches have been carried out to utilize the concentrated solar power in various fields. To utilize the solar energy different patterns of the collectors have been designed previously considering advantages as well as disadvantages [4]. From the previous literature survey it was found that parabolic concentrating collectors were developed to use the solar energy in an efficient way. Non tracking concentrator was also designed to avoid the handling of a tracking device [1, 3]. To increase the performance innovative design was also proposed and modeled with reflectors without increasing the system cost. In that research work aluminum-polymer-laminated steel reflector for use in solar concentrators was evaluated with respect to its optical properties, durability, and reflector performance in solar thermal and photovoltaic systems [2]. In this paper a novel and innovative design of a solar collector which is basically Closed Environment Collector Trough (CECT) has been proposed. This novel CECT system lessens

the rapid heat declination and improves the system overall efficiency. This paper mainly focuses the detail designing of the collector with accurate explanation.

2. Methodology

2.1. Description of the system

This paper proposes a new design of compound solar collector trough. The collector effectively combines Lenses, Reflectors and Closed Environment. The general structure of the trough is sphere shaped with two halves consisting a pipe at the center (Fig: 1). Different parts of the trough are labeled on the figure. A detailed description of different parts of the collector trough is given below.

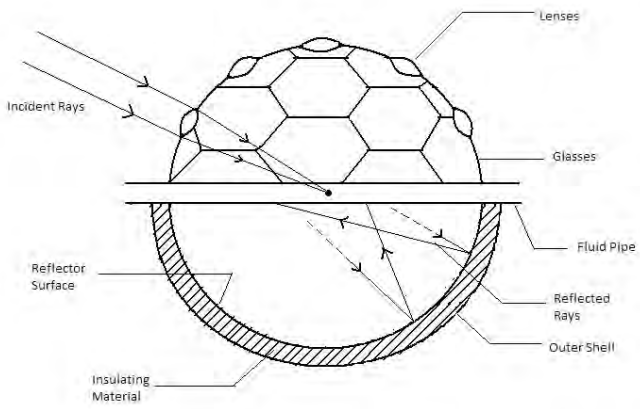

Figure 1: Closed Environment Collector Trough

The whole sphere shaped is main constructional shell of the system. It consists of two parts: Upper Shell and Lower Shell.

Lower Shell: Lower shell of the system is made of glazing metal (i.e. Aluminum). The outer surface is blackened and the inner surface is a reflector. There is another half sphere outside of this surface which is made of non-heat conductor material (i.e. asbestos). The inner diameter of the sphere is 40 c.m and outer diameter is 50 c.m. The space between the two surfaces is filled with cotton or rubber type materials (Fig: 2)

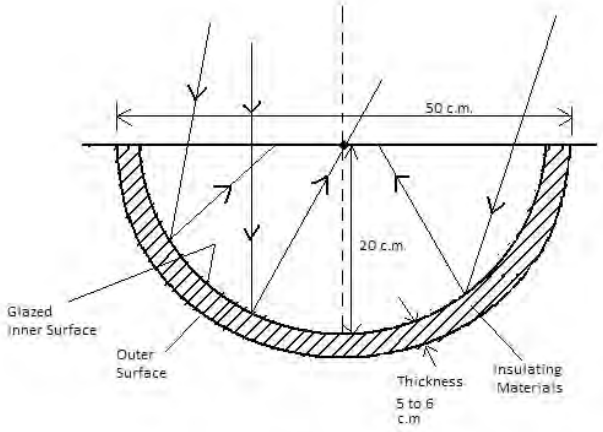

Figure 2: Lower shell

Upper Shell: The upper shell of the system is made of metal three dimensional lattice of hexagonal shape (Fig: 3). These shapes will accommodate small pieces of mirrors, which will allow the visible light to enter into the chamber but will trap the longer wavelengths of the infrared re-radiation from the heated objects are unable to pass through the glasses. The trapping of the long wavelength radiation leads to more heating and a higher resultant temperature.

There will be five lenses, evenly distributed on the upper surface of the mirror section. The lenses will be 30^o apart from each other (Fig.4). The center lens will be at 90^o angle. These lenses will concentrate the sunlight in to center line (for the lenses the center line will be the focus plane) of the sphere.

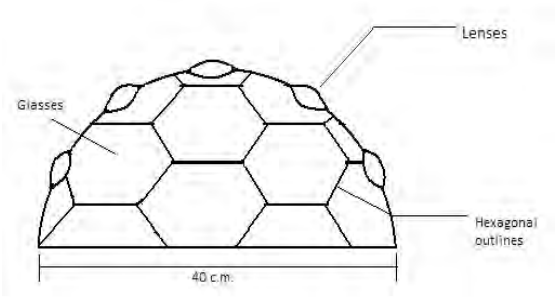

Figure 3: Upper Shell

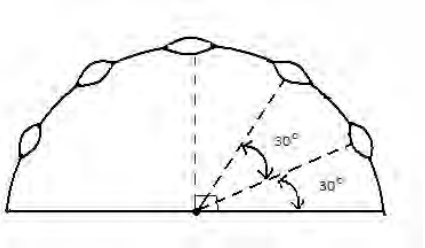

Figure 4: Arrangement of Lenses

Fluid Pipe: At the center of the sphere there will be a fluid carrying pipe. The fluid pipe will be consisted of two concentric pipes (Fig.5). The material of the outer pipe will be of transparent material (i.e. glass).The inner pipe will be metallic (i.e. Aluminum). The space between these two pipes will be evacuated. The inner pipe will carry the Heat Transfer fluid.

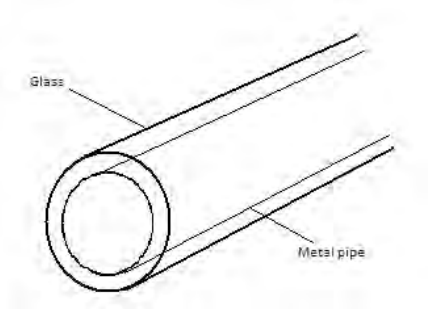

Figure 5: Fluid pipe

2.2. Calculation of Sun's Position in Bangladesh

To eliminate solar tracking mechanism effectively we have to calculate the sun's position throughout the year. Sun's position depends on local solar, elevation and azimuth angles. The equation to find the elevation and azimuth angles are given below:

$$\text{Elevation} = \sin^{-1}\left[\sin\gamma\sin\phi + \cos\gamma\cos\phi\cos HRA\right] \qquad (1)$$

$$\text{Azimuth} = \cos^{-1}\left[\frac{\sin\gamma\cos\phi - \cos\gamma\sin\phi\cos HRA}{\cos\alpha}\right] \quad (2)$$

Where HRA is the Hour Angle

Sun's position throughout a year is given in Fig.6

As from the figure we can see that sun follows a specific path throughout the year, the solar tracking mechanism can be effectively eliminated by preparing a solar chart at a specific interval. The solar trough can be setup as shown in the Fig.7 and can be manually tracked daily basis [5].

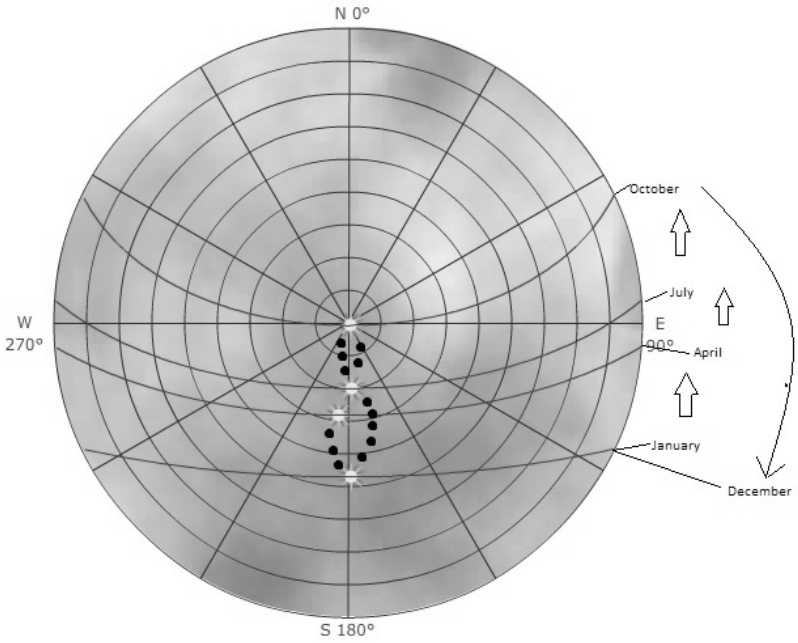

Figure 6: Sun's Position at 3 months interval. Dots represent the solar path

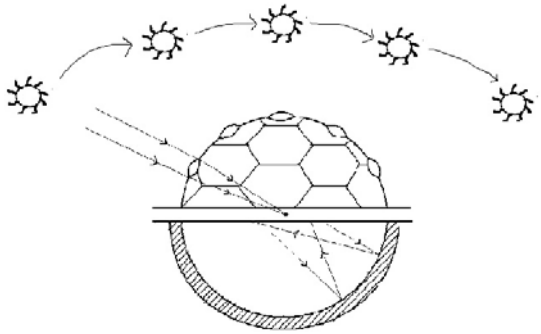

Figure 7: Collector position with respect to sun

2.3. Calculation of Solar Insolation in Bangladesh

Bangladesh is situated at 24° 00' North latitude and 90° 00' East longitude. At this position the amount of hours of sunlight each day throughout a year is shown in the following graph (Fig.8). The highest and the lowest intensity of direct radiation in W/m² are also shown in the

Fig.9. This data shows that using solar collector for high temperature is feasible in Bangladesh.

3. Calculation of useful energy delivered by the Collector

The generation of heat inside the chamber will occur in three different methods:

Lens concentrator: The lenses placed on the surface of the upper half of the heat chamber will concentrate the sunlight directly in to the focus plane of the lenses which in this case is the center of the heat chamber where the fluid pipe will be placed Fig 10. This will directly heat up the heat transfer fluid.

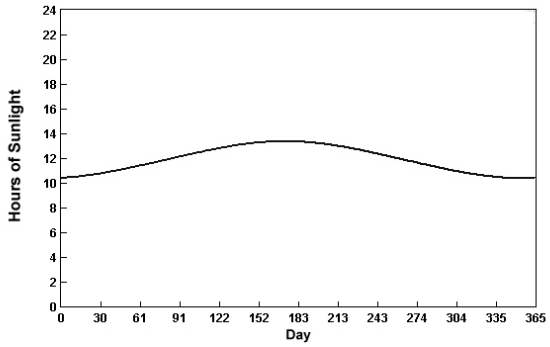

Figure 8: The amount of hours of sunlight in Bangladesh

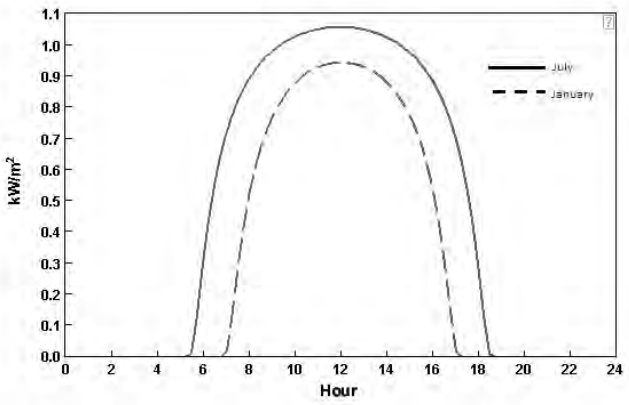

Figure 9: The highest and the lowest intensity of direct radiation in W/m²

The heat (in joules) generated by the lenses could be found by the following equation:

$$Q = ms\ (T_i - T_f) \qquad (3)$$

Where Q is generated heat in joules, m is mass of fluid in KG, T_i is initial temperature of fluid in Kelvin and T_f final temperature of fluid.

Reflector concentrator: This method will heat both the fluid pipe and the inner environment of the heat chamber. The concave bottom surface will act like a reflector mirror and most of the sunlight will be again concentrated on the pipe. This will result a thorough pipe heating (Fig. 11).

The Green House: The hexagonal glasses of the upper half of the heat chamber will allow entering the visible light, but will trap the longer wavelengths of the infrared re-radiation from the heated objects. The trapping of the long wavelength radiation leads to more heating and a higher resultant temperature. This will keep the temperature of the chamber high.

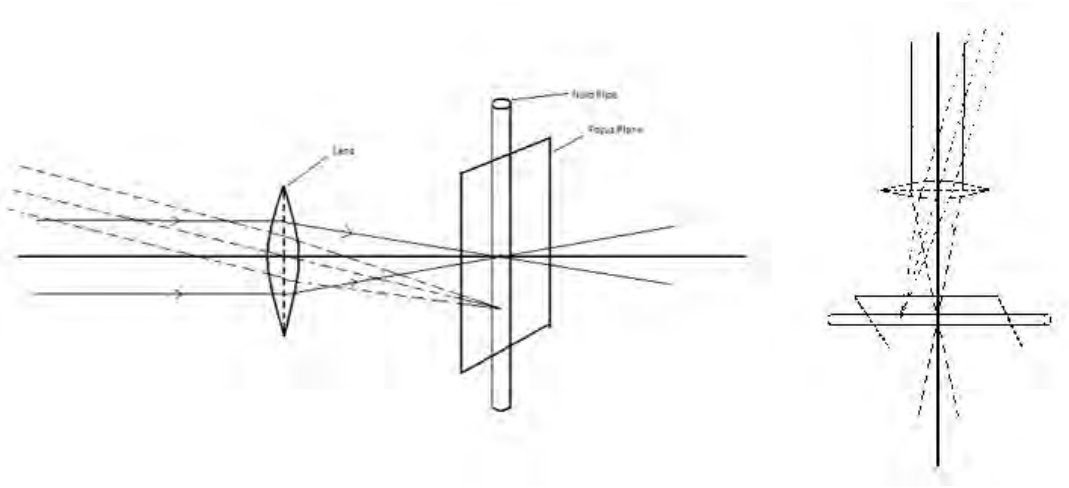

Figure 10: Lens and fluid pipe position

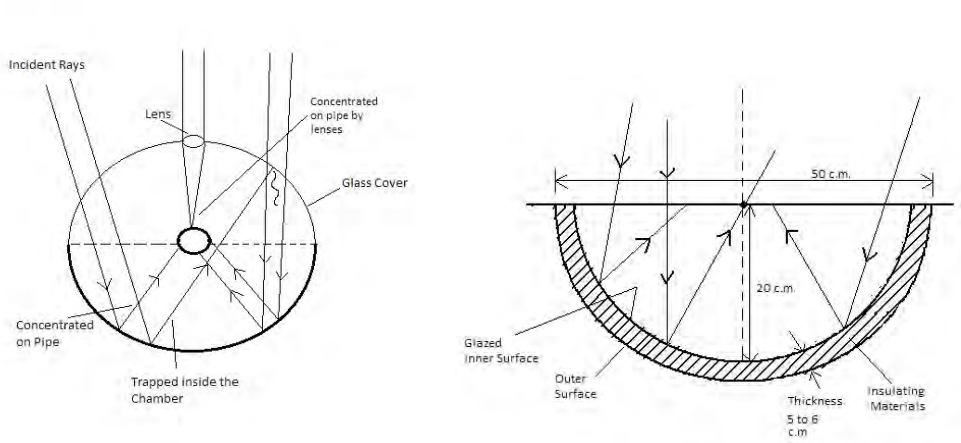

Figure 11: Front view and Section view of the collector

3.1. Overall energy calculation

The rate of useful energy delivered by the collector is governed by the following equation:

$$Q_u = D_s n_o A_a - A_r U_L (T_r - T_a) \quad (4)$$

As the system is a combination of Parabolic Collector Trough (PCT) the optical efficiency can be found from the PCT optical efficiency from the following equation:

$$n_o = \rho \tau \varepsilon \partial [(1 - A_f \tan(\varphi)) \cos(\varphi)] \quad (5)$$

As the system use a green house the heat loss coefficient is determined by the following equation:

$$U_L = \left[\frac{A1}{R1} + \frac{A2}{R2}\right] (t_i - t_o)\, f_w f_c \qquad (6)$$

4. Results

A preliminary screening of the CECT is conducted in order to identify the best match of the load. The result is shown on a plot of efficiency as a function of the heat loss parameter in the following graph.

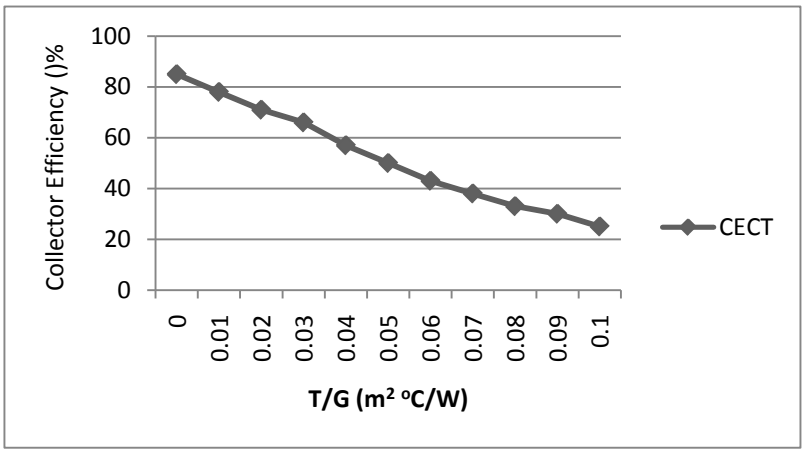

Figure 12: Collector efficiency

5. Discussion

Although Closed Environment Collector Trough is relatively a new concept, the system was expected to be more efficient than that of preliminary screening data. The future work should be based on the improvement of current design and optical as well as thermal optimization.

Abstract: In this paper the problem of increasing the capacity of an already constructed solar thermal power plant has been studied through the concept of lost available work. The required increased capacity has been proposed to be achieved by means of a new large size collector and an auxiliary boiler. Two different schemes along with an extra scheme for night operation of the power plant have been considered in the present work. For each scheme, three different operating conditions have been assumed, resulting in a total of nine operating options. For these options, results of analysis based on the second law of thermodynamics have been presented. These results might then be used to choose the optimum solar hybrid power plant configuration.

1. Introduction

1.1. Problem description

Renewable energies play the key role in sustainable development and are the most promising remedy to the problem of air pollution worldwide. Among various sources of renewable energy, the usage of solar thermal energy in generating electricity can be regarded as the most reliable and developed one in the path of commercialization [1].

In Shiraz, Iran, the first solar thermal power plant (STPP) has been designed and constructed for 250 kW power generation [2]. For the first phase of development, this plant has been constructed and tested only to produce high pressure and high temperature steam (21 bar, and $250\,^{o}C$). This steam is then fed into the steam turbine of a conventional Rankine cycle. Based on the new feasibility study, it has been decided to increase the nominal capacity of this plant to 500 kW by adding a new large size (100 meters long) parabolic trough collector and employing an auxiliary boiler to provide the deficiency of steam as well as running the system during night periods (or day periods in which the solar radiation is insufficient).

Various schemes are possible to integrate the new collector to the field of available collectors. In this paper, two different cases (A, B) along with a night case are considered to be suitable for the new system. Assuming three different operating conditions (by setting the turbine outlet pressure) for each case, a total of nine configurations have been analyzed. The three outlet pressures considered are 10, 25 and 100 kPa.

In the present article, these options are studied based on the first and second laws of thermodynamics. Each configuration has some advantages and disadvantages regarding

overall thermal performance, installation and operating costs. To assess the overall performance of various configurations in a comparative manner, exergy method has been applied to the corresponding cycles (as a representative of the second law analysis). Exergy and exergoeconomic methods have received considerable attention during the past decade in the analysis and optimization of power plant cycles to achieve higher efficiencies and to reduce the operating cost of the corresponding power plants [3,5].

For each case of the aforementioned cycles, results of exergy analysis are presented and exergetic losses due to various components (e.g. turbine, boiler, condenser etc) have been calculated. Finally the system with the best exergy efficiency to combine the new collector and increase the power rate of the plant is suggested for construction and operation.

1.2. Current Configuration

Shiraz solar thermal power plant consists of two separate cycles namely the oil cycle and the steam cycle. The oil cycle absorbs the solar radiation through collector field and transmits the harvested thermal energy to the steam cycle which is a classic Rankine cycle. The energy transfer between the two cycles takes place at three heat exchangers in series (E-201, E-202 and E-203). The collector field is composed of 8 parallel loops, each consisting of 6 collectors in series. The current configuration is able to produce 0.671 kg/s of steam at 21 bar and $250\,^{o}C$. This steam will be termed "field generated steam" as opposed to "boiler generated steam" which is the steam that is expected to be generated by the auxiliary boiler. A schematic of the plant is shown in Fig 1.

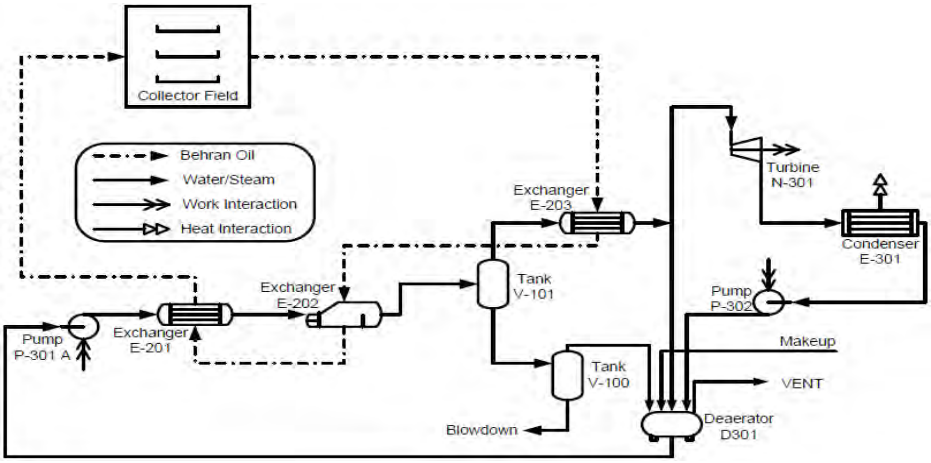

Fig. 1. Schematic of the current solar power plant.

1.3. Integration of the new collector

The new collector has been designed to bring Therminol VP-1 from 294^{O}C to 313^{O}C, supplying 200 kW of energy to the system. This energy can be introduced into the current configuration in a variety of ways. Two different approaches have been considered in the present work namely case A and case B. In case A the boiler provides steam at 21 bar 250^{O}C. This steam is then mixed with the field generated steam and the mixture is then becomes more superheated (to 294^{O}C) using available extra energy from the new collector in an extra heat exchanger (E-204). However, in case B, the boiler produces steam at 21 bar 294^{O}C and in exchanger E-204, only the field generated steam becomes more superheated. The remaining energy from the new collector is then used to make the outlet oil from the field warmer, thus, increasing the amount of field generated steam. Therefore another extra exchanger is needed

in case B to bring the VP-1 oil from the new collector and the Behran oil from the existing farm into thermal contact. Simplified depictions of cases A & B are shown in Fig 2 and Fig 3.

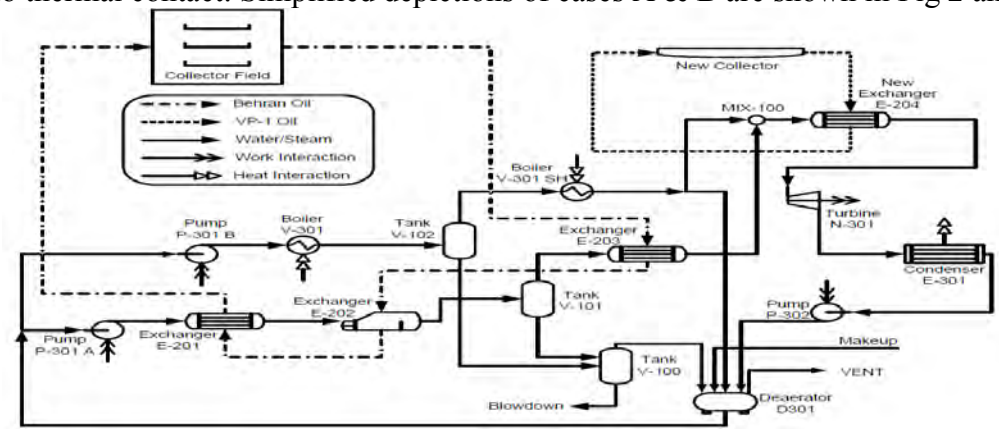

Fig. 2. Schematic of the proposed case A.

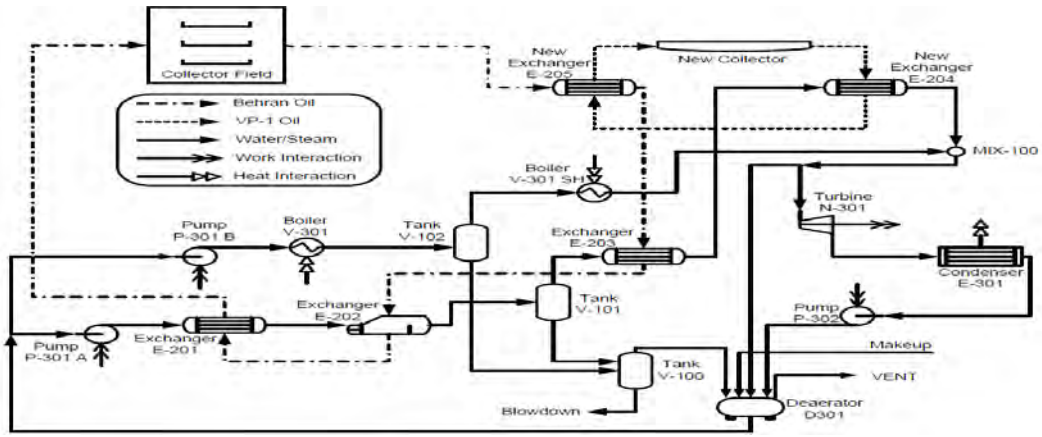

Fig. 3. Schematic of the proposed case B.

2. Methodology

As shortly explained in the preceding section, the problem at hand is a sort of semi-fixed system in which very few parameters are allowed to be altered. This is a direct consequence of the fact that we are dealing with a designed and constructed system and our attempt is to integrate a device into such a system which was not considered before. Thus we're not dealing with an ordinary optimization process in which particular parameters are allowed to vary in order to find the optimum set of parameters. Rather we are investigating the optimum case among a predefined set of choices. In other words, instead of optimizing the cycle, various predefined cases are compared based on the second law and the best can be *chosen*. The assessment of available options is done based on the destructed exergy associated with various components in each option. The destructed exergy (lost available work) is closely related to the rate of entropy generation through the following equation [4]:

$$\dot{W}_{lost} = T_0 \dot{S}_{gen} \qquad (1)$$

where T_0 is the lowest temperature available for the system to reach theoretically (dead state). In this work the dead state has been assumed to be at $25\,^{o}C$ and atmospheric pressure. Thus by calculating the rate of entropy generation for each component, the contribution to lost available work due to that component can be determined. The rate of entropy generation for

each component is readily derived from the general statement of the second law for open systems [4]:

$$\dot{S}_{gen} = \frac{dS_{cv}}{dt} - \sum_{i=0}^{n} \frac{\dot{Q}_i}{T_i} + \sum_{out} \dot{m}s - \sum_{in} \dot{m}s \qquad (2)$$

where $\dot{Q}_i$ is the i[th] heat interaction of the corresponding component with the surrounding (positive when heat transfer takes place from surrounding to the control volume) and T_i is the temperature of that portion of the control surface through which the i[th] heat interaction occurs. In calculating last two terms on t he right hand side of Equation (2) one may frequently encounter the case of calculating Δs terms for steam and oil. For steam the corresponding terms are read from standard thermodynamic tables while for oil (both the collector field oil and the new collector oil) the Δs terms are determined using their specific heats as a function of temperature. Starting from the well-known first law relation [4] and treating oil as an incompressible liquid the Δs term associated with oil can be written as:

$$Tds = dh - vdP \xrightarrow{dP=0} ds = dh/T \xrightarrow{dh=C_p dT} ds = C_p \, dT/T \qquad (3)$$

$$\Delta s = \int_{T_{in}}^{T_{out}} \frac{C_p}{T} dT \qquad (4)$$

It should be noted that in the use of equation (4), the temperatures should be considered in an absolute temperature scale (Kelvin in this work). Having the complete set of states for the current configuration and assuming that the states of steam cycle remain unchanged (which seems reasonable) the new intermediate temperatures have been determined by applying energy balance using an available solver code.

3. Results

After satisfying energy balance for the whole system in every configuration, the state at each node becomes fixed. Knowing the fixed states, the values of entropy generation and subsequently the values of lost available work can be readily determined. In the following four tables the values of $\dot{W}_{lost}$ for the main components in each configuration have been presented.

Example calculation 1:

The lost available work for exchanger E201 in case B for a turbine outlet pressure of 10kPa:

$\dot{m}_h = 14\,kg/s, \dot{m}_c = 0.7525\,kg/s, T_{h,i} = 231.6^o C, T_{h,o} = 221.1^o C, T_{c,i} = 98.53^o C, T_{c,o} = 217.9^o C$

$P_c = 22.3bara \Rightarrow s_{c,i} = 1.28866\,kJ/kg.K, s_{c,o} = 2.49896\,kJ/kg.K \Rightarrow \Delta s_c = 1.2103\,kJ/kg.K$

For hot fluid (Behran Oil): $C_p = 0.8132 + 3.706 \times 10^{-3}(T + 273) \Rightarrow \Delta s_h = -0.05601\,kJ/kg.K$

$\dot{Q}_{c.v.} = 0 \Rightarrow \dot{S}_{gen} = \dot{m}_h \Delta s_h + \dot{m}_c \Delta s_c = 0.1266\,kW/K$

$T_0 = 25^o C = 298K \Rightarrow W_{lost} = 37.72kW$

Table 1. Values of lost available work for cases A & B with turbine outlet pressure of 10 kPa.

	V-102	0.00	0.16	V-102	
Mixer	MIX-100	0.53	0.00	MIX-100	Mixer

Example calculation 2:

The lost available work for condenser E301 in case A for a turbine outlet pressure of 25kPa:

$\dot{m}_h = 1.1375 kg/s, P_{h,i} = 0.25 bara, T_{h,i} = 65.0^o C, P_{h,o} = 0.2 bara, T_{h,o} = 60.09^o C, x_{h,o} = 0.967$

$$\Rightarrow s_{h,i} = 7.59958\,kJ/kg.K, h_{h,i} = 2540\,kJ/kg, s_{h,o} = 0.83217\,kJ/kg.K, h_{h,o} = 250\,kJ/kg$$

$$\Rightarrow \Delta s_h = -6.76741\,kJ/kg.K$$

$$\dot{Q}_{c.v.} = \dot{m}\Delta h_h = -2605kW \Rightarrow \dot{S}_{gen} = -\frac{-2605}{298} + 1.1375(-6.76741) = 1.04368\,kW/K$$

$$T_0 = 25^oC = 298K \Rightarrow W_{lost} = 311.02kW$$

In the above calculation, the dryness fraction at the turbine outlet has been determined by considering an isentropic efficiency of 60% for the turbine which is a reasonable value for a turbine of this capacity.

It is worth mentioning that, generally in solar thermal power plants the major fraction of total exergy loss takes places in the collector field (mainly due to the ultra high temperature of the

sun)[5]. However, in the present work, the operating conditions of the collector field are the same in all configurations. Thus the exergy loss due to the collector field is not reported for comparison. It should also be noted that the night cycle is essentially either cases A or B in which no collector is at service and boilers are the only suppliers of thermal energy to the system. A quick study of tables 1-4 reveals the fact that, generally by decreasing the turbine outlet pressure, the value of lost work decreases in the corresponding devices. Moreover reducing the turbine outlet pressure increases the amount of power which can be extracted from the turbine. But, as expected, these advantages have their own counterparts; the need for creating vacuum condition for condenser, the need to change the condenser type from air-cooled to water-cooled, etc. Another implication is that in each configuration the dominant sources of lost work are boilers, condensers and turbines and that the contribution made by pumps, mixers and tanks are negligible.

From another point of view, comparing the values of lost available work for same devices, one may conclude that, in the same operating conditions, case A is thermodynamically superior to case B.

4. Conclusions

- The concept of lost available work has been utilized to select the best choice of integration of a hybrid solar power plant.
- Regarding various cases, it is found that case A is thermodynamically the preferred case for integration.
- Case A has the advantage of requiring one less extra heat exchanger to be integrated into the current configuration.
- For optimum integration, one must also take into account the economic aspect of each case. In other words, a thorough thermo-economic analysis might be proper to further assess these two proposed cases.
- Moreover one should also consider water consumption rate for each case. Water is rarely available especially for regions where solar energy is considerable and such limitation might sacrifice higher efficiencies or lower available lost work for the final decision.

Abstract: Results of theoretical simulations of the steady-state operation of the dynamic solar thermal desalination unit with a fluid piston are presented in this paper. A laboratory prototype of a dynamic thermal water distillation unit was developed and it was built around an engine with fluid pistons. In the calculation scheme, the internal circuit of the desalination unit was split into several control volumes, namely the evaporator, the condenser and the cylinder. The lumped parameter mathematical model was derived based on the differential energy and mass conservation equations written for each of the control volumes and describing heat and mass transfer processes taking place during water evaporation and condensation under the cyclic variation of the pressure and temperature inside the system when the engine operates. The solution of the set of governing equations produces information on the variation of temperatures and pressure inside the system over the thermodynamic cycle and on the water desalination capacity of the unit.

1. Introduction

The shortage in clean drinkable water supply has become one of the most important problems due to the continued growth in the world's population. Kalogirou [1] states that the fresh water represents only about 3% of all water on the earth. Approximately 0.25% of fresh water can be directly used from lakes and rivers and the rest is in the ice form or deep ground water which is difficult to reach. As a result, novel drinkable water production technologies are being continuously developed to resolve this important problem.

Desalination techniques are among feasible solutions to produce fresh water from saline water but such technologies require significant amount of energy. Using fossil fuels for water desalination results in high plant running costs and causes a considerable negative environmental impact. As a consequence, numerous studies are being performed on utilisation of an alternative energy source, namely renewable energy, for running desalination plants. The aim of the above research studies is to make the process of water desalination with the use of renewable energy safer for the environment and sustainable.

The literature review performed in this subject demonstrates that the majority of research carried out has been focused on the static solar stills in which the saturation pressure and temperature remain constant during the desalination process. Shatat and Mahkamov presented theoretical and experimental study of a static solar thermal distillation unit in [2]. The effect of the design parameters on the performance of the unit was investigated and an optimization of unit's design parameters have been conducted. Mahkamov and Belgasim described in [3] the concept of the dynamic solar distillation system in which an evacuated tube solar collector was coupled with a fluid piston thermal engine. The laboratory prototype of the proposed system was built and tested to demonstrate its functionality and preliminary experimental results were very encouraging. Furthermore, a comparative study between static and dynamic solar distillation systems was performed in the same study which demonstrates considerably higher fresh water production capacity of the dynamic system.

2. Model Description

The dynamic solar thermal desalination unit integrated with fluid piston engine is described in *fig.1*. This unit operates under a cyclic change in the pressure and temperature during the operation of the unit due to the expansion and the compression of the volume of the fluid piston engine. Such working conditions considerably intensify the desalination processes and fresh water production.

The plant's operation can be described as follows. Saline water is heated up and evaporated in the solar collector (1) causing pressure rise in the system. The initial increase of the pressure initiates oscillations of water columns (3) and (4) of the fluid piston engine and the whole system operates as a dynamic thermal oscillation system, in which the water evaporation is intensified by volume and pressure variations in the internal circuit. In its turn, this sustains oscillations of water columns. In this particular design, the distilled water is formed in the condenser (2) surrounded by the water jacket with the saline water and the condensate is collected in the distilled water vessel (6). The heated saline water from the water jacket of the condenser is pumped to the water storage tank.

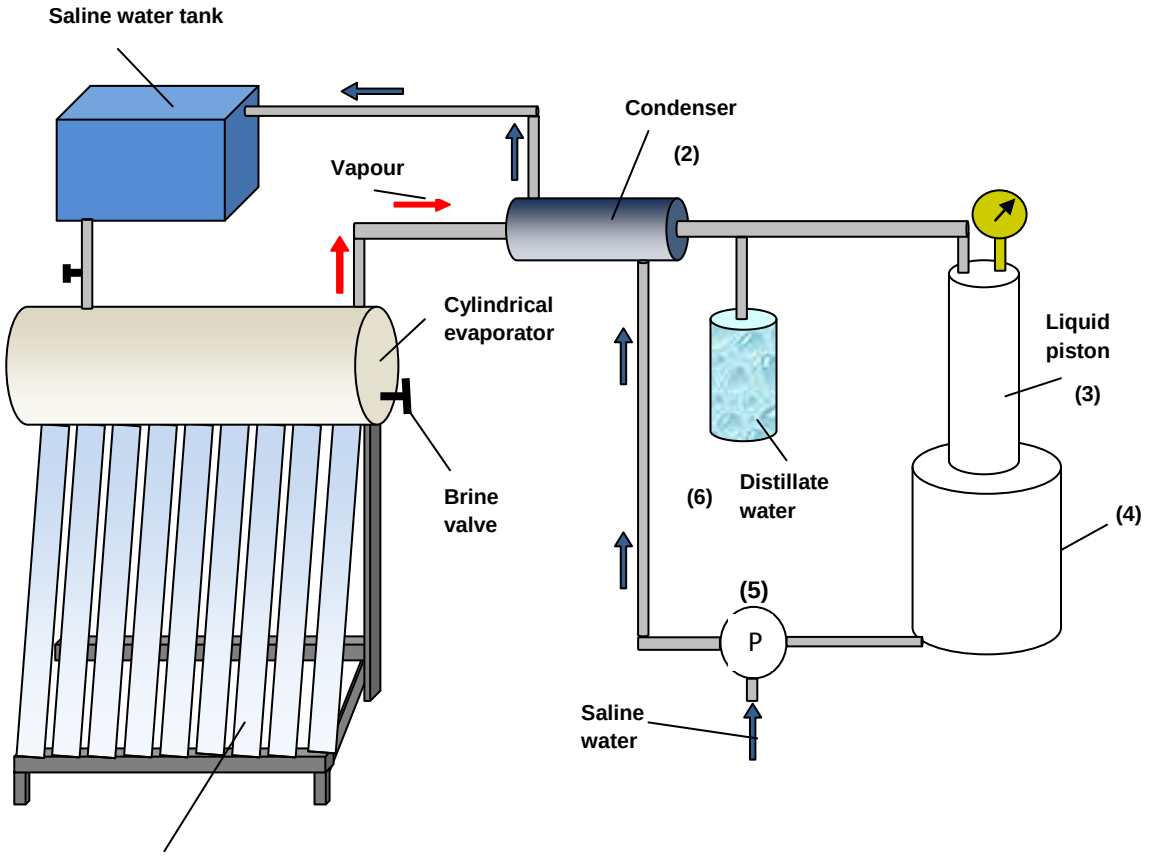

Fig. 1 **(1) Evacuated tube solar collector**

The above system was tested under a number of constant heat flux conditions created with application of a sun simulator: an array of 110 halogen floodlights placed above evacuated tubes. The heat flux magnitude is set using a three-phase transformer which controls the voltage of the electrical current supplied to the floodlights. Preliminary results obtained clearly show that such dynamic system has a considerable advantage in fresh water production capacity over conventional static systems. Currently the unit is being equipped with sensors to record oscillations of the liquid piston, temperature and pressure variations in components of the installation.

3. Theoretical Modelling

In order to perform the theoretical analysis, the unit was divided into three separate control volumes, namely the evaporator, the condenser and the fluid piston cylinder. The lumped mathematical model was derived based on energy and mass conservation differential equations written for each control volume taking into accounts the cyclic variation of the pressure and temperature inside the system during its operation.

3.1. Evaporator

The mathematical model of the system consists of the mass and energy balance equations written for each component. The mass conservation equation could be written as

$$\frac{d}{dt}(\rho V) = (\rho \dot{v})_{sw} - (\rho \dot{v})_{v} - (\rho \dot{v})_{b} \quad (1)$$

where t is time, V is volume, ρ is density and $\dot{v}$ is volume flow rat.

The initial condition for the above equation is the amount $(\rho V)_0$ of the seawater at the beginning of the operation. Two assumptions are made: the amount of saline water inside the evaporator is constant; all the vapour produced in the evaporator will be then condensed in the condenser.

The salt concentration conservation equation is

$$\frac{d}{dt}(\rho V c) = (\rho \dot{v} c)_{sw} - (\rho \dot{v} c)_{b} \quad (2)$$

where c is salt concentration.

The initial amount of salt is $(\rho V c)_0$

Finally, the energy conservation equation can be derived by applying the energy balance principle for the same control volume.

$$\frac{d}{dt}(\rho V c_p T) = Q_{in} + (\rho \dot{v} c_p T)_{sw} - (\rho \dot{v} h_{fg})_{v} - (\rho \dot{v} c_p T)_{b} - Q_{loss} \quad (3)$$

where Q is the heat flow, T is temperature h is enthalpy and c_p is heat capacity at constant pressure.

The energy $(\rho V c_p T)_0$ is at the starting time. In this equation the heat capacity of the system material has been neglected so no heat storage is considered in the evaporator substance.

3.2. Condenser

It was assumed in the simulation process that all the produced vapour is converted into fresh water. The condenser design represents the counter flow tube-in-tube heat exchanger in which the condensation process takes place on the internal surface of the inner tube while the cooling water passes through the outer tube. In order to enhance the productivity and the thermal efficiency of the system, the seawater fed to the evaporator is first used as cooling water in the condenser's water jacket to gain the latent heat of condensation.

The mathematical description of the condensation process depends on a number of factors including the condenser shape, the flow pattern and the condensation rate. The inner heat transfer coefficient in the case when the condensation rate is low and the vapour has a low velocity in a short condenser, can be calculated as [4]

$$h_i = 0.555\left[\frac{g\rho_l(\rho_l-\rho_v)k_l^3 h_{fg}^{'}}{\mu_l(T_{sat}-T_s)D}\right]^{1/4}$$

where the modified condensation heat is $h_{fg}^{'} = h_{fg} + \frac{3}{8}c_{p,l}(T_{sat}-T_s)$

The outer heat transfer coefficient is mainly effected by Nusselt Nu number which is a function of the flow pattern and depends on the Reynolds number Re. If $Re < 2300$ the flow is laminar and if $Re > 2300$ then the flow is turbulent. The outer heat transfer coefficient can be calculated as $h_o = \frac{k_l}{D_h}Nu_i$ [5]. Therefore, the overall heat transfer coefficient is $U = \frac{h_o h_i}{h_o + h_i}$

The condenser is considered as a control volume and using the mean temperature difference technique, the governing energy equation for the condenser can be written as:

$$Q = UA_s\frac{\Delta T_2 - \Delta T_1}{\ln(\Delta T_2/\Delta T_1)} = \dot{m}c_{p,sw}\left(T_{c,in} - T_{c,out}\right) \quad (4)$$

where U is the overall heat transfer coefficient, A surface area, $\dot{m}$ is mass flow rate, $\Delta T_1 = T_{sat} - T_{c,out}$ and $\Delta T_2 = T_{sat} - T_{c,in}$

In the above equation, the produced fresh water is assumed to be condensed at the saturation temperature.

3.3. Fluid piston engine

The fluid piston engine consists of two concentric cylinders attached to the collector at the top of the inner cylinder. The two cylinders are filled with water to work as a piston in both cylinders. After the solar collector starts to heat up the saline water, its temperature gradually increases leading to the rise in the pressure in the system. The pressure continue to rise until the inner cylinder piston, which is at the top position in the beginning of heating process, is pushed down. This results in expanding the volume of the system. The expansion process continues until the air pressure at the top of the outer cylinder balances the system pressure and then the system returns to the original position under the effect of the water weight and air pressure leading the cycle to be repeated again.

The expansion and compression processes are repeated continually allowing the unit to work under variable volume and pressure conditions. The change in the volume is important to estimate the change in pressure and in this study, the volume has been assumed to vary harmonically:

$$V_{tot} = V_{dead} + \pi A\frac{D^2}{8}\left[1 - cos(\omega t)\right] \quad (5)$$

where V_{dead} is the dead volume of the system, A is the amplitude of the fluid piston oscillations; D is the diameter of the piston and f is the frequency of oscillations.

The relationship between the change in volume and in the pressure is calculated as

$$\Delta P = P_{sat}\left[\left(\frac{V_{tot(1)}}{V_{tot(2)}}\right)^{k} - 1\right] \quad (6)$$

where ΔP is the pressure change due to the variation in the total volume of the system.

It was assumed that the expansion and the compression processes are isentropic processes.

4. Results and Discussion

The governing equations of the theoretical model are the set of ordinary differential equations with the time being the independent variable. The input parameters of the system include the initial conditions, the properties of water, the value of constant solar radiation and dimensions of the unit. In order to simulate the operation of the system, a MATLAB program has been written which uses Euler technique to solve the differential equations with a time step $\Delta t = 0.01\ sec$.

The theoretical simulations have been carried as set of a number cases with constant heat flux values, which are typical for different hours of the mid-summer day in the Middle East region.

The theoretical results on pressure and temperature variations inside the system for the heat flux corresponding to 12 noon are illustrated in *fig. 2* and *fig. 3*, respectively. During the expansion in the cylinder, the pressure drops to approximately 0.7 *bar* (minimum pressure) and rises to 1.15 *bar* (maximum pressure) during the compression stroke. These values are also close to experimental values of the minimum amd maximum pressures in the cycle, measured using a manometer. The temperature during the cycle varies between 92 and 105 degrees C.

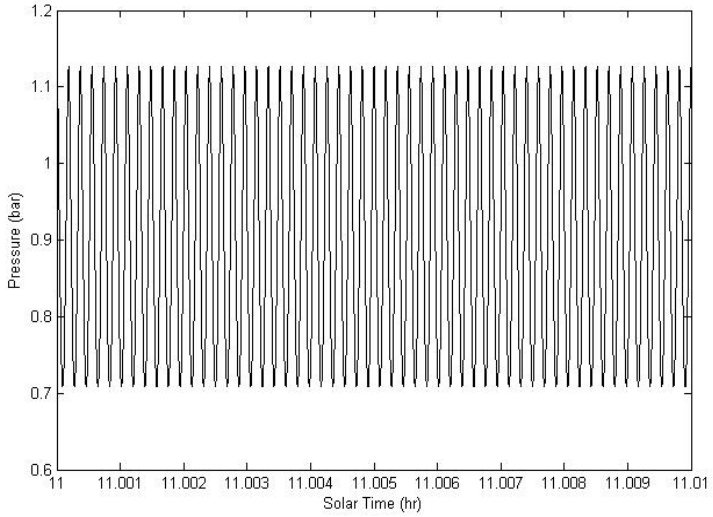

Fig. 2 The saturation pressure oscillation.

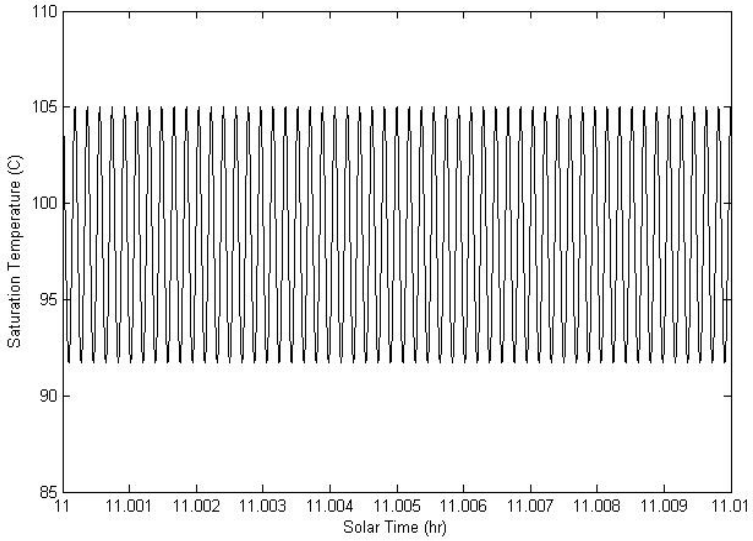

Fig. 3 The saturation temperature oscillation.

Theoretical results on the fresh water production capacity obtained by using the above mathematical model for a number of constant heat fluxes typical for different periods of the mid-summer day were used to produce the variation of the fresh water production capacity over the day, as shown in *fig 4*.

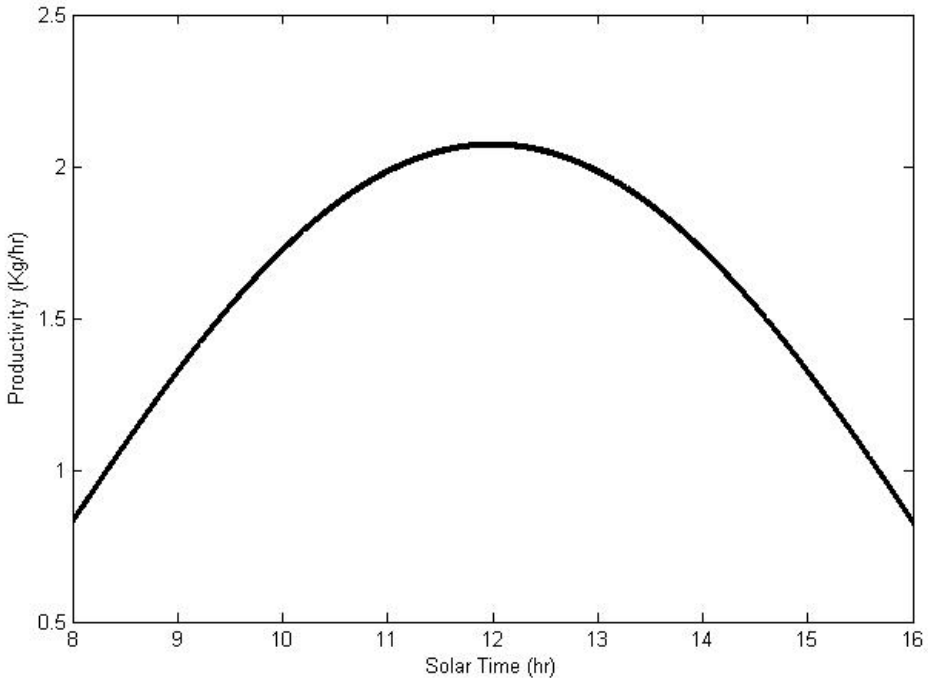

Fig.4 The productivity variation during the mid-simmer day

The theoretical value for the daily fresh water production capacity is obtained by integration water production capacity curve in *fig. 4* and it is about 9 litres, which is greater than 6 litres for the conventional static solar stills. During preliminary experiments at the same heat flux value the fresh water production capacity was about 8.2 litres.

5. Conclusions

The paper presents results of theoretical modelling of the steady-state operation of the proposed dynamic water desalination system with a number of constant heat flux values upon the evacuated tubes of the solar collector. The heat flux values used are typical for a different periods of the mid-summer in the Middle East region. The fresh water production, obtained from this study, was found to be about 9 litres/day which is greater than the most of conventional static solar distillation designs. The theoretical data obtained on the fresh water production capacity is in a good agreement with data obtained on the test rig which was run simulating variation of insolation over the summer day.

Currently the unit is being equipped with sensors to record oscillations of the liquid piston, temperature and pressure variations in components of the installation. Such experimental information can be used for calibration of the mathematical model.

It is planned to conduct modelling of unsteady operation with at variable heat flux conditions in the future. The unsteady model also will describe processes taking place in the evaporator and condenser in more details making it possible to take into account the effect of the insolation variation on the levels of the saturated pressure and temperature.

The further development of the mathematical model will also include an optimization procedure for design parameters of the unit.

Abstract: Clean water is essential for good health which influences the social and economic development of any nation. However, there is limited access to safe water on a global scale. This challenge can be overcome through a multi-faceted approach, including the development of appropriate technologies for water treatment and decision-making tools. Solar distillation is one of the commonest non-conventional methods for improving the quality of water. In this vein, the most widely-exploited solar distillation system is a conventional solar still, which has a thin layer of saline water in a shallow basin with a transparent cover over the water and one or two slopes. The productivity of a solar distillation system is influenced by design, climatic and operational factors, with solar radiation being the most influential meteorological parameter. It is therefore necessary to optimize solar radiation that effectively reaches the base of the solar still. Previous attempts have sought to improve the design characteristics of conventional solar stills through the consideration of system geometry and optical properties of construction materials. One of the important geometric parameters is the ratio (R) of length to width (aspect ratio) of the still base. For a single-slope solar still (SSS), R has been examined in preceding studies. Nevertheless, there is a paucity of information on the aspect ratio of a double-slope solar still. In this study, a state-of-the-art software (ESP-r) was used to simulate the variation of effective insolation with R for a double-slope solar still (DSS) in the east-west and north-south orientations and a SSS facing south. Meteorological data captured at the University of Strathclyde (55^o 52′ N, 4^o 15′ W) and Guantanamo Bay (19^o 54′ N, 14^o 51′ E) was employed in this analysis. Simulation results show that the optical performance of a DSS was lower (in both orientations) than that of a SSS at both sites. The DSS collected more solar energy in the east-west than north-south orientation, for a given value of R. In addition, effective insolation increased with R to an optimum level for both the DSS and SSS. Approximate optimum values of R were 3.0 and 2.0 for the University of Strathclyde and Guantanamo Bay respectively. However, the optimum value of R was not sensitive to the orientation of the DSS at the two sites. Further, the DSS and SSS exhibited the same optimal value of R at a specific site. It appears that R significantly affects solar collection in a DSS.

1. Introduction

Clean water is essential for good health which influences the social and economic development of any nation. However, a large proportion of the available water on the earth's surface is saline [1]. This problem is exacerbated by environmental pollution predominantly

caused by anthropogenic activities. Consequently, there is limited access to clean water, especially in developing countries [2]. Solar distillation is one method of producing fresh water from salty water.

A conventional solar still is the most-widely exploited solar distillation system. It has a thin layer of water in a horizontal basin, transparent cover over the water with one or two slopes (Fig.1). The single-slope solar still (SSS) has a back wall which acts as an internal reflector while the double-slope solar still (DSS) has no back wall. Transparent covers in a DSS may be symmetrical ($\beta_1=\beta_2$) or symmetrical ($\beta_1\neq\beta_2$), with a gable along each breadth. In both the SSS and DSS, saline water in the basin is heated by solar radiation passing through the transparent cover and absorbed by the water and bottom part of the still basin. Vapour flows upwards from the hot water and condenses when it comes into contact with the cooler inner surface of the transparent cover. The condensate (clean water) is collected in a channel fitted along the lower edge of the transparent cover. For a given set of system design parameters, the distillate output from the system is influenced by climatic and operational factors, and a SSS intercepts a higher proportion of solar radiation than a DSS at locations with both high and low latitudes [3]. Moreover, solar radiation is the most influential environmental parameter [4], and the DSS is economically more viable than the SSS [5]. So, it is necessary to optimize the design of the DSS in order to maximize its capability of solar collection.

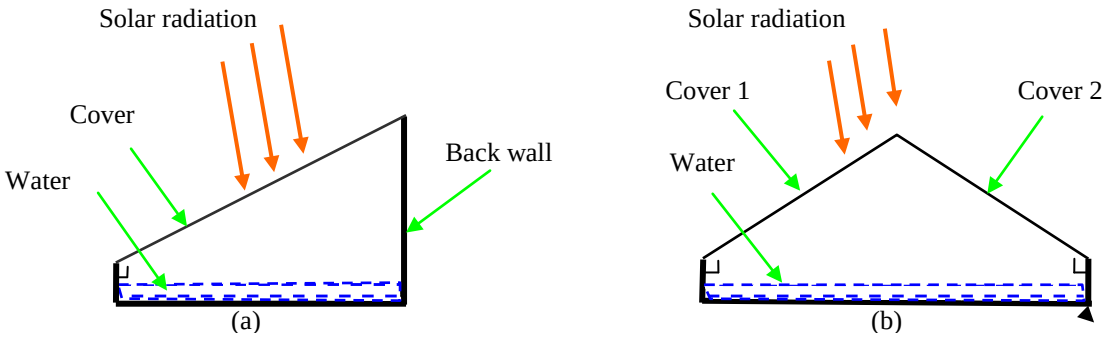

Fig.1: Cross-section of a basic solar still with a) single slope and b) double slopes.

Attempts have been made to establish materials with suitable optical properties of various components of a basin-type solar still. The cover absorbs and reflects part of the incoming solar radiation, with the remaining fraction being transmitted onto the still walls, the surface of saline water and basin liner. So, transmittance is the most important optical property of the cover layer, which may be plastic or glass. Different cover materials for solar stills have been investigated in previous work [6, 7]. It was found that solar stills with glass covers perform better than those with plastic covers. In addition, the internal surfaces of the walls of the still absorb and reflect part of the received solar radiation onto the surface of water. The reflectance of the walls of a solar still influences the effective insolation on saline water in the basin [8]. The basin liner also absorbs part of the solar radiation intercepted by the transparent cover. Consequently, the absorptance of the basin liner is an essential optical property. The various still components are assembled into a structure with specific geometry which affects the optical performance of the distillation system.

A solar still may be mounted on a tracker or fixed plane. A tracking solar still follows the sun on daily (one-axis) or daily and seasonal (two-axis) basis to maintain a low angle of incidence and thereby increase the transmission of solar radiation through the transparent cover. However, tracking solar systems are costly and unsuitable for large-scale production of

distilled water. In contrast, there is no cost associated with tracking in stationary solar stills. So, this variety of solar stills is more feasible for practical applications. The transparent cover of a fixed solar still is inclined at an angle (β) to the horizontal plane. It is reported that the optimum value of β is 10^{o} which just enables the distillate to flow downwards on the inner surface of the cover without dropping back into the basin [3, 9]. Nevertheless, β also affects the transmission of solar radiation through the cover [10]. So, $\beta > 10^{o}$ is sometimes used depending on the latitude (ϕ) of the site [4]. Generally, $\beta=\phi-10^{o}$ for summer season ($\phi>10^{o}$), $\beta=\phi$ for annual performance and $\beta=\phi+10^{o}$ for winter season [11]. In addition, a stationary DSS is oriented with the covers facing the east and west directions to optimize solar collection [12, 13]. On the other hand, a stationary SSS is commonly mounted facing the Equator for optimum performance. Capture of solar energy is also affected by the ratio of the length to width of the still base (R). Optimization of R is reported for a SSS [14] but there is a paucity of information on the aspect ratio of a DSS. The objective of this study was therefore to overcome this limitation

$$R=L/B \quad (1)$$

2. Methodology

2.1. System description and computational tool

Solar collection in a DSS with symmetrical slopes and a SSS has been studied theoretically. The major components of the systems were a) a horizontal basin, b) transparent covers and c) opaque walls and base (Fig.1).The basin liner was constructed from a steel material (0.001 m thick) while the covers were constructed from clear float glass (0.004 m thick) to allow solar radiation reach the internal surfaces of the still. Each cover was inclined at 55.9^{o} to the horizontal at the University of Strathclyde (55^{o} 52′ N, 4^{o} 15′ W) and 19.9^{o} to the horizontal at Guantanamo Bay (19^{o} 54′ N, 14^{o} 51′ E) to optimize solar collection on annual basis. The same slope was used for the DSS and SSS at a given site. Each wall was triple-layered with expanded polystyrene (0.05m thick) sandwiched between two plywood layers (0.005 m thick, each layer). Similarly, the base of each still was also triple-layered with plywood external (0.005 m thick), expanded polystyrene middle (0.05 m thick) and steel internal layers. The surface area of the base remained constant for different values of the aspect ratio. In addition, the height of the lower vertical sides was fixed at 0.05 m above the still base while the height of the higher vertical sides varied with R. Other design parameters are presented in Table 1.

Table 1. Design parameters of a double-slope solar still.

Parameter	Unit	Value
A	m^2	1.00
α_b	dimensionless	0.90
ρ_g	dimensionless	0.2
ρ_w	dimensionless	0.2
τ_1, τ_2	dimensionless	0.837

A state-of-the-art software (ESP-r, version11.9) was used to compute hourly irradiance on the basin liners of the DSS and SSS. This software has a robust algorithm for computation of insolation and shading effects [15]. Beam and diffuse components of solar radiation are treated separately, and optical view factors and multiple reflections are taken into consideration. A geometric construction of each solar distillation system was made in ESP-r with the origin at x=0, y=0 and z=1 m to simulate the system in a mounted mode (the x-, y- and z-axes are mutually perpendicular, z-axis is vertical and x-y plane is horizontal). The still

base was in the x-y plane, with the diagonals of the base intersecting at the origin. The orientation of the DSS was varied by rotating the system about the vertical axis through the origin (x=0 and y=0). For each system configuration, view factors were calculated by using the ray tracing technique, and the computed optical view factors were used in the computation of effective irradiance on the base of the solar still in any given hour. The DSS was simulated with the covers oriented in the east-west and north-south directions while the SSS faced south at both sites. Effective hourly insolation (I_i) was computed from irradiance on each still base. The total annual effective insolation (E) was determined by summing up the hourly insolation for a given value of the aspect ratio (R). Then, the mean annual daily insolation (H) was computed from E. In addition, the area of the still base remained constant as R was varied from 0.5 to 4.0. At successive increments in R, the percentage solar gain (Q) was calculated. Equations for these calculations were as follows:

$I_i=3600G_i$ for i=1, 2, 3, …, m (2)
where m=number of hours in a year.

$E=\sum_{i=1}^{i=m} I_i$ (3)

$H=E/j$ (4)
where j=number of days in a year.

$Q_k=100(H_k-H_{k-1})/H_i$, for k=1, 2, 3, … (5)

Mean hourly normal-incident beam and diffuse irradiance data, captured at the University of Strathclyde and Guantanamo Bay, was used in this study. This data covered the periods from 1 January to 31 December 2001 at the University of Strathclyde and 1 January to 31 December 1971 Guantanamo Bay. It should be noted that the University of Strathclyde and Guantanamo Bay are at high and low latitudes respectively.

2.2. Some assumptions

The following assumptions were made:

a) the distribution of incoming diffuse radiation was anisotropic. So, an anisotropic model was employed in calculating the amount of diffuse radiation received by a given surface. It should be mentioned that anisotropic models are more accurate in estimation of diffuse radiation than isotropic models [16],
b) the ground reflected diffusely because it is rough and so the reflected radiation is scattered,
c) the basin liner was black on the interior surface to optimize solar absorption on the still base, and
d) the solar still was not obstructed by other structures within the vicinity to reduce the effect of shading from these structures.

3. Results and discussion

The variation of mean annual daily effective insolation (H) on the base of the DSS and SSS simulated at the University of Strathclyde is shown in Fig.2. It is observed that the DSS collects less solar radiation than the SSS for a given value of the aspect ratio (R). This observation is attributed to the presence of a back wall in the SSS. The back wall reflects part of the incoming solar radiation onto the still base [8]. Garg and Mann [3] also found that the

DSS was optically less efficient than the SSS. In addition, the DSS captures more solar radiation in the east-west orientation than the north-south orientation, probably due to the effect of shading from the gables. For the east-west orientation, the gables are on the north and south of the still. So, one of these gables would cast a shadow on the still base when the sun is due north or south of the solar still, except when the sun traverses the sky over the local latitude. The sun traverses the sky to the south of the University of Strathclyde throughout the year. In this case, the southern gable would cast a shadow on the still base. However, solar radiation would be able to directly reach the still base even at low solar altitudes in the morning or afternoon. For the north-west orientation, the gables are on the east and west of the still. Thus, one of the gables would cast a shadow on the still base in the morning or afternoon times, except at local solar noon. The effect of shading is significant at low solar altitudes in the morning or afternoon, which accounts for the observed effect of orientation on the optical efficiency of the DSS [12, 13].

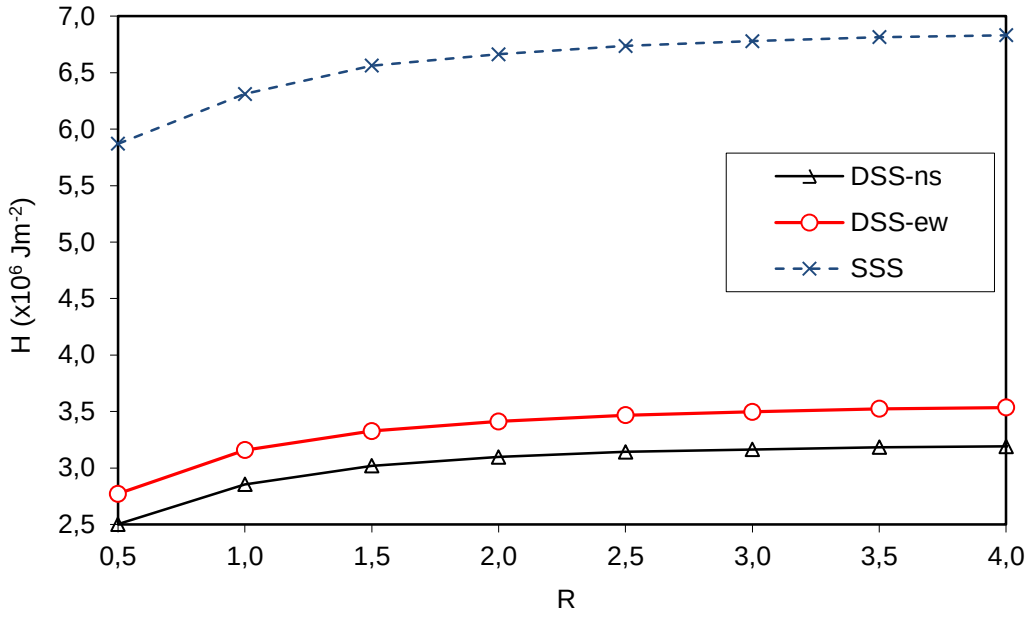

Fig. 2. Variation of mean annual daily effective insolation (H) with aspect ratio (R) for the DSS oriented east-west (DSS-ew) and north-south (DSS-ns), and the SSS facing south at the University of Strathclyde.

Fig.2 also shows that H increases with the aspect ratio (R) of the still base to an optimum level for both the DSS and SSS. This observation is ascribed to a reduction in self-shading arising from the wall along the breadth of the stills. It should be mentioned that R increases as the width (B) of the still decreases, leading to a decrease in the height and area of the slanted wall of the still (for a constant slope) and its shading effect on the internal part of the still base in both the DSS and SSS. Under the prevailing meteorological conditions, the optimum value of R (when Q<1.0 %) was approximately 3.0 for the DSS (in both the east-west and north-south orientations) and SSS. For the SSS, El-Swify et al. [14] reported an approximate optimum value of R=2.0 for climate data from Cairo (30° 3′ N, 31° 10′ E), which is lower than the present optimum value probably due to variations in site parameters. The latitude and longitude of a site affect solar angles and the distribution of solar radiation in a still.
Fig.3 shows the variation of H on the base of the DSS and SSS for the climate data from Guantanamo Bay. It is again observed that the DSS collects less solar energy than the SSS for a given value of R. In addition, the DSS captures more solar radiation in the east-west

orientation than the north-south orientation, in agreement with results for the climate data from the University of Strathclyde. For the east-west orientation, one of the gables would cast a shadow on the still base when the sun is due north or south of the solar still, except when the sun traverses the sky over the local latitude. It should nevertheless be noted that the sun traverses the sky over head, to the south and north of Guantanamo Bay during certain times of the year. In this case, a gable would cast a shadow on the still base when the sun is not crossing the sky over head but beam radiation would be able to directly reach the still base even at low solar altitudes in the morning or afternoon. For the north-west orientation, one of the gables would cast a shadow on the still base in the morning or afternoon times, except at local solar noon. Solar radiation would be unable to directly reach the still base at low solar altitudes during certain times in the morning or afternoon, which accounts for the observed effect of orientation on the optical efficiency of the DSS.

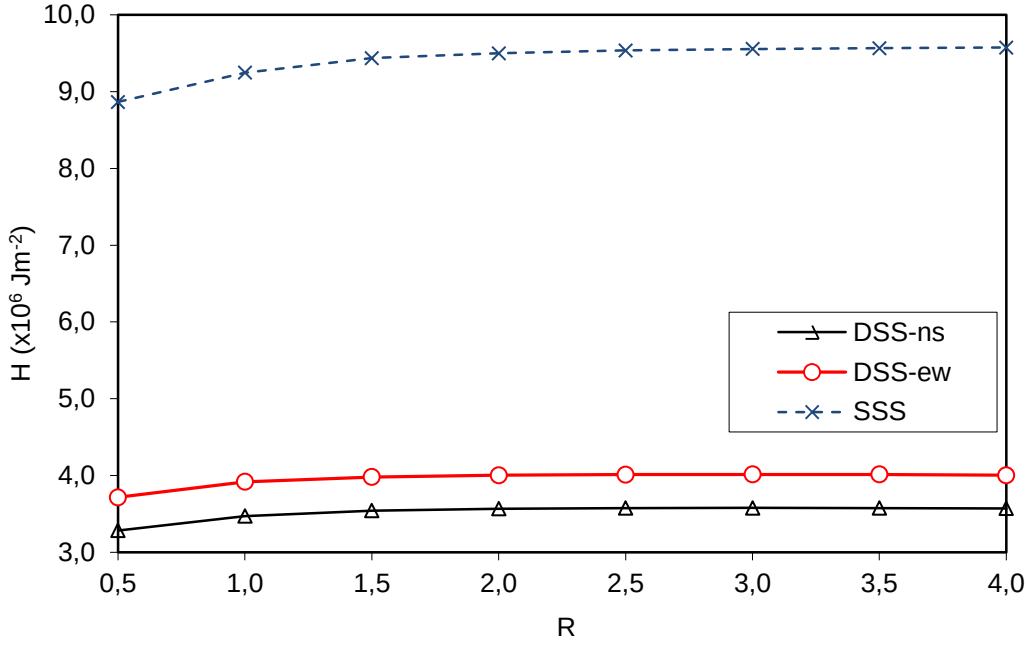

Fig.3. Variation of mean annual daily effective insolation (H) with aspect ratio (R) for the DSS oriented east-west (DSS-ew) and north-south (DSS-ns), and the SSS facing south at Guantanamo Bay.

It is also observed from Fig.3 that H increases with R to an optimum level for both the DSS and SSS. This observation is again attributed to a reduction in self-shading arising from the walls along the width of the stills. Under the prevailing meteorological conditions, the optimum value of R (when Q<1.0 %) was approximately 2.0 for the DSS (in both the east-west and north-south orientations) and SSS, which is in close conformity with findings of El-Swify et al. [14]. This observation is probably because of the influence of site parameters. The the latitude of Guantanamo (19^{o} 54′ N) is closer to that of Cairo (30^{o} 3′ N). It should be mentioned that the zenith angle (θ) is low around solar noon during most of the days at low latitude, with θ=0 at solar noon during some days of the year. Low values of θ would tend to reduce the effect of shading and optimal values of R. In contrast, θ is relatively high around solar noon during most of the days at high latitude, with θ>0 at solar noon throughout the year. High values of θ would tend to increase the effect of shading and optimal values of R. These findings show that site parameters influence the optimum value of R.

4. Concluding remarks

The effect of aspect ratio (R) on solar collection in a double-slope solar still (DSS) has been simulated by using ESP-r software. Optical performances of the DSS and single-slope solar still (SSS) were compared under the same meteorological conditions. The DSS was studied with its transparent covers facing the east-west and north-south directions while the SSS faced south. Meteorological data captured at the University of Strathclyde (high latitude) and Guantanamo Bay (low latitude) was employed in this analysis. Simulation results show that the optical performance of a DSS (in both orientations) was lower than that of a SSS at these sites. The DSS collected more solar energy in the east-west than north-south orientation, for a given value of R. In addition, effective insolation increased with R but the increase was insignificant for values of R>3.0 for both the DSS and SSS at a high latitude. Similarly, effective insolation increased with R but the increase was insignificant for values of R>2.0 for both the DSS and SSS at a low latitude. It is therefore concluded that a) R significantly affects the collection of solar energy by a DSS, b) the approximate optimum value of R is sensitive to site parameters, c) the orientation of the DSS does not affect the optimum value of R, and d) the optimum value of R is approximately the same for the DSS and SSS at a given site.

Abstract: Electricity and water are two commodities which are usually both required in arid countries having a high solar insolation. A number of technologies exists for both systems, which are briefly reviewed in this paper. Among the most matured and suitable concentrated solar power (CSP) plants for electricity generation are the solar tower (ST) and the parabolic trough collector (PTC) systems, whereas for desalination these are the multiple effects distillation (MED) type evaporator and the reverse osmosis (RO). The paper shows also the possibilities that exist and the ways that these technologies can be combined in order to produce simultaneously electricity and water. The equipment required to be used for these systems (steam cycle components, MED or RO) is usually very expensive therefore, the system is required to operate continuously without complete shut down during the night. Such a system would be very suitable for arid countries, which due to the water shortage problem they face, locate power plants in coastal areas in order to use the seawater for the cooling needs of the steam cycle system (condenser). Therefore, in this case it would be comparatively easy to combine the power system with desalination as the resource for such a system, i.e., seawater would be readily available.

Keywords: *Parabolic trough collectors, power tower, multiple effect boiling, reverse osmosis, desalination*

1. Introduction

Cyprus does not have at the moment any sources of energy and depends exclusively on imported oil for its energy needs. The only inexhaustible natural source of energy that Cyprus posses abundantly, is solar energy. It is well known that other forms of renewable energy, like the wind energy, wave energy and biomass have limited potential in Cyprus. Cyprus Government decided to erect a solar thermoelectric power generation station with a capacity of about 50 MW. The characteristics that need to be considered when selecting the right type of thermoelectric system are the cost of electricity produced and the land area that would be required to install the solar plant. The latter is very important as Cyprus has no desert land near the sea but on the contrary seaside areas are very expensive as they are used for touristic development. It should be noted that all existing power stations are located near the sea so the solar power station should also be located near to one of those stations to ease access to the grid and for the use of the seawater for the condenser.

2. Concentrating solar power

Concentrating solar power plants, use mirrors to generate high temperature heat that drives steam turbines traditionally powered from conventional fossil fuels. Some of these systems incorporate also heat storage which allows them to operate during cloudy weather and night-time. The main systems that are operational today in various countries are the parabolic trough collector (PTC) system and the central receiver or power tower system. More details about these systems can be found in [1].

2.1. Parabolic trough collector system

From the technologies available the most industrially matured is the parabolic trough system. This is mainly due to the nine large systems installed and operating in California, USA since 1985, which have a total installed capacity equal to 354 MWe. Mainly due to the plants

operating in California for more than 20 years, parabolic trough is the most proven technology and today they produce electricity at about US$ 0.10/kWh. The success and durability of these plants has demonstrated the robustness and reliability of the parabolic trough technology. Compared to other technologies, this system has a high solar-to-electrical efficiency and low area per MWh requirement.

Parabolic trough collectors are the most mature solar technology to generate heat at temperatures up to 400°C for solar thermal electricity generation or process heat applications. Parabolic trough technology proved to be tough, dependable and proven. Today the second-generation parabolic troughs have more precise mirror curvature and alignment, which enables them to have higher efficiency than the first plants erected in California. Other improvements include the use of a small mirror on the backside of the receiver to capture and reflect any scattered sun rays back onto the receiver, the direct steam generation into the receiver tube to simplify the energy conversion and reduce heat losses, and the use of more advanced materials for the reflectors and selective coatings of the receiver.

2.2. Power tower systems

Power towers or central receiver systems use thousands of individual sun-tracking mirrors called "heliostats" to reflect solar energy onto a receiver located on top of a tall tower. The receiver collects the sun's heat in a heat-transfer fluid (molten salt) that flows through the receiver. This is then passed optionally to storage and finally to a power-conversion system which converts the thermal energy into electricity and supply it to the grid. In many solar power studies it has been observed that the collector represents the largest cost in the system, therefore, an efficient engine is justified to obtain maximum useful conversion of the collected energy. The power tower plants are quite large, generally 10 MWe or more, while the optimum sizes lie between 50-400 MW. It is estimated that power towers could generate electricity at around US$ 0.04/kWh by 2020 [2].

The heliostats should reflect solar radiation to the receiver at the desired flux density at minimum cost. A variety of receiver shapes has been considered, including cylindrical receivers and cavity receivers. The optimum shape of the receiver is a function of radiation intercepted and absorbed, thermal losses, cost and design of the heliostat field. For a large heliostat field a cylindrical receiver is best suited to be used with Rankine cycle engines. Another possibility is to use Brayton cycle turbines which require higher temperatures (of about 1000°C) for their operation and in this case cavity receivers with larger tower height to heliostat field area ratios are more suitable. For gas turbine operation, the air to be heated must pass through a pressurized receiver with a solar window. Combined cycle power plants using this method could require 30% less collector area than the equivalent steam cycles. Rankine cycle engines driven from steam generated in the receiver operate at 500 to 550°C.

2.3. Heat storage and hybridization

An interesting feature of parabolic troughs and power tower systems is that it is possible to store heat, which enables them to continue producing electricity during the night or cloudy days. For this purpose, concrete, molten salts, ceramics or phase-change media can be used. The parabolic trough and the power tower systems produce superheated steam which is used to drive the turbines of a conventional Rankine type power station or an Integrated Solar Combined Cycle System, i.e., they replace the conventional steam boiler with the solar collection system. It has been proved in a previous publication that a system with four hours of storage is the optimum for Cyprus [3]. Both systems can also be operated with fossil fuel (usually natural gas) so as to continue the production of electricity at low irradiation hours and

during the night. This is due to the fact that the equipment involved is expensive and it is not viable to leave the systems to cool down and stay idle for a long time.

All existing power stations in Cyprus are located near the sea. Such a solar power system should also be located near the sea close to an existing power station to ease access to the grid and for the use of the seawater for the condenser. The erection of such a system inland is not possible due to the lack of water required for the condensation of the steam. This is because Cyprus suffers from a water shortage problem, so it has no adequate water supply inland and the proximity of the solar to an existing station means it will also be close to existing power lines and maintenance personnel form the station. Moreover, the location of the solar plant near the sea will enable it to be combined with solar desalination, for the production of fresh water which is also a required commodity for the island.

3. Desalination processes

Desalination can be achieved by using a number of techniques. Industrial desalination technologies use either phase change or thermal processes, or involve semipermeable membranes or single-phase processes to separate the salts from the seawater. All processes require a chemical pre-treatment of raw seawater to avoid scaling, foaming, corrosion, biological growth, and fouling and also require a chemical post-treatment. Here only two desalination methods are considered the multiple effect boiling system, falling in the first category, and the reverse osmosis system, falling in the second. These are the most suitable for the application considered as will be presented in the following sections.

3.1. The MED process

The multiple effect distillation (MED) process is composed of a number of elements, which are called effects. The steam from one effect is used as heating fluid in another effect, which while condensing, causes evaporation of a part of the salty solution. The produced steam goes through the following effect, where, while condensing, makes some of the other solution evaporate and so on. For this procedure to be possible, the heated effect must be kept at a pressure lower than that of the effect from which the heating steam originates. The solutions condensed by all effects are used to preheat the feed [4]. In this process, vapour is produced by flashing and by boiling, but the majority of the distillate is produced by boiling. The MED process usually operates as a once through system without a large mass of brine recirculating around the plant. This design reduces both pumping requirements and scaling tendencies [5].

Early plants were of the submerged tube design and used only two to three effects. In modern systems, the problem of low evaporation rate has been resolved by making use of the thin film designs with the feed liquid distributed on the heating surface in the form of a thin film instead of a deep pool of water. Such plants may have vertical or horizontal tubes.

Another type of MED evaporator is the Multiple Effect Stack (MES) type. This is the most appropriate type for solar energy application. It has a number of advantages, the most important of which are its stable operation between virtually zero and 100% output even when sudden changes are made and its ability to follow a varying steam supply without upset [4]. In Fig. 1, a four-effect MES evaporator is shown. Seawater is sprayed into the top of the evaporator and descends as a thin film over the horizontally arranged tube bundle in each effect. In the top (hottest) effect, steam from a steam boiler or from a solar collector system condenses inside the tubes. Because of the low pressure created in the plant by the vent-ejector system, the thin seawater film boils simultaneously on the outside of the tubes, thus creating new vapour at a lower temperature than the condensing steam.

The seawater falling to the floor of the first effect is cooled by flashing through nozzles into the second effect, which is at a lower pressure. The vapour made in the first effect is ducted into the inside of the tubes in the second effect, where it condenses to form part of the product. Furthermore, the condensing warm vapour causes the external cooler seawater film to boil at the reduced pressure. The evaporation-condensation process is repeated from effect to effect in the plant, creating an almost equal amount of product inside the tubes of each effect. The vapour made in the last effect is condensed on the outside of a tube bundle cooled by raw seawater. Most of the warmer seawater is then returned to the sea, but a small part is used as feedwater to the plant. After being treated with acid to destroy scale-forming compounds, the feedwater passes up the stack through a series of pre-heaters that use a little of the vapour from each effect to raise its temperature gradually, before it is sprayed into the top of the plant. The water produced from each effect is flashed in a cascade down the plant so that it can be withdrawn in a cool condition at the bottom of the stack. The concentrated brine is also withdrawn at the bottom of the stack.

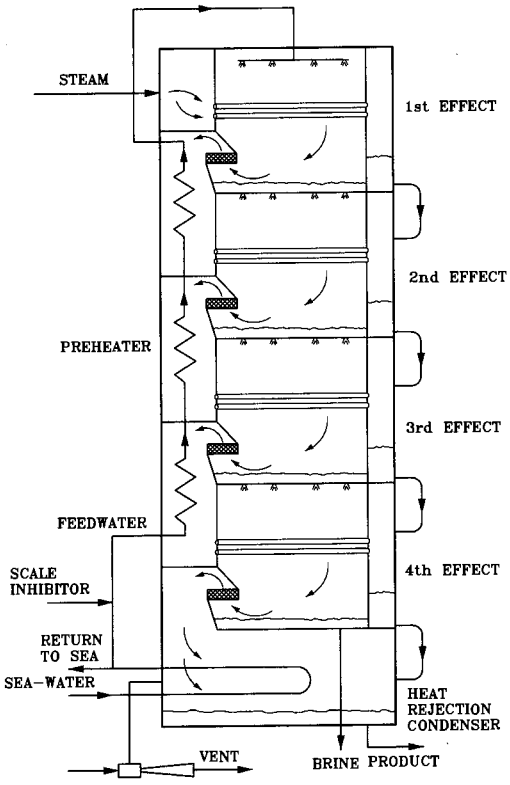

Fig. 1. Schematic of the MES evaporator.

The MES process is completely stable in operation and automatically adjusts to changing steam conditions even if they are suddenly applied, so it is suitable for load-following applications. It is a once-through process that minimises the risk of scale formation without incurring a large chemical scale dosing cost. The typical product purity is less than 5 ppm total dissolved solids (TDS) and does not deteriorate as the plant ages. Therefore, the MED process with the MES type evaporator appears to be the most suitable for use with solar energy.

3.2. The reverse osmosis process

The reverse osmosis (RO) system depends on the properties of semi-permeable membranes which, when used to separate water from a salt solution, allow fresh water to pass into the brine compartment under the influence of osmotic pressure. If a pressure in excess of this value is

applied to the salty solution, fresh water will pass from the brine into the water compartment. Theoretically, the only energy requirement is to pump the feed water at a pressure above the osmotic pressure. In practice, higher pressures must be used, typically 50-80 atm, in order to have a sufficient amount of water pass through a unit area of membrane [4]. With reference to Fig. 2, the feed is pressurised by a high-pressure pump and made to flow across the membrane surface. Part of this feed passes through the membrane where the majority of the dissolved solids are removed. The remainder, together with the remaining salts, is rejected at high pressure. In larger plants, it is economically viable to recover the rejected brine energy with a suitable brine turbine. Such systems are called energy recovery reverse osmosis (ER-RO) systems.

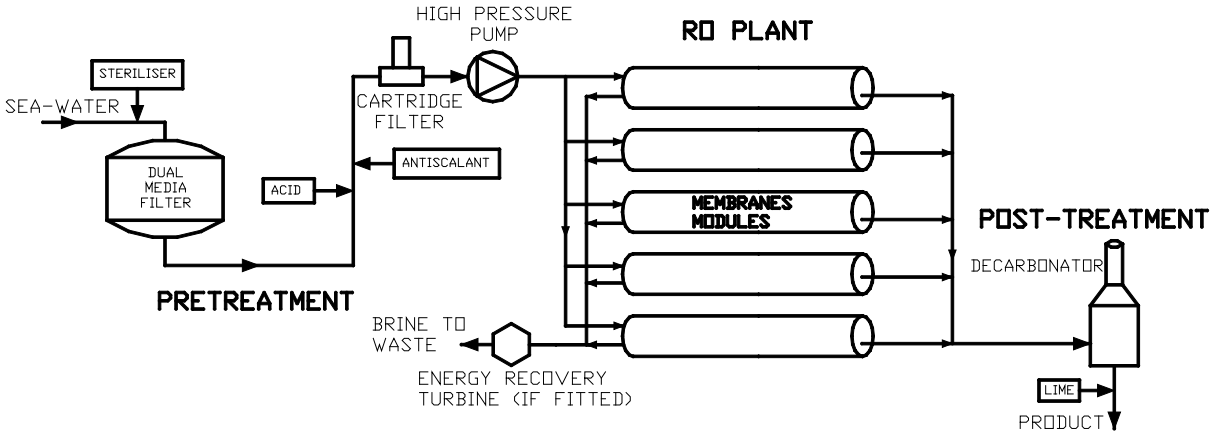

Fig. 2. Principle of operation of a reverse osmosis (RO) system.

Solar energy can be used with RO systems as a prime mover source driving the pumps or with the direct production of electricity through the use of photovoltaic panels. As the unit cost of the electricity produced from photovoltaic cells is high, photovoltaic-powered RO plants are not considered here. The membranes are in effect very fine filters, and are very sensitive to both biological and non-biological fouling. To avoid fouling, careful pre-treatment of the feed is necessary before it is allowed to come in contact with the membrane surface.

3.3. Characteristics of both processes

The identification and evaluation of the renewable energy resources (RES) in an area, is the primary step to be performed when designing a RES-driven desalination system. Such systems should be characterized by robustness, simplicity of operation, low maintenance, compact size, easy transportation to site, and simple pre-treatment and intake system [6].

The energy required for the two desalination processes considered, as obtained from a survey of manufacturers' data, is shown in Table 1 [4]. It can be seen from Table 1 that the process with the smallest energy requirement is RO-ER followed by RO and the MED.

Table 1. Energy consumption of desalination systems.

Process	Heat input (kJ/kg of product)	Mechanical power input (kWh/m^3 of product)	Prime energy consumption (kJ/kg of product)[1]
MED	123	2.2	149.4
RO	-	5-13 (10)	120
ER-RO	-	4-6 (5)	60

Notes: 1. Assumed conversion efficiency of electricity generation of 30%
2. Figure used for the prime energy consumption estimation shown in last column

A comparison of the desalination equipment cost and the seawater treatment requirement, as obtained from a survey of manufacturers' data, is shown in Table 2. The MED is the cheapest of all the indirect collection systems and also requires the simplest seawater treatment. RO although requiring a smaller amount of energy is expensive and requires a complex seawater treatment.

Table 2. Comparison of desalination plants.

ITEM	MED	RO
Scale of application	Small-medium	Small-large
Seawater treatment	Scale Inhibitor	Sterilizer, Coagulant Acid, Deoxidiser
Equipment price (Euro/m^3)	900-1700	900-2500 Membrane replacement every 5-6 yrs
Note: Low figures in equipment price refer to bigger size in range indicated and vice versa.		

4. Options considered

In this section, various options are considered to combine CSP with desalination. The first option considered is a thermal desalination system shown schematically in Fig. 3. In this option a solar field is used which provides thermal energy to a MED evaporator to produce fresh water. This solar heat can be given directly to the MED unit or in days with good irradiation the excess energy can be stored for use in periods of low sunshine and during the night. The system can also be hybridized using conventional fuel to run the desalination sub-system during the night. A very small quantity of electrical energy (compared to thermal) is required by the MED unit to drive the pumps. As the present RES system is thermal only, this quantity of electricity can be produced either from a PV system or obtained from the grid.

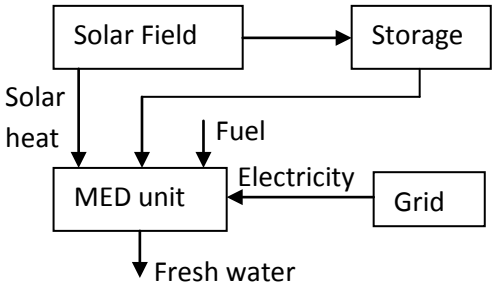

Fig. 3. Combination of a solar thermal system with MED for desalinated water production only.

The second option, shown in Fig. 4, concerns a solar thermoelectric system producing electricity with a CSP system. In this case some of the electricity produced can be used to drive a RO desalination system and the rest is supplied to the grid. This system has the advantage that the operators can decide according to the demand to produced either both, fresh water and electricity, or one of the two only. Any form of hybridization can go directly to the power plant as is normal to all such systems, when the storage is depleted a few hours after sunset, according to the size of the storage used.

The third option, shown in Fig. 5, is a combination of a normal solar thermoelectric power system with a MED unit to produce both electricity and fresh water. The MED requires thermal energy to operate in the form of high temperature hot water (>100°C) or low temperature steam. Therefore, this energy can be supplied either directly from the CSP system or from the waste heat of the power plant system, in the form of condensation heat. For this purpose the MED evaporator can be an integral part of the steam condenser of the Rankine

power plant cycle. In this option the hybridization is done directly on the power plant as is normal to all CSP power systems. The small quantity of electricity required by the MED is taken from the power plant.

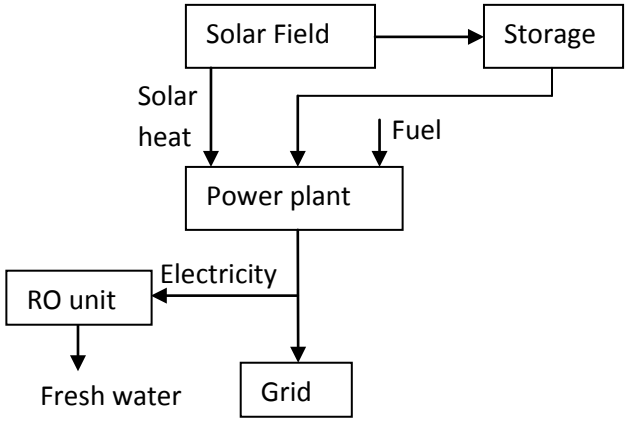

Fig. 4. Combination of a solar thermoelectric power system with RO to produce both electricity and fresh water.

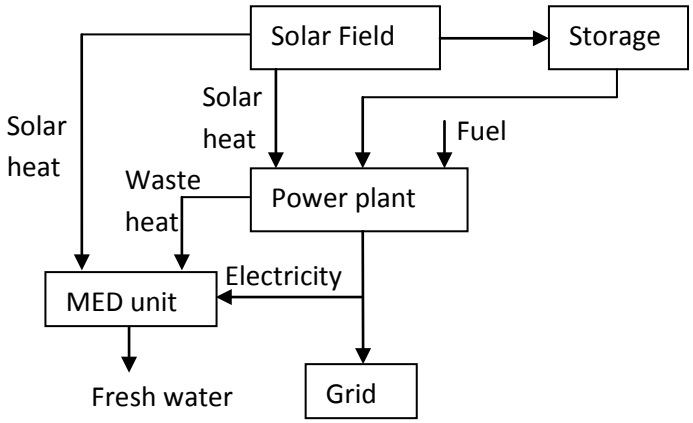

Fig. 5. Combination of a solar thermoelectric power system with MED, operated from solar and waste heat, to produce both electricity and fresh water.

The fourth option, shown in Fig. 6, is a combination of a solar thermoelectric power system with MED and RO systems for fresh water production. The RO unit operates as in the second option with the electricity produced by the CSP system, whereas the MED subsystem, which requires thermal energy to operate, can use either some of the thermal energy produced by the CSP system or the waste heat from the power plant, therefore the MED is part of the condensation system of the power plant. Again here the hybridization is done directly on the power plant as is normal to all CSP power systems. This option gives a larger number of operation options concerning the production of electricity and water according to the demand of each commodity however, it is a more expensive system as both MED and RO need to be purchased and installed.

All CSP systems shown in the above figures can use either a parabolic trough collector or a power tower system. As can be seen from the configurations presented above, there are a number of options to be considered when either only desalinated water or both electricity and fresh water are required. The choice of which system to apply for a particular case should depend on the particular requirements of each commodity and the characteristics of the load and water demand. Due to the high cost of the required equipment however, all systems needs

to be hybridized so as to operate the plants round the clock to reduce the idle time, the energy required to bring the systems to their operating limit and the problems associated with the frequent starts and stops of the equipment and thermal cycling. Before considering any hybridization though, the optimum size of storage needs to be used to minimize the adverse effects of the burning of fossil fuels on the environment. For this purpose a less polluting fuel needs to be employed, like the natural gas.

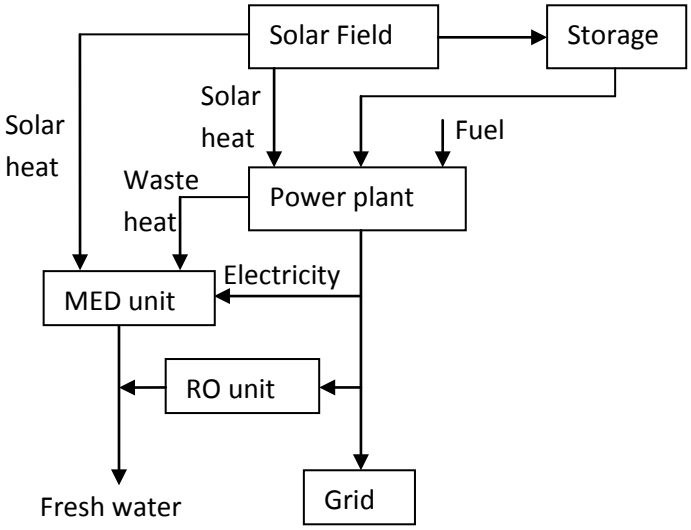

Fig. 6 Combination of a solar thermoelectric power system with RO and MED to produce both electricity and fresh water.

5. Conclusions

The parabolic trough and the power tower systems produce superheated steam which can be used to drive the turbines of the common Rankine cycle. Both systems can be supplied with conventional fuel (usually natural gas) so as to operate during hours of low irradiation and during night-time. For the reasons explained above such a solar plant need to be located near the sea. In such a case the solar plant can be combined with solar desalination to produce fresh water from seawater which is also a precious commodity for Cyprus. As shown in this paper a number of options exist for the combination of a CSP system with a desalination one to produce both electricity and water.

Abstract: Solar energy applications in Iran for supplying domestic hot water, space heating and cooling have been considered severely in last decade. The purpose of this research is to analysis of solar single effect lithium bromide-water absorption cooling system in a typical office building in Tehran. The solar energy is absorbed by heat pipes and stored in an insulated storage tank. This system has been designed to supply the cooling load of mentioned typical office building where the cooling load is 35.17KW (10 tons of refrigerant) which events in July. Results demonstrate that depending on the Tehran climate and the specification of the building by means of optimized design of solar heat pipe collectors, up to 2400 m^3/year Natural Gas energy saving can be reached by use of solar absorption cooling system. Achieving this purpose requires utilizing 16 collectors which everyone compromises 30 tubes with total absorber area of 45 m^2 which is the optimum collector area for this plant in Tehran. According to this replacement the investment payback rate would be 13 years which would be much shorter than the payback time of a solar cooling system combined with conventional all air systems.

1. Introduction

The energy demand for refrigeration and air-conditioning appliances has been increased continuously in last decades. World energy demand-and CO_2 emissions- is expected to rise by some 60% by 2030 respect to the beginning of this century [1]. The cooling load in summer is associated with high solar energy, which offers a suitable opportunity to utilize solar energy for cooling. Conventional vapor compression chillers require high quality energy, electricity which is produced from initial energy resources. Furthermore, vapor compression cooling systems use chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs) as working fluids. These materials will lead to global warming and ozone depletion. Thermal-driven air-conditioning systems are using heat as motive energy to provide cold energy. These systems can be categorized on absorption systems, adsorption systems, duplex rankine, desiccant cooling and ejector refrigeration systems. The heat could be obtained from waste heat sources, combined heat and power technologies (CHP), and solar energy. Lithium Bromide (LiBr)-water absorption cooling systems are conventional in thermal-driven air-conditioning systems and have too many benefits in comparison with other cooling

systems; because their performance is good and cost is low. The single effect LiBr-water absorption systems operate at a generator temperature range 70 to $95\,°c$ and the coefficient of performance (COP) of these systems are between 0.6 to 0.8, which are higher than NH3-H_2O absorption cooling systems [2].

Sparber et al [3] reported that till 2007 there were 81 installed large scale solar cooling systems, eventually including systems which are currently not in operation. 73 installations are located in Europe, 7 in Asia, China in particular, and 1 in America (Mexico). 60% of these installations are dedicated to office buildings, 10% to factories, 15% to laboratories and education centers, 6% to hotels and the left percentage to buildings with different final use (hospitals, canteen, sport center, etc). They also cited that 56 installations are belong to absorption systems and the overall cooling capacity of the thermally driven chillers amounts to 9 MW 31% of it is installed in Spain, 18% in Germany and 12 % in Greece.

Bong et al [4] designed and installed solar absorption chiller in Singapore. The system included 7KW absorption chiller, heat pipe collectors with a total area of 32 m^2, a hot water storage tank, an auxiliary heater and a 17.5 KW cooling tower. They cited that the overall average cooling capacity provided was 4KW, solar fraction of 39% and COP of 0.58.

Balghouthi et al [5] accomplished a simulation using TRNSYS program in order to select and size different components of solar absorption chiller. They reported that solar absorption cooling systems were suitable for Tunisian's condition.

Alizadeh et al [6] simulated and optimized a solar LiBr-water absorption cooling system that has been design for Malaysia using evacuated tube solar collectors. The modeling of the solar absorption chiller was accomplished with TRNSYS program.

Yeung et al [7] designed and installed a solar driven absorption chiller at the University of Hong Kong. This system included 4.7KW absorption chiller, flat plate collectors with a total area of 38.2m^2 , a cooling tower, a 2.75m^3 hot water storage tank and the other equipments. They reported that the collector efficiency was estimated at 37.5%, the annual system efficiency at 7.8% and an average solar fraction at 55%, respectively.

The objective of this work is to evaluate and investigate the energy conservation capacity of a sample office building in Tehran, using solar LiBr-water absorption chiller and heat pipe solar collector. Furthermore, the payback time for initial investments of the system has been calculated.

2. Methodology

A cooling system possessing solar-operated absorption chiller provides the cooling demands for the typical office building in Tehran-Iran. Tehran is located at $35.68\,°N$ and $51.32\,°E$. Figure 1 demonstrates both the variability of ambient temperature and relative humidity and in figure 2 the monthly solar radiation on horizontal surface is demonstrated. The office has a single storey and its floor area is 280m^2. The daily occupancy schedule is from 8:00 to 17:00, totally 9hours and the daily cooling system schedule is considered during June 1 to September 22. The daily average of global solar radiation of Tehran is about $23\,{Mj}/{m^2}$ for the summer months [8]. The major components of the plant are heat pipe solar collectors, a 35.17KW (10 RT) single effect LiBr-water absorption chiller, a hot water storage tank, a cooling tower, a control system and some other auxiliary equipments.

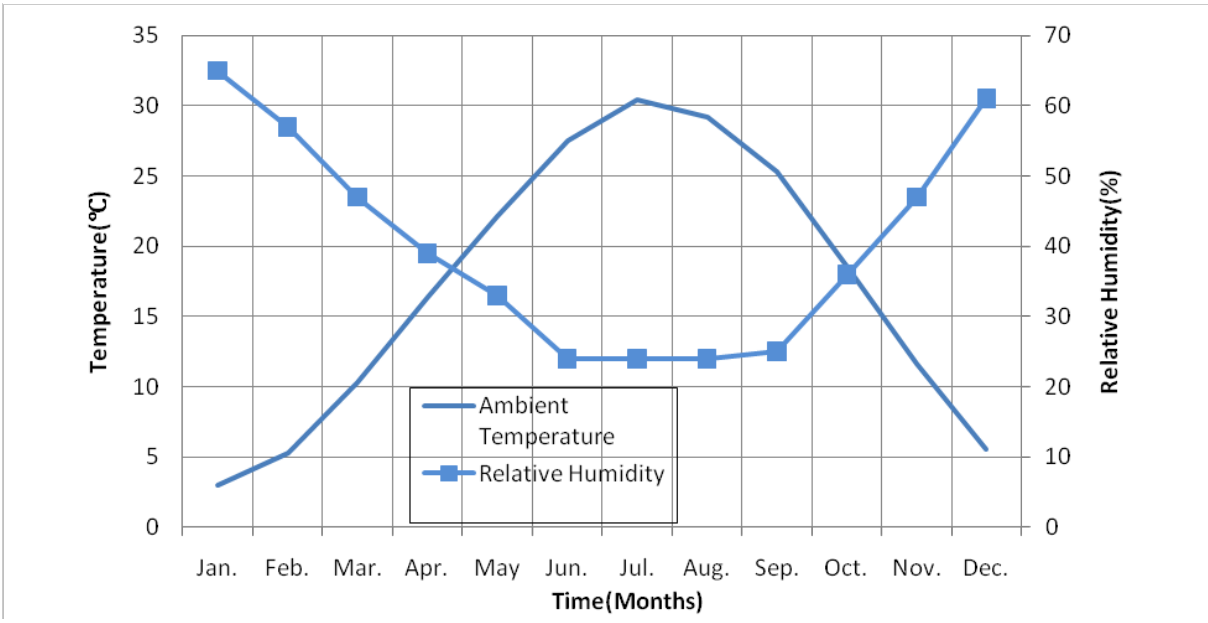

Fig. 1. Variability of ambient monthly temperature and monthly relative humidity for Tehran.

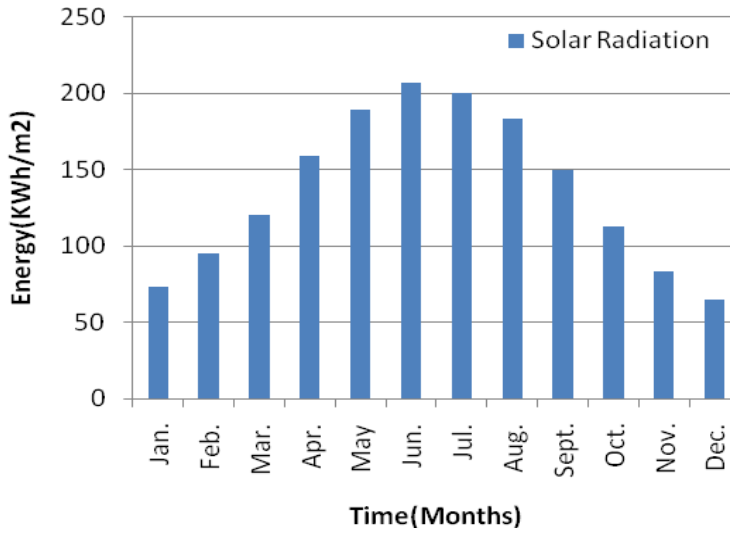

Fig. 2. Monthly solar radiation on horizontal surface in Tehran.

2.1. Solar Energy

The plant primary energy source is the solar energy, which is absorbed by heat pipe solar collector and stored in an insulated storage tank. Heat pipes are widely used for heat recovery and energy saving in various ranges of applications because of their simple structure, special flexibility, high efficiency, good compactness and excellent reversibility [9]. The heat pipe vacuum tube collects heat from the sun at high efficiency. It is important that heat pipe solar collectors must be installed with a tilt of at least $25°$. They operate like a thermal diode where the flow of heat is in one direction only [10]. This type of collector commonly filled with alcohol or water in a vacuum and operates in two versions, one with a dry and one with a wet connection [11]. The most important difference between evacuated tube solar collectors and heat pipe solar collectors is that the heat carrier fluid inside of the copper heat pipe is not connected to the solar loop. The heat pipe collectors are mounted on a roof and tilted by $25°$ with the roof to utilize more radiation in summer and it is produced by APRICUS.

2.2. Absorption chiller

A water fired chiller (WFC) with a related capacity of 35.17KW cooling (10RT) produced by YAZAKI when it is operating at a hot water driving temperature of $88°c$, coolant water temperature of $31°c$ and output chilled water at $7°c$. The coefficient of performance (COP) of this chiller is 0.7 as reported by the manufacture.

2.3. Presentation of parameters

The thermal capacity of the equipments is determined by Eq. (1):

$$Q = \overset{\circ}{m}.c_p.\Delta T\,, \tag{1}$$

Where $\overset{\circ}{m}$ is the mass flow rate, c_p is the specific heat at constant pressure and ΔT is the temperature difference.
The energy during a fixed period is determined by Eq. (2):

$$E = \int_{ti}^{to} Q dt\,, \tag{2}$$

Where t_i is initial time and t_o is final time. Afterwards, the efficiency of solar collectors is obtained by Eq. (3) [2]:

$$\eta = \frac{q_u}{\overline{R}.\overline{H}}\,, \tag{3}$$

Where q_u is the useful energy output of a collector per square meter, $\overline{H}$ is monthly average daily total solar radiation on a horizontal surface. It should be noted that the efficiency of solar heat pipe collector is about 63% as reported by the manufacture. $\overline{R}$ is the proportion of monthly average total radiation on tilted surface on the monthly average total radiation on horizontal surface which is determined by Eq. (4) [2]:

$$\overline{R} = \left(1 - \frac{\overline{H_d}}{\overline{H}}\right)\overline{R_b} + \frac{\overline{H_d}}{\overline{H}}\left(\frac{1+\cos\beta}{2}\right) + \rho_g\left(\frac{1-\cos\beta}{2}\right), \tag{4}$$

Where $\overline{H_b}$ is monthly average daily beam solar radiation on a horizontal surface, $\overline{H_d}$ is monthly average daily diffuse solar radiation on a horizontal surface, ρ_g is the diffuse reflectance of the ground and β is the slope of the collector, $\overline{R_b}$ is the ratio of the average daily beam radiation on the tilted surface on that on a horizontal surface which is determined by Eq. (5) [2]:

$$\overline{R_b} = \frac{\cos(\phi-\beta)\cos\delta\sin\omega_s' + \left(\frac{\pi}{180}\right)\omega_s'\sin(\phi-\beta)\sin\delta}{\cos\phi\cos\delta\sin\omega_s + \left(\frac{\pi}{180}\right)\omega_s\sin\phi\sin\delta} \quad (5)$$

Where ω_s' is the sunset hour angle for the tilted surface for the mean day of the month and ω_s is the sunset hour angle, which are obtained by Eq. (6) and Eq. (7) [2]:

$$\omega_s' = Min\begin{bmatrix}\cos^{-1}(-\tan\phi\tan\delta)\\ \cos^{-1}(-\tan(\phi-\beta)\tan\delta)\end{bmatrix} \quad (6)$$

Where φ is the latitude and δ is the solar deviation angle.

$$\omega_s = \cos^{-1}(-\tan\varphi\tan\delta) \quad (7)$$

3. Results

3.1. Determining the optimum solar collector area

With calculating $\overline{R}$ through equations 4 to 7, the useful energy output of a collector is determined. Figure 4 demonstrates the monthly energy derived from one square meter of collector in Tehran. The surface area for the heat pipe collector is determined by the proportion of the required energy for cooling the environment on the useful energy output of the collector.

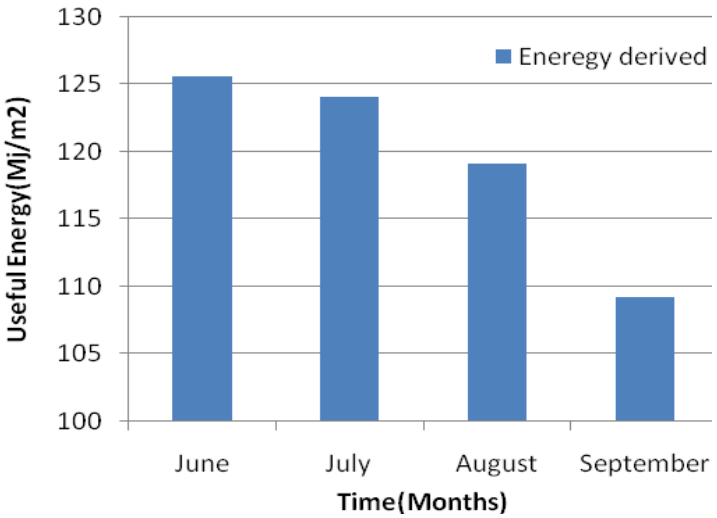

Fig. 3. Monthly energy derived from one square meter of collector in Tehran from June to September

Optimized solar collector area depends on some important factors such as: Solar radiation, intensity, cost increasing and amount of consumption [12]. To estimate the optimal surface of heat pipe solar collector, we should determine the solar cooling fraction (SCF). The solar cooling fraction is described as the ratio of solar heat yield to the total energy required to drive solar absorption chiller.

Finally, the optimum surface of heat pipe collectors for typical office building in Tehran is determined in each situation as presented as figure.4.

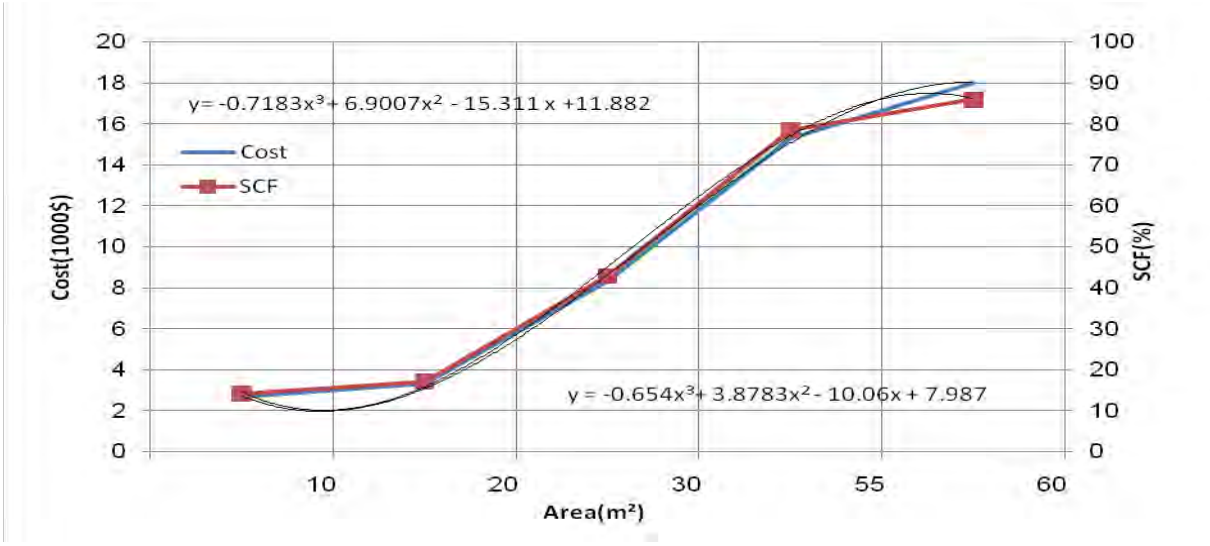

Fig. 4. Estimation of optimum solar heat pipe collectors for typical office building in Tehran

3.2. Economic analysis

Solar systems are commonly known by high investment and low operating cost. In order to estimate the payback time, total annual energy saving must be determined.
The payback time is determined by Eq. (8) [13]:

$$PB = \frac{\log\left[\frac{C}{E}.\frac{i}{100}+1\right]}{\log\left[1+\frac{i}{100}\right]} \qquad (8)$$

Where C is the capital cost of installed solar cooling equipment, E is the energy saving, i is the energy inflation and PB is the payback time.

The cost of equipments are summurized in table 1 and the cost of energy is shown in table 2.

Table 1. Cost of equipments

Equipment	Cost
LiBr-H_2O Absorption chiller	500 \$/KW
Heat pipe solar collector	278 \$/m^2absorber area
Auxiliary heater	50 \$/KW
Storage tank	790 \$/m^3
Cooling tower	65 \$/KW

Table 2. Cost of Energy

Energy	Cost
Electricity	0.330 \$/KWh
Oil	1.580 \$/t
Natural Gas	0.40 \$/m^3(2010)

Furthermore, during the economic analysis some basic assumptions are needed, such as maintenance costs, installation costs, the energy inflation and natural gas heating value. The maintenance costs are 1% of investments cost [13], installation costs are 12% of the equipment costs [14], the energy inflation is about 2% [5] and natural gas heating value is about 38376 Kj/m^3.

Consequently, the total energy and money saving are shown in table 3.

Table 3. total energy and money saving

Annual energy saving (MWh)	Annual money saving ($)	Annual natural gas saving (m^3)
25.5	960	2400

Thus, with calculating PB through equation 8, the payback time is estimated approximately 13 years which would be reasonable for solar cooling systems.

4. Conclusions

In this investigation the technical and economical analysis for single effect LiBr-water solar absorption system was done. The analysis was accomplished for a typical office building in Tehran. The plant provided air conditioning for a floor space of 280m^2. Furthermore, the plant included an auxiliary fossil system and its capacity was about 13KW. The most important advantage of this system is that it offers the highest environmental benefits. The other advantage is that we utilize the highest total energy saving.

It was shown that the solar cooling fraction for mentioned office building was 64.3% and the optimum solar heat pipe collector area was 45m^2. It means that this plant utilizes 16 collectors which everyone compromises 30 tubes. Finally, the payback time of this plant was estimated about 13 years.

Abstract: Various projects have been developed to use solar energy and some of them are in the course of developing all around the world. In Iran a 250 kW pilot solar power plant is constructed using parabolic trough collectors from 2001 to 2006. Results of thermal tests of the plant leads to the generation of steam with 250 ^{o}C temperature and 2 MPa pressure. Based on several years of experiments (from 2006-2010) it is decided to expand the solar thermal power rate to produce 500 kW electricity by combining the present system with a larger size collector and an auxiliary boiler. This article, explains the thermal design of the new collector and then various design options for combination of the new collector to the present plant have been studied and the most practical method of producing 500 kW is selected applying first law of thermodynamics utilizing a hybrid system.

1. Introduction

One of the most important problems for industrial countries in the upcoming decades is the replacement of fossil fuel energy sources with renewable energy technologies. Environmental pollutions, increasing price rate of fossil fuels and their limited sources has led to the development of new design and concepts for their replacement with cheap and available environmental friendly energy sources. Among them solar energy is one of the most important and available source of renewable energy all around the world and especially in Iran. The use of solar energy is daily growing in different fields such as generation of electricity [1]. In Iran several projects are defined to use this source of energy along with other countries of the world [2]. Among them, Shiraz solar Thermal Power Plant (STPP) is the first parabolic trough solar power plant constructed and tested successfully at Fars province at south of Iran. After the basic design and simulations [3-4], construction, installation and start-up of this power plant has been done to produce superheated vapor. For this plant different studies and simulations are made to find the overall performance of the plant [5-11]. Table 1 shows general specifications of the 250 kW STPP(Refer to [12] for more information on existing system operation).

After the successful` testing of this parabolic solar power plant (from2006-2010), it is decided to promote the system with advanced technologies and use an advanced parabolic trough collector for steam generation. This is made by beginning the constructing and installing a new parabolic trough collector with larger dimension and combining it with the existing system while increasing the power rate to 500 kW. The existing 250 kW Shiraz solar power plant, having been successfully tested for steam generation, uses old design, small parabolic trough collectors. Achieving the technology of parabolic trough collectors in the 250 kW power plant the following decisions were made:

1- Design and construction of a new collector, in the same dimensions as used in the new solar power plants of the world (such as Andasol plants).
2-Electicity generation

Table 1. Specification of 250kW Shiraz solar thermal power plant

Capacity	250 kW	Electricity generation System	Turbine+ Generator
Collectors Type	Parabolic Trough	Collector's Field Inlet Oil Temperature	231°C
No. of Collectors	48	Collectors Field Outlet Oil Temperature	265°C
Collector's Dimension	25×3.4 m^2	Oil Mass Flow Rate	13.7 Kg/s
Collectors' Driven System	Hydraulic	Steam Mass Flow Rate	0.673 Kg/s
Collector's Structure	Truss with Torsion Bar	Generated Steam Temperature	250°C
Heat Transfer Fluid	Thermal Oil	Generated Steam Pressure	2 MPa

These steps would lead to an increase in power plant capacity from 250 kW to 500 kW and at the same time design and construction of a new collector in length of 94 m and aperture width of 5.27 m. The main problem in the way of developing the power plant (except for the cost increase due to low capacity of turbo-generator system and high price of electricity generated) id the method of combining the new collector with the existing system. Due to the high operating temperature of the new collector compared to the existing system, optimal usage of the absorbed heat is the most important issue in the process of combining the two system of heating the old cycle primary fluid (oil) or its secondary fluid (superheated steam) or a combination of the two above. In addition to the above mentioned issue, the next step would be the selection of the appropriate turbo-generator considering the efficiency and price at the same time. Some explanations in this regard will follow. The most important equipment in the existing plant include the parabolic trough collectors field, heat storage and expansion tanks, three heat exchangers, deairetor and etc. To achieve the 500 kW power generation the equipment that shall be added to the system would be the new 100m collector, turbo-generator, storage and expansion tanks, fossil fuel boiler and condenser. In the following sections further explanation and results of thermodynamic analysis of the new design system are presented.

2. Design of new parabolic trough collector

After preliminary assessments [12] it was decided to construct and install a new collector and increase the capacity of the plant from 250kW to 500 kW. Based on these available technologies the design of the new collector of Shiraz solar power plant is made by following steps:

1-Thermal and thermodynamic design of collector
2-Design of structure and hydraulic system
3-Design of control and tracking system

2.1. Thermal design of Shiraz thermal solar power plant (STPP) with new collector

For thermal design and simulation of the new collector a program has been developed with Matlab software [13]. This program takes some primary data into account such as collector rim angle, optical properties of the mirror like its thickness and reflectance coefficient, errors in construction and installation of the collector, temperature of inlet and outlet of oil from the collector, temperature rise in the collector, date and day of design and its relevant data such as cloud factor, wind speed and ambient temperature, geographical location of the design point

and length of the collector. Some other information for the receiver tube such as absorbtivity coefficient of the tube, transmisivity coefficient of the glass tube, thickness of the glass cover tube and its diameter would be considered as input data to this program. The input data screen of software is shown in Fig.1.

Fig. 1. Data input of developed collector design software

The output of this simulation program include the total optical error, concentrating ratio, direct radiation (based on Daneshyar model[5]) effective length , oil mass flow rate, optical and thermal efficiency, heat loss and heat absorbed in each m^2 of the receiver tube surface. The allowable total error for the design of collector is calculated based on [14].

Collector design is based on Rabl et al. [15] procedure. The details of calculation procedure are explained in [13]. The thermal design of the collector is made for September 23rd at in the noon time for Shiraz (with latitude of 29.53°). Solar radiation is modeled from [5] relations, wind speed is assumed to be 7 m/s and ambient temperature is considered 30^{o}C. Regarding the limitation of construction of collector structures hydraulic system and etc it is decided to construct a new collector parallel to the existing field of collectors, therefore the length of new collector is considered to be 100 m equal to the available space in the field. Results of calculation and specifications of the new collector of Shiraz solar power plant is presented in Table 2.

3. Combining the new collector with present system

The next step after designing the collector is to combine the collector to the present system showing in Fig 2. Regarding the differences between the oil used in the present collectors field (Behran thermal oil) and the new collector (VP1) and also the higher oil temperature of fluid in the new collector, combining the new collector to the present system need some considerations such as the transferring the absorbed heat in new collector to the secondary

fluid (the oil in the present cycle or produced steam), selection of turbine type, new control philosophy, etc. Therefore it was decided to study the two important issues of the new cycle:

1- The way of using the absorbed heat (either transmitting the absorbed heat to the steam in order to superheat it or to heat the oil or a combination of these two).
2- Selecting the exhaust pressure of steam turbine.

Table 2. Specifications of the new collector of Shiraz solar power plant

Input Parameters

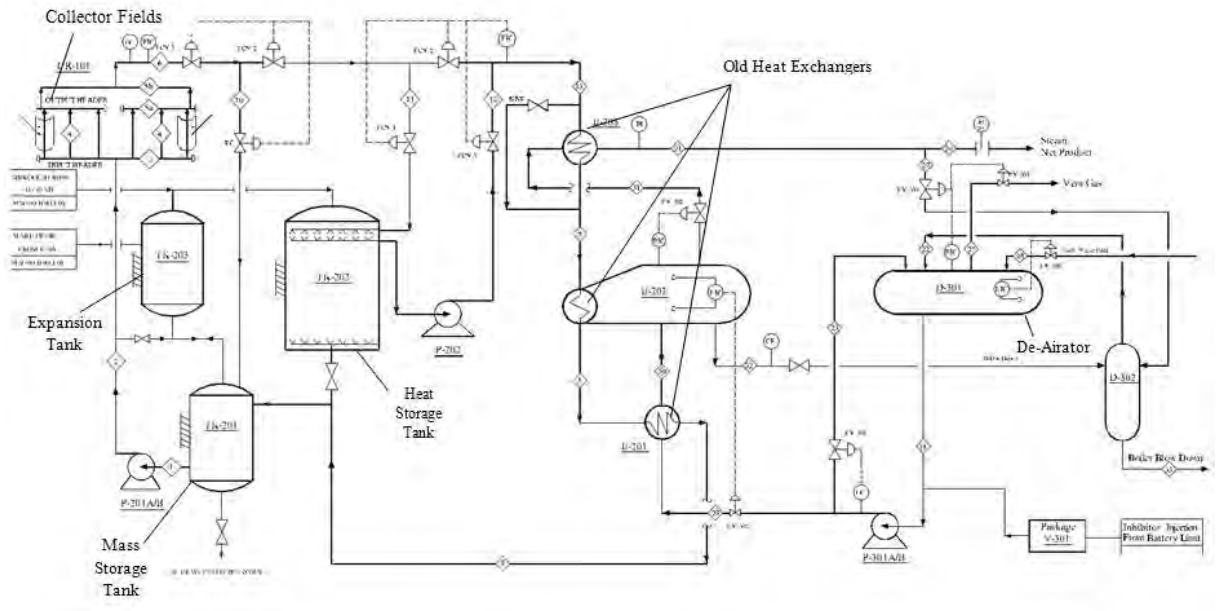

Fig. 2. The present PFD (Process & Flow Diagram) of STPP

Regarding the above objects, thermal design of the integration is made for two cases A and B. In case A, it is assumed that all the heat absorbed by the new collector would be transferred by an exchanger to heat generated steam in the present cycle and generated steam in the boiler, that leads to temperature rise of operating fluid in the new cycle. The heat absorbed will consequently lead to increasing steam temperature which leads to producing more electricity. In case B, the assumption is that a part of the heat absorbed in the new collector would be used to increase the temperature of superheated steam from the existing system and the rest of absorbed heat is used for heating up the outlet oil of existing collector field in order to increase the steam mass flow rate and consequently increasing the electricity generation. In this case 120 kW of the absorbed heat in the new collector is transferred to raise oil temperature and the rest (about 80 kW) will be used for superheating the generated superheated steam in the present cycle.

For each of the above cases 3 turbine outlet steam pressures of 100 kPa , 25kPa (using back pressure type turbine) and 10 kPa (using condensing type turbine) has been considered and the thermodynamic analysis for each case is carried out separately.

Considering the goal to produce 500 kW electricity power from the combination of the present plant and the new system, it is decided to add an auxiliary boiler to the system in order to compensate the superheat steam for generating 500 kW electricity and to provide possibility of using the power plant at night time. Fig. 3 shows results of thermodynamic analysis and condition for various cases studied. The estimated capacity for each equipment in each condition are provided in this table.

CASES		Farm Generated Steam			Boiler						Turbine				Condenser
		Temp (°C)	Press (kPa)	Flow rate (kg/h)	Working Capacity (kg/h)	Installed Capacity (kg/h)	Boiler load (%)	Press. (kPa)	Temp. (°C)	Considered Shaft Power (kW)	Inlet Press. (kPa)	Inlet Temp. (°C)	Exhaust Pressure (kPa)	estimated steam consumption (kg/h)	Duty (kW)
CASE A	100 kPa	250	2130	2399	3112	6000	52	2130	237	532	2100	294	100	5490	3429
	25 kPa	250	2130	2437	1951	5000	39	2130	215	532	2100	294	25	4095	2605
	10 kPa	250	2130	2486	1466	4500	33	2130	215	532	2100	294	10	3566	2286
CASE B	100 kPa	294	2130	2573	2912	6000	49	2130	294	532	2100	294	100	5467	3409

Fig.3. Results of calculators for the 6 primary plans cases

4. Selection of the appropriate plan

After considering the primary plans and the economical evaluation, one of the plans should be selected as the design plan. Each plan has some advantages and disadvantages. A list of the most important ones are summarized in Table 3.

The next step to choose a proper plan based on cost and other parameters. The most expensive equipments are condenser, turbine and boiler. Price quotations are gathered from local and international manufacturer for these three equipments. The relative cost with respect to case A of 100 kPa turbine outlet pressure is presented in Table 4.

Table 3. Results Advantage and disadvantages of case A and B

Case	Advantages	Disadvantages
A	Higher thermodynamic efficiency for exhaust pressure of 10 kpa Lower expenses due to use of a single heat exchanger Shutting down of present collectors there will be a possibility of using the heat absorbed by the new collector Boiler working at a lower temperature Lower boiler loss for lower exhaust pressures.	Dependency of electricity generation on the solar part Impossibility of complete heat absorption of the new collector in the system Impossibility of separating contribution of solar part & fossil fuel part power generation Un-available of the new collector, steam for turbine would not be at design condition Lower performance of one exchanger compared to two exchangers Impossibility of the new collector operation without boiler for produce power
B	Possibility of performance tests of new collector without boiler Equal importance of solar part and fossil fuel part Independency of solar and fossil fuel parts Possibility of electricity generation in case of an availablity of solar part Possibility of electricity generation with lower capacity in case that new collector is out of service Better performance of two exchangers compared to one exhanger Lower capacity of boiler in the exhaust pressure of 25 Kpa	Two heat exchangers needed Complicated control system With shutting down of present collectors field the new collector can be used to heat the oil in collectors field

Table 4. The relative cost of the new cycle for various cases

Case	Boiler	Turbine	Condenser	Total
A (Pout=100 kPa)	1	1	1	1
A (Pout=25 kPa)	0.8704	2.5129	2.0218	1.8140
A (Pout=10 kPa)	0.8055	2.5086	0.5523	1.4142
B (Pout=100 kPa)	1	1	1	1
B (Pout=25 kPa)	0.8704	2.5129	2.0218	1.8140
B (Pout=10 kPa)	0.8055	2.5086	0.5523	1.4142

One of the most important issue to be addressed before selection of a proper case is the type of condenser needed for the 3 exhaust pressures of the steam turbine. According to the estimations and calculations for turbine with 100 kPa and 25 kPa exhaust pressure the condenser needed could be air cooled type condenser, whereas for 10 kPa exhaust pressure, the condenser should be water cooled type. In case of using water cooled type condenser water a significant amounts of will be vaporized in the cooling tower.

According to Table 5, for the 3 items (turbine condenser and boiler) for each case A and B the final cost. A direct function of turbine price and consequently the boiler and condenser. Therefore it is observed that for both cases A and B for the different exhaust steam pressure the final cost is equal but regarding Fig. 3 the load of boiler in case of 10 kPa exhaust pressure is less than the case of 25 kPa exhaust pressure. In the same manner less than 100 kPa steam exhaust pressure, which would lead to lower fuel consumption and less fuel cost in the long term. But it must be mentioned that the weakness of 10 kPa exhaust pressure in comparison to the two other exhaust pressures is the requirement of water to cool the exhaust steam from turbine. Calculations show that the consumption of water in the power plant with capacity of 500 kW would be approximately 6.8 m^3/hr. Due to the great limitations of water in the present plant location and for most part of Iran the case B with an exhaust steam pressure of 25 kPa has been selected as the final plan. This is due to relatively higher efficiency, lower water consumption and lower risk with air cooled condenser in spite of higher final cost. Fig. 4 shows the PFD (Process Flow Diagram) of the selected plan.

5. Conclusion

For Expansion of STPP the case B with exhaust turbine of 25 kPa is selected based on following advantages:

1-The selected power plant configuration has lower water consumption, which is critical for the arid region of Iran. This will be more economical to install large plant in the semi-arid region of Iran with no available water sources.
2-In the selected configuration, lower fossil fuel needed for generating 500 kW electricity energy (because of lower boiler load).
3-Solar and fossil part of the plant can operate and be assessed separately.
4-Performance of new designed collector can be measured during normal operation of the plant or individually.

Abstract: In this paper the physics of linear receivers is analyzed. This analysis is oriented to evaluate the dependence of the thermal performance of the receiver on the characteristics of the concentrated solar radiation. It will be seen that two thermal regimes can be distinguished in that dependence, what will point out the need of studying at depth the features of systems with moderate concentration factors.
A fundamental question can be formulated as follows: what is the concentration factor required for obtaining the best solar energy exploitation within a design window established by some technical constraints?
In this performance analysis it has been found that moderate concentration factors (about 20 to achieve 400ºC) can be close to optimal in a cost benefit analysis, taking into account temperature constraints. Beyond these values, thermal and exergetic efficiency curves advice to limit the concentration factors to values that could be achievable by linear Fresnel reflecting collectors, avoiding mobile parts such as ball-joints or flexible joints that could be important leak-points, as well as metal-glass welds, which are another cause of failure in trough collectors

1. Introduction and background

One of the most critical decisions in the design of a solar thermal power unit is the choice of the radiation concentration geometry [1] [2], which is in turn connected with the thermal flux needed in the receiver for fulfilling the objectives of the plant. In this context, technical coherence is a major word. In particular, if a high value is chosen for the concentrated radiation thermal flux, the global heat transfer coefficient of the transfer from the receiver surface to the heat carrier fluid must have a similarly high value [1] [2]. Otherwise, the temperature difference between the receiver and the fluid would be very large, which would enhance thermal losses from the receiver. Besides that, large temperatures differences between different parts of the receiver will convey important differential dilation effects, which can be a major cause of concern in the durability of a solar power collector.

There are two main approaches for concentrating solar radiation [1] [2]:

- Parabolic troughs [3] and linear Fresnel concentrators [4], with one axis tracking.
- Revolution parabolic disks and central tower receivers [1], with a two axes tracking system.

The latter is out of the scope of this article, aimed at analysing the thermal features of linear technologies. The receivers involve a long pipe (or a set of parallel pipes, in a general approach) with a selective coating [5] covering its absorbing surface, i.e., the surface where the concentrated solar radiation impinge. This coating is chosen for having a high absorptivity to solar photons and a low emissivity for photons of the planckian spectrum at similar temperatures to the working ones in the receiver.

Inside the tube, the heat carrier fluid circulates from one end to the other. In most of the cases, collectors are placed in a parallel lay-out, with a high pressure header for distributing the fluid from the central block of the plant (the BOP) and a low pressure header that collects the streams of all the parallel solar receivers and sends the total hot stream into the BOP.

A third line of solar power plant configuration can be cited, the Solar Boiler [6], which is based on a central tower, but without a single central receiver in the top of the tower. The receiver is a bundle of tubes going up along the wall of the tower. This set of tubes can be considered as a linear receiver, although radiation would be concentrated by reflection from a field of heliostats very similar to the central receiver case.

The selective coating is the radiation absorbing element, and it is the component reaching the highest temperature. The useful heat is carried by the fluid and its actual exergy value will depend on the temperature achieved when it leaves from the collector. In some applications, boiling inside the receiver tube is considered, and the steam title will also be a relevant parameter. In general, the increase in specific enthalpy and the mass flow are the variables characterizing the heating of the fluid. In this context, two energy balances must be taken into account: the overall heating of the fluid, which is equal to the total energy transferred from the absorbing surface to the heat carrier fluid, and the detailed heat transfer balance, which depends on the temperature map attained in the collector due to the transmission processes among the components of the collector, with two main results:

- Heat transfer to the carrier fluid, which is the basis of the overall energy balance
- Losses to the environment, mainly through convection to air and radiation to the surroundings

Heat transfer to the carrier fluid depends on its velocity. The convection coefficient between the tube and the fluid can be increased by increasing its speed, but this fact has other effects, as an increase in pressure drop and pumping power [7] [8]. For liquids, this effect can be of second order as compared to the thermal problem. For gases, the mechanical problem can be as important as the thermal one, and the pumping power needed to keep the gas flow at the level required by the thermal requirement, can be as large as the power collected from the sun, what makes the plant useless.

Another important point in the design of the system is the actual limitations in the temperature of the different components. This is the case of the selective coating, which sets up a ceiling to the maximum temperature allowed in the collector. Coatings resisting 500 ºC without degradation are commercially available, but this is not usually the binding limitation, because in current trough-collector power plants, the most popular heat carrier fluid is synthetic oil, such as Therminol VP1 and the maximum working temperature is below 400 ºC.

Those limitations in temperature convey similar limitations in the maximum thermal flux impinging on the receiver, and therefore in the concentration factor. Nevertheless, those

limitations in the temperature of some materials have to be assessed in the full analysis of the system. If it is effective in transferring the heat to the carrier fluid, and the flow is large enough for guaranteeing a controlled heating, all temperatures will be within the corresponding limits. However, this guarantee relies on the proper circulation of fluid, and it embodies the afore-mentioned problem of the required pumping power.

This coupling of thermal and hydraulics constraints can be characterized in the case of linear collectors, to identify optimum solutions in some design windows, particularly aimed at reducing the cost of solar power plants. This optimization process will embody an exergy analysis of a system featured by the working temperature reached by the heat carrier fluid.

2. Methodology: A linear collector model

There are detailed physical and numerical models to calculate trough collectors and reflection Fresnel devices [6] [9] [10]. They are particularly useful to feature a power plant in nominal conditions, which include the set of variables to define the calculation of the collector for the reference conditions chosen as nominal ones, and they can also be used for integrating the performance along the year.

The model used for this study works in similar form to that used in Muñoz et al [6], but does not take into account neither the way used for concentrating the solar radiation, nor the natural aperture of the sun beams, which is an important factor when the concentration geometry involves large distances.

This model can be described as a lumped-parameters representation of the collector. It includes an expression for featuring the useful heat, which is associated with a temperature in the carrier fluid at the collector outlet. The model can be used for investigating the relative importance of some parameters, or equations coefficients, and for identifying relevant trends in the evolution of the system when the boundary conditions change, including the change in the concentration of solar radiation.

The simplicity of the model does not allow using it for designing purposes, or for optimizing a system, but the model is easily followed, unlike many computational codes, which are managed as black boxes. The model is based on the equations listed below, and it can be used to feature general trends in the behaviour of the linear receivers. It is obvious that some hypotheses can not be kept in detailed computations, which are needed for calculating a given design in specified conditions.

The model is an integrated energy balance where the impinging radiation on the receiver goes to useful heat or to thermal losses (convection through the air and radiation to the background). Both thermal phenomena involve several heat transfer mechanisms, but they can be lumped into a single step, expressed in terms of the difference between relevant temperatures, and they include a coefficient, to which an effective value must be assigned. Those values can be estimated from previous detailed calculations of similar systems or from the bibliography. Moreover, sensitivity calculations can easily be carried out by varying those values and other parameters characterizing the boundary conditions.

Four temperatures are sufficient to define the model:

- The temperature T_c of the absorbing surface (selective coating) where the concentrated radiation impinges. It represents an average value of the coating temperature

- The temperature of the heat carrier fluid as an average value as it is heated along the receiver, T_f
- The bulk temperature of the air, T_a
- The temperature of the background radiation or environment, T_{env}. It can represent either the temperature of the earth's surface, T_{grnd} , or the temperature of the high atmosphere [1][11], T_{sky}, each one being affected by their corresponding view factor from the receiver (detailed analysis of this matter demonstrates that for the considered values this dependence has no r elevant effect on the results)

Additional parameters of the model are the following ones. (Values assumed for the first set of calculations are given within brackets.):

- DNI = direct normal irradiation (1 kW/m^2)
- C_f = concentration factor (variable)
- ε = selective coating emissivity (0.1)
- α = selective coating absorptivity (0.9)
- U = global coefficient for convection losses (8 W/m$^2\cdot$K)
- h = g lobal coefficient for heat transfer from the absorbing surface to the heat carrier fluid (2 kW/m$^2\cdot$K)

In general, for all calculations the boundary conditions temperatures are:

- T_{air} = 25 ºC (=298 K)
- T_{grnd} = 25ºC (=298 K)
- $T_{sky} = 0.0552\cdot T_{air}^{1.5}$ [K] [11]

The model is defined by the following equations:

$$Q_{sun} = Q_{conv} + Q_{rad} + Q_{use} \quad (1)$$

$$Q_{sun} = C_f \cdot \alpha \cdot DNI \quad (2)$$

$$Q_{conv} = U \cdot (T_c - T_{air}) \quad (3)$$

$$Q_{rad} = \varepsilon \cdot \sigma \cdot (T_c^4 - T_{env}^4) \quad (4)$$

$$Q_{use} = h \cdot (T_c - T_{use}) \quad (5)$$

The absorbed energy and losses that are produced by convection and radiation, adding the cooling effect of the heat transfer fluid (thermal oil) determines the temperature level and the energy efficiency in the receiver itself that can be given, in function of the enthalpy increase in the heat transfer fluid (Q_{use}) by:

$$\eta_{th} = \frac{Q_{use}}{Q_{sun}} \quad (6)$$

Thermal efficiency is not sufficient to characterize a s ystem designed to yield useful work against the environment: we also use the exergetic efficiency (η_{ex}) that take into account the

required blower power (W_b) with $\eta_{th\rightarrow e}$ is the conversion efficiency from thermal to electrical energy, evaluated as 33% [6]:

$$\eta_{ex} = \frac{Q_{use} - W_b / \eta_{th\rightarrow e}}{Q_{sun}} \cdot \left(1 - \frac{T_a}{T_{use}}\right) \quad (7)$$

3. Results

This physical model has been applied to some simplified cases with the coefficients already given (first series of calculations) and the results are depicted in Fig. 1 and Fig. 2. It is worth commenting on the shape of the efficiency curve (thermal and exergetic), with two branches that are associated to two thermal regimes: a first branch with rapid increase in efficiency, followed by an almost horizontal second branch, where the heat transfer process from the collector's absorbing surface to the heat carrier fluid is saturated, and the efficiency value reaches a maximum value. A threshold can be marked as the beginning of the second regime. This threshold can be featured by the value of the slope of the curve, or by the relative value to the asymptotic level of the efficiency. In the case 400ºC of fluid temperature the threshold of the second regime can be marked around a concentration factor of 20. If the fluid temperature is 300 ºC, the threshold in the concentration factor is about 15. With a fluid temperature of 1000 ºC the threshold is at 70.

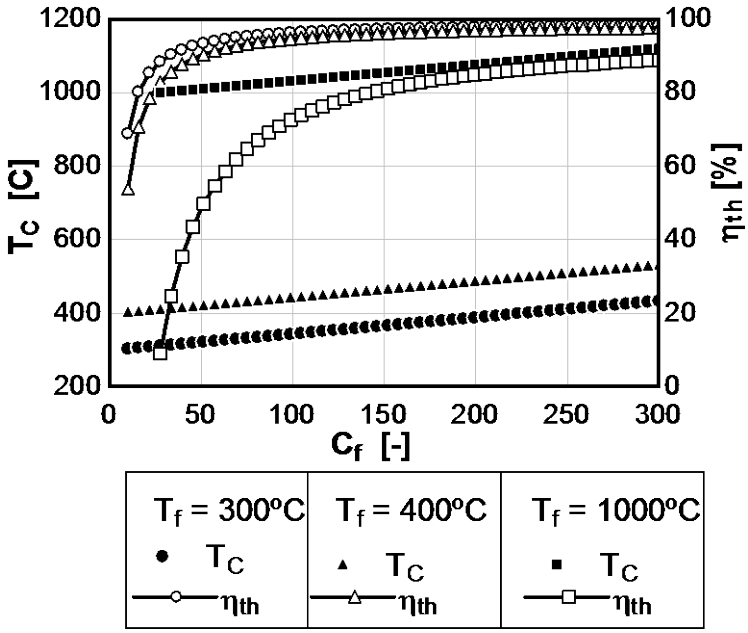

Fig. 1. Collector thermal efficiency and absorbing surface temperature Vs. concentration factor, for three values of T_f: 300 ºC, 400 ºC and 1000 ºC. The global coefficient for heat transfer from the absorbing surface to the fluid, "h", has a value of 400 W/m^2·K

It should be noted as well that the collector's absorbing surface temperature increases linearly with the concentration factor. This effect is influenced by some obvious limitations, because all materials, from the selective coating to the heat carrier fluid, have maximum operational temperatures (which can also depend on the mechanical stresses, in the case of structural materials).

As an initial advice from this analysis, it can be stated that linear collectors should be designed to operate in the saturated regime, limiting the concentration factor in order to limit

the temperatures. Moreover, the design point can be placed slightly above the threshold for that regime, if this option conveys a significant cost reduction because a lower concentration factor can be achieved with simpler and more robust collectors. Of course, this advice must be properly checked in a cost/benefit analysis, after reviewing in detail the thermo-physical features of collecting solar radiation in linear receivers.

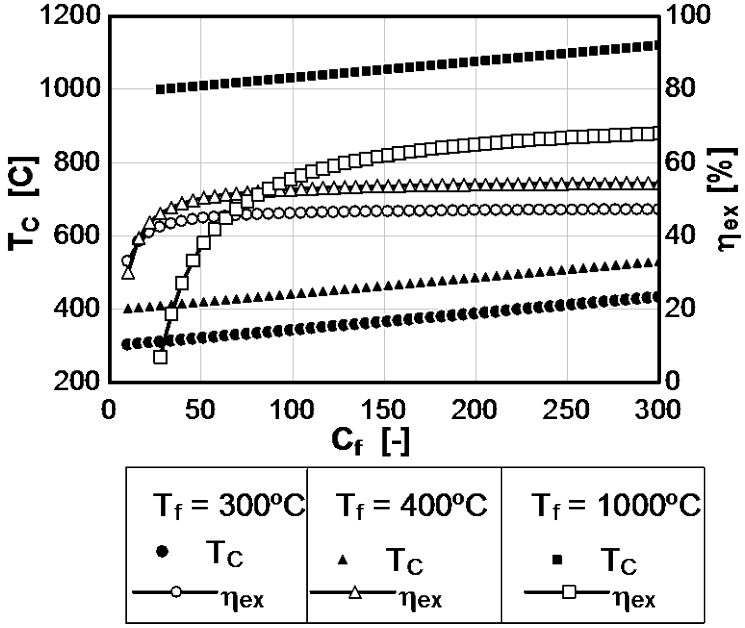

Fig. 2. Collector thermal efficiency and absorbing surface temperature Vs. concentration factor, for three values of T_f: 300 °C, 400 °C and 1000 ° C. The global coefficient for heat transfer from the absorbing surface to the fluid, "h", has a value of 400 W/m^2·K

This finding opens a new way for Concentrated Solar Power, because a Fresnel of large size can be used for heating synthetic oil up to 390 ºC, for activating a Rankine cycle similar to those of current power plants with parabolic trough collectors as Fig. 3 shows, with five Fresnel systems, each one of one total length, and all with the same impinging power: 2.5MW$_{th}$. The intensity goes from 5 to 25 kW/m^2, corresponding to lengths varying from 500 m from the former to 100 m for the latter.

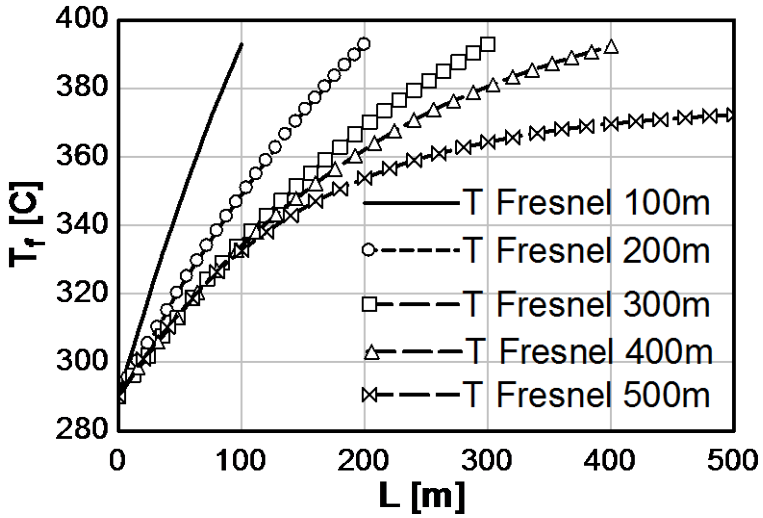

Fig. 3. Evolution of the fluid temperature along the collector length for a set of linear collectors receiving the same total power, with different radiation intensities and lengths.

It is seen that the case of 5 kW/m^2 does not reach the objective T (392 ºC, corresponding to Therminol VP1 as heat transfer fluid), which implies that this case is below the threshold. Energy and exergy efficiencies are shown in Fig. 4, and it is seen how fast they decrease as the radiation intensity goes down. It must be said that this effect is produced, to a large extent, by the objective of achieving a final T of 392 ºC.

It is obvious that requiring higher temperatures in the fluid makes the receiver less efficient, because the temperature gap from the irradiated surface to the bulk of the fluid is shorter than the gap of less demanding collectors, and thermal losses to the surrounding materials increase, as it remains the same. So, if the fluid temperature required for a particular plant is much higher than 400ºC, a Fresnel is not likely to be suitable, because its efficiency will be modest.

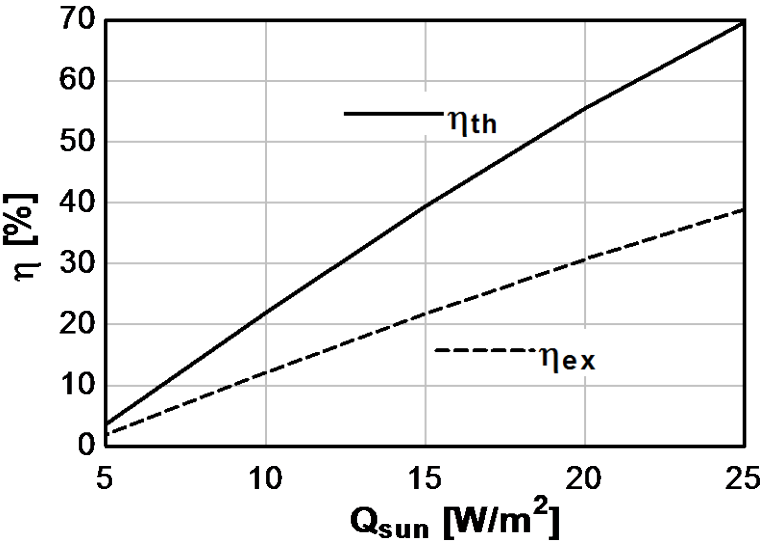

Fig. 4. Energy and exergy efficiencies of the collectors of the set introduced in the previous figure.

4. Conclusions

The analysis of thermal performance of linear collectors in the field of concentrated solar power shows the existence of two regimes: a lower regime, corresponding to small values of intensity impinging on the receiver and an upper regime, where the relevant thermal variable (notably, the efficiency) is almost saturated, opposite to the lower regime, where it increases very rapidly as radiation intensity does. The change from the lower to the upper regime is usually very well identified by a value, or a short range of values. It exists therefore a threshold for reaching the saturated regime. All these features depend on the temperature required in the heat-carrier fluid.

In this performance analysis it has been found that moderate concentration factors can be close to optimal values, due to temperature constraints. Thermal and exergetic efficiency curves show that beyond these values, i.e. increasing the concentration factor, the threshold is exceeded, and therefore efficiency increases slowly.

In the specific case of 400ºC as objective temperature – usual in current solar thermal plants with through collectors that uses thermal oil – the concentration factor takes the value 20 approximately.

This observation must be properly exploited by identifying the simplest and most robust concentration scheme able to attain the upper regime of a given application, for feeding the

boiler of a Rankine cycle with given working temperatures. This is the case of linear Fresnel reflecting collectors, which avoid mobile parts such as ball-joints and flexible joints that could be important leak-points, as well as metal-glass welds, which are another cause of failure in trough collectors

Abstract: Usual constructions of solar energy receivers are not efficient enough in Latvia and others northern countries, and new constructions are required, that would be able to collect energy from all sides as well as to use the diffused radiation more efficiently.
The aim of the paper is to elaborate method for calculation of energy received by solar collector, usable for developing of new constructions of solar collectors, and to develop a new construction of solar collector using this method.
Such new construction can be a semi-spherical solar collector. Such collector has been made, and measurements of water heating have been carried out.
Method of calculations of received energy has been elaborated. Theoretical calculations of the energy gain from semi-spherical solar collector have been performed and verified by comparison of calculated daily energy sums with measured ones, and good coincidence has been obtained.
Method of calculations allows calculating not only integral received energy, but also distribution of the received energy along the surface. The measured distribution of surface temperature of the semi-spherical solar collector corresponds to the calculated one. There are no spot on the semi-spherical surface which would never get warm.
Such semi-spherical solar collector could be appropriate for use of solar energy in Latvia and other countries with similar geographical and climatic conditions.

Keywords: *Solar collector, Semi-spherical, Distribution of surface temperature, Energy gain*

Nomenclature

E_W	daily energy gain from solar collector ..... J	I	intensity of the solar radiation ..... $W\,m^{-2}$
E	daily energy sum at cloudy conditions..... J	I_D	intensity of the diffused radiation..... $W\,m^{-2}$
E_C	daily energy sum at clear sky conditions.. J	z	zenith angle of the sun..... rad
c	specific heat of water.....$J\,kg^{-1}\,K^{-1}$	δ	altitude of the sun ..... rad
K	productivity of the water pump..... $kg\,h^{-1}$	Φ	azimuth of the sun..... rad
t_1	temperature of inlet water ..... °C	S	solar constant ..... $W\,m^{-2}$
t_2	temperature of outlet water ..... °C	P	lucidity of the atmosphere ..... r.u.
Δt	time between two measurements.....s	m	air mass ..... r.u.
β	angle of incidence of solar rays .....rad	M	nebulosity .....grades

1. Introduction

Align with decrease of reserves of fossil fuel, as well as impact of use of fossil fuel on climate, in the world more attention has been paid to renewable sources of energy, including solar energy.

Also in Latvia the solar energy has been used, mostly in solar collectors for hot water production [1,2]. However in Latvia because of its geographical and climatic conditions there are some features in comparison with traditional solar energy using countries [3, 4]. Latvia is located at 57° northern latitude and 24° eastern longitude near the Baltic Sea. In Latvia at summer the length of day excides twelve and maximally reaches seventeen hours, accordingly is also long path of sun, but rather small altitude of sun (maximally 56 degrees above horizon) and therefore also small intensity of solar radiation. There is also frequently considerable nebulosity.

At winter the altitude of sun is very small (10^o) and the length of day 7 h, therefore use of solar energy at winter in Latvia is not possible.

Because of mentioned above features traditional flat plate collector without tracking to sun is not appropriate enough for use in Latvia, but new collector constructions are required, that would be able to collect the energy from all sides as well as to use the diffused radiation more efficiently. To these requirements a collector with a semi-spherical absorber considered in this article could correspond [5]. Energy gain from such collector is similar to that from flat plate collector tracking to sun, but tracking device is complicated, expensive and hard to exploit, while semi-spherical collector is rather simple, with good appearance, durable against wind.

For a better elaboration and evaluation of new constructions of solar collectors, also new, more precise, complete and convenient methods for calculation and forecasting of the received energy are required, capable to calculate received solar energy of surface of any shape and orientation, taking into account also the nebulosity. Such method is proposed in this article. Calculations consist from three steps. At first, solar coordinates at every moment must be calculated. These calculations are based on astronomical considerations [6]. Second step is calculations of the energy received by some surface, depending on its shape and orientation. Third step is evaluation of impact of clouds. There is a new improved model of taking into account impact of the nebulosity used in these calculations.

The method has been verified by comparison of results of calculations with experimentally measured values. A collector with the semi-spherical absorber has been used in these measurements.
Method of calculations allows calculating not only integral received energy, but also distribution of the received energy along the surface. The measured distribution of surface temperature of the semi-spherical solar collector corresponds to the calculated one. There are no spot on the semi-spherical surface which would never get warm.

2. Methodology

Calculations and measurements of the solar radiation as well as the received energy of the solar collector have been performed in this article.

2.1. Measurements

Measurements of the global solar radiation have been performed using an ISO 1. class pyranometer from “Kipp&Zonen”. Measurements have been performed automatically, taking intensity of radiation after every 5 minutes and accumulating data in a logger. Thereafter from these data the daily energy density has been calculated. Measurements have been carried out from April 2008 till November 2010.

Data on the nebulosity from "Latvian Environment, Geology and Meteorology Centre" have been obtained. The nebulosity is evaluated visually in grades from 0 (clear sky) to 10 (entirely overcast) accordingly the World Meteorology Organization methodology after every 3 hours.
Measurements of the received energy of the solar collector have been performed using a new construction – solar collector with a semi-spherical absorber, shown in Fig. 1.

The collector is made from a copper sheet shaped as semi-sphere and coloured black. Inside the dome is a copper tube shaped close to dome. Diameter of the tube is 10 mm, length 21 m. In this tube flows heat remover – water, transporting heat to the reservoir. The collector is covered with transparent polyethylene terephthalate (PET) dome. Radius of the collector is

1.12 m, what corresponds to 1 m^2 base area. In order to determine the received energy of collector temperatures of incoming and outgoing water have been measured after every 5 min. Water flow ensured a pump, which productivity was 30 l/h. Measurements with the semi-spherical solar collector have been carried out at 2009 from 1 August to 31 October and at 2010 from 1 Jun to 30 August.

Energy gain from solar collector has been calculated from Eq. (1)

$$E = \sum c \cdot K(t_2 - t_1) \cdot \Delta t \cdot 10^{-6} \quad (1)$$

where E is daily energy gain from solar collector (J), C is specific heat of water (4190 J kg^{-1} K^{-1}), K is productivity of the water pump (kg/h), t_1 and t_2 are inlet and outlet water temperatures respectively (°C) and Δt is time between two measurements. All positive E values must be summed.

Fig. 1. Semi-spherical solar collector.

The distribution of the surface temperature of semi-spherical solar collector also has been investigated. For this investigation there are 30 thermocouples mounted onto surface of the semi-spherical solar collector at even distances from each other. Measurements of temperatures have been carried out using termologgers Pico TC08. Surface temperature investigations have been carried out with and without water flow in tubes.

2.2. Theoretical calculations

For the theoretical calculation of the received energy of some surface [7] at first solar coordinates (declination and azimuth) must be calculated at every moment (we used interval 15 min). From solar coordinates and the orientation of the surface (normal of the surface) the angle of incidence of solar rays β can be calculated. Then the intensity of the radiation received of a surface element can be calculated from Eq. (2).

$$I = SP^m \cos\beta + I_D \quad (2)$$

where S is solar constant (equal to 1367 W m^{-2}), P is lucidity of the atmosphere, r.u., m is air mass, r.u., and I_D is intensity of the diffused radiation, assumed to be constant and equal to 75 W m^{-2}.

The air mass *m* accordingly to literature [8] can be calculated from empirical expression Eq. (3).

$$m = \frac{1.002432\cos^2 z + 0.148386\cos z + 0.0096467}{\cos^3 z + 0.149864\cos^2 z + 0.0102963\cos z + 0.000303978} \quad (3)$$

where z is zenith angle of the sun.
In order to determine the daily energy sum received by some surface the intensity calculated from Eq. (1) have to be integrated (summed up) in time from sunrise to sunset as well as over all irradiated surface.

Calculation of the clear sky energy according to Eq. (2) and (3) has been explained in our previous works [3,4,7] and therefore is not considered here.
Impact of clouds has been taken into account using a new empirical model Eq. (4) with experimentally evaluated numerical coefficients A, B and C.

$$E = E_C\left(A - B\exp(CM)\right) \quad (4)$$

where E is daily energy sum at cloudy conditions (J), E_C is the same at clear sky conditions, and M is nebulosity (grades).

Comparison of calculated and measured values has been done using graphical method. The model can be evaluated from the scatter plot of calculated daily energy sums via measured ones. About correspondence of calculated values to measured ones indicate slope (must be close to one) and intercept (must be near to zero) of best-fit line, as well as coefficient of determination R^2 (must be close to one).

3. Results

3.1. Impact of clouds

Impact of clouds has been taken into account via Eq. (4). Coefficients A, B and C has been evaluated from comparison of calculated daily energy sums with those measured with pyranometer, then the model for calculating of daily energy sum at cloudy conditions is Eq. (5)

$$E = E_C\left(1.01 - 0.0425\exp(0.295M)\right) \quad (5)$$

Such model gives good coincidence of calculated daily energy sums with measured ones, shown in Fig. 2.

The slope of the best-fit line in this case is 1.005, i ntercept 1.13, and coefficient of determination R^2= 0.88.

3.2. Surface temperature distribution of semi-spherical solar collector

Energy received by semi-spherical solar collector surface element, which is determined with spherical coordinates θ and φ, can be calculated from Eq. (2), where β is angle of incidence of solar rays and can be expressed as scalar product of two vectors: surface normal $\vec{n}$ and solar rays direction $\vec{l}$, Eq. (6).

$$\cos\beta = \vec{n}\cdot\vec{l}_1 = \sin\theta\cos\varphi\cos\delta\cos\Phi + \sin\theta\sin\varphi\cos\delta\sin a + \cos\theta\sin\delta = \\ = \sin\theta\cos\delta\left(\cos\varphi\cos\Phi + \sin\varphi\sin\Phi\right) + \cos\theta\sin\delta \quad (6)$$

where δ is the altitude of the sun and Φ is the azimuth of the sun.

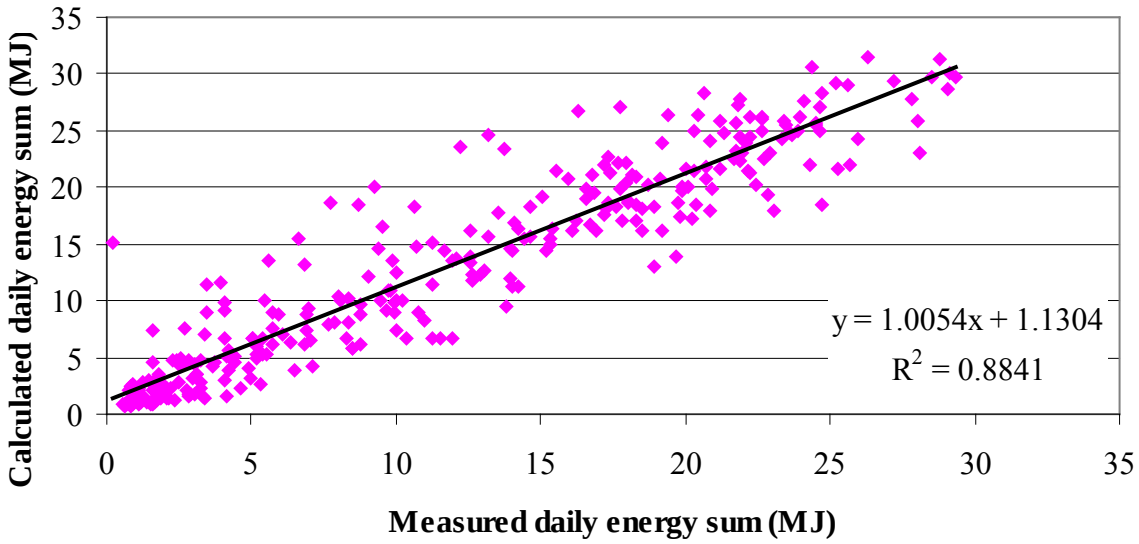

Fig. 2. Comparison of daily energy sums of solar energy, calculated from Eq. (5) with those measured with pyranometer from 1 January 2009 to 31 October 2009.

Results of these calculations in Fig. 3 b ha s been shown in comparison with measured distribution of surface temperature of semi-spherical solar collector Fig. 3 a.

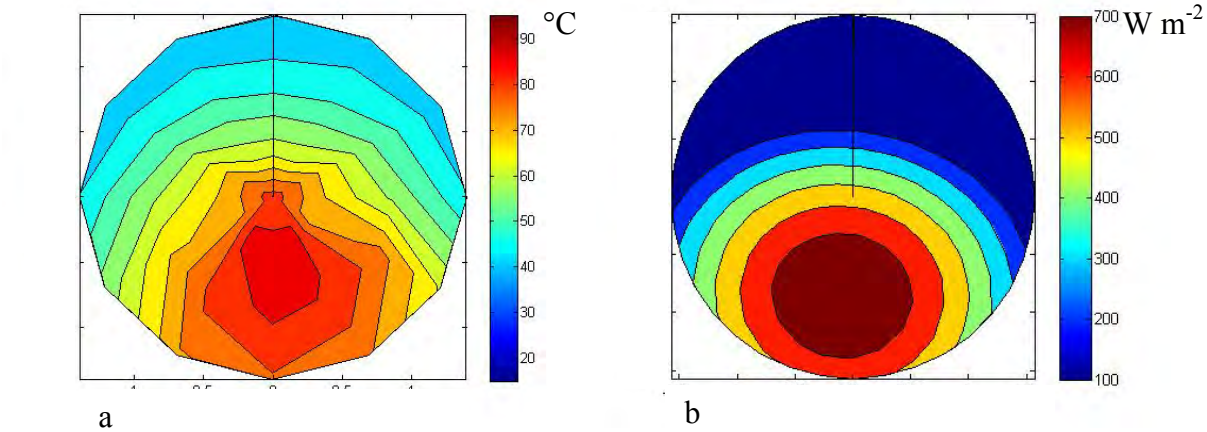

Fig. 3. Distribution of: (a) measured surface temperature and (b) calculated received energy of semi-spherical solar collector at 11 April 2010 at 13:00

Picture shows good correspondence between calculated and measured distributions. Measured distribution is more even because of heat conduction and convection in collector.

Fig. 4 shows daily mean distribution of measured surface temperature (a) and calculated received energy (b). Also good correspondence has been obtained.

Fig. 5 shows daily course of mean temperature at eastern and western sides (arithmetical mean from measurements of 6 thermocouples mounted at corresponding side) of semi-spherical solar collector, but Fig. 6 of northern and southern sides. Of course, eastern side receives more energy at morning, but western side at evening. It is not explained yet why maximal temperature at eastern side is higher than that at western side. Temperature of southern side is certainly higher than that of northern side, with the exception early at morning at late at evening in the middle of summer, when sun rises at northeast and sets at northwest.

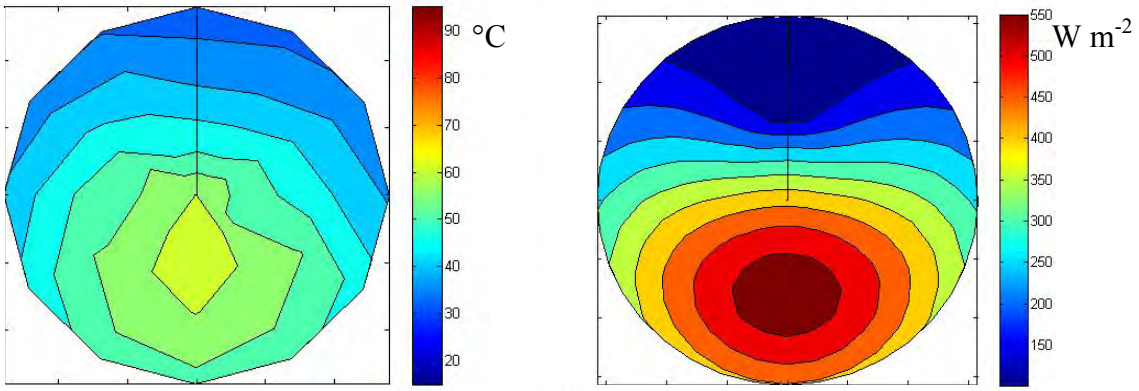

Fig. 4. Distribution of daily mean values of: (a) measured surface temperature and (b) calculated received energy of semi-spherical solar collector at 11 April 2010

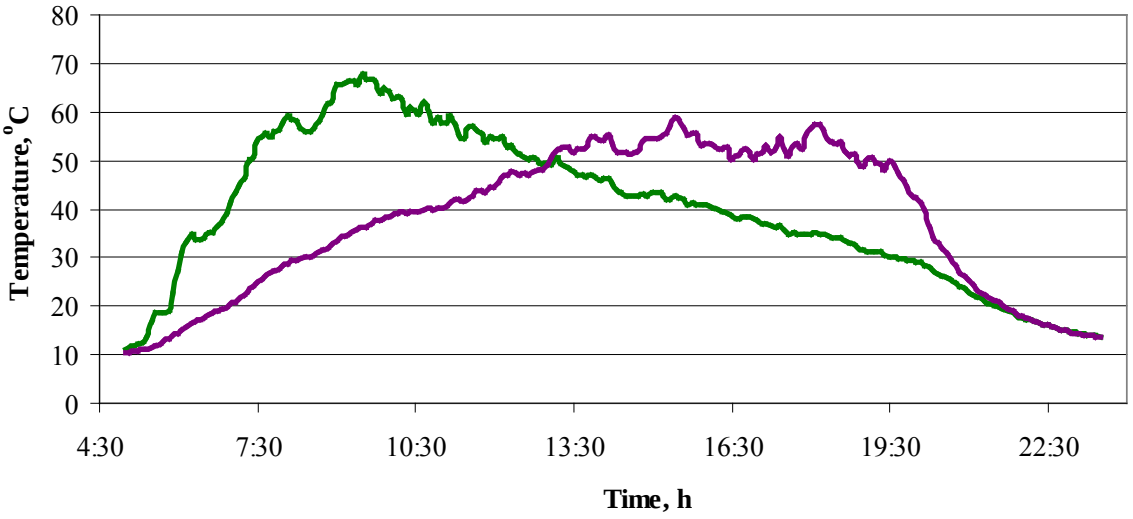

Fig. 5. Daily course of mean temperature at eastern (——) and western (——) sides of semi-spherical solar collector

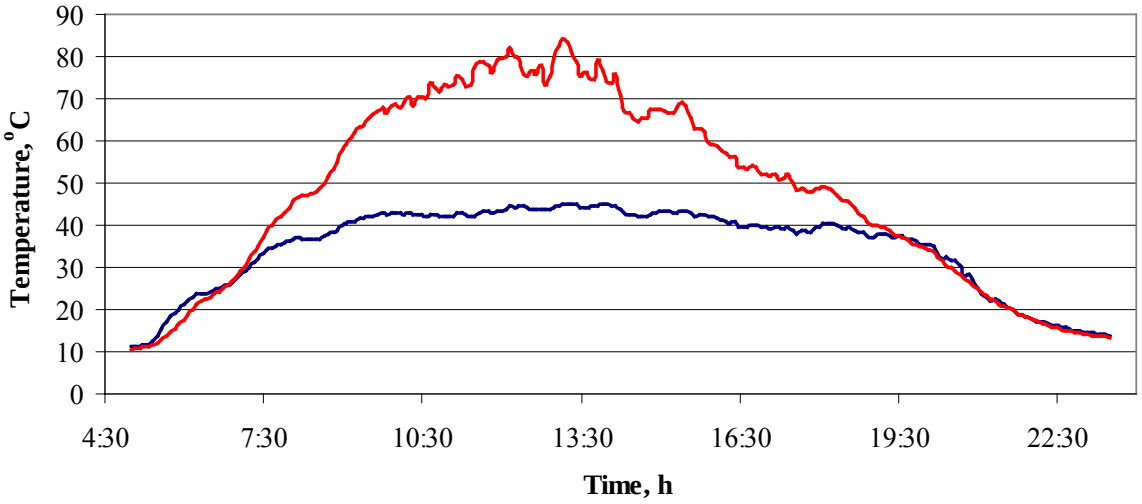

Fig. 6. Daily course of mean temperatures at northern ( ) and southern ( ) sides of semi-spherical solar collector

But at middle of day, when temperature of southern side reaches 80 ºC , temperature of northern side reaches 40 ºC. There is no s pot on the surface of the semi-spherical solar collector, which never gets warm.

3.3. Energy gain from semi-spherical solar collector

Daily energy gain from semi-spherical solar collector has been calculated from Eq. (1). Results are shown in Fig. 7. There is daily energy gain from semi-spherical solar collector compared with daily sum of solar energy, measured with pyranometer. A linear coherence can be observed, with coefficient of determination R^2= 0.87.

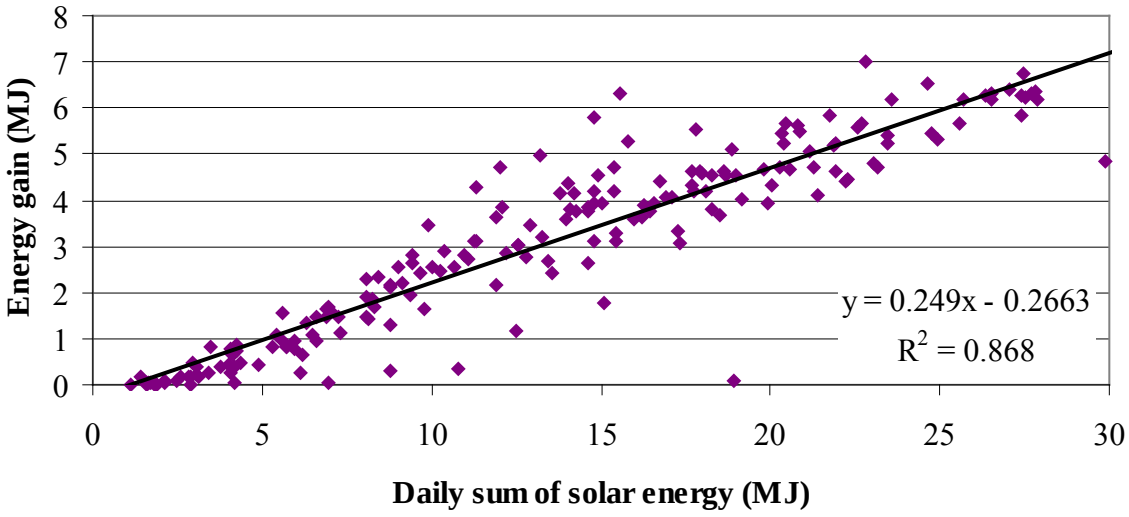

Fig. 7. Daily energy gain from semi-spherical solar collector via daily sum of solar energy, measured with pyranometer from 1 August to 31 October 2009 and from 1 Jun to 30 August 2010.

The slope of the best-fit line (0.25) in this case characterises efficiency of collector. It can be increased using up-to-date materials in the construction of the collector.

4. Discussion and conclusions

Obtained results suggest that semi-spherical solar collector can be appropriate for use of solar energy in Latvia and other countries with similar geographic and climatic conditions. Daily course of surface temperature suggests that semi-spherical solar collector better than common flat plate collector collects solar energy at morning and at evening.

The strong linear coherence between daily energy gain from solar collector and daily sum of solar energy can suggest on independence of work of semispherical solar collector on other circumstances. It can also be because the semi-spherical solar collector uses solar energy evenly all day. However this question needs to be studied additionally, as well as difference between maximal temperatures at eastern and western sides of semi-spherical solar collector.

Other result of this work is method of calculation of received energy of some surface, including impact of clouds. This method is rather simple, precise and not need many input data. This method is usable not only for solar collectors, but also for solar cells, also possible at several forms for better receiving of solar energy. Further study would be interesting on impact of several forms of clouds.

1. Introduction

Water and energy are indispensable for human life and our industry. However arid regions and demand for water sources have been year by year expanding in the world with drastic increases in industrialization. The consumption of natural resources, particularly fossil fuel, for generating the huge energy causes environmental problems such as global warming. Therefore we should aggressively utilize inexhaustible natural resources such as ocean for water and solar energy as one of renewable energy. Utilization of renewable energy for desalination is one of the promising technologies for simultaneously resolving energy and water problems and for the soft global process as reviewed in reference [1].

Desalination is one of chemical separation processes which remove salt from seawater or saline or brackish water. Practical desalination processes are classified in thermal and non-thermal processes. Thermal processes utilize phase-change process, evaporation and

condensation, to produce to distillated water such as Multi-stage flash, Vapor compression and solar still. Non-thermal processes are membrane separation processes such as Reverse osmosis and Electrodialysis. Only Membrane Distillation (MD) is classified into both thermal and membrane process. MD has the advantages of high selectivity of separation, lower temperature or pressure operation and the high-mass transfer rate as reviewed in reference [2]. A solar driven membrane distillation is suitable for the combination of desalination process and utilization of renewable energy [3].

On other hands solar energy is one of the most promising and all ranged renewable energy according to the rapid and diverse development of a solar cell. However the maximum conversion efficiency of a cell is below at most 35% in spite of the active research of a new type of solar cell. The low efficiency results from the independent reuse of solar energy that is solar ray or solar heat. Therefore several hybrid photovoltaic–thermal systems have been researched in order to improve the conversion efficiency due to the dependence of cell temperature [4] or recover waste heat [5-7].

We have been developing a flat type of solar distillator for environmental problem of the global warming by irrigation [8-10]. The flat type of a membrane distillator has the easy combination with other processes due to supporting the water surface with a membrane. In order to effectively utilize solar energy in both energy sources, solar ray and heat, a new solar membrane distillator directly hybridized with a solar cell was set up not in conventional desalination process [11] but in solar distillator unified with a solar cell. A double glass solar cell manufactured by KANEKA Co.LTd and a wide PTFE membrane by NITTO DENKO were selected for the direct hybridization. The effectivity of our hybrid solar membrane distillator was experimentally and numerically investigated. .

2. Experimental set-up

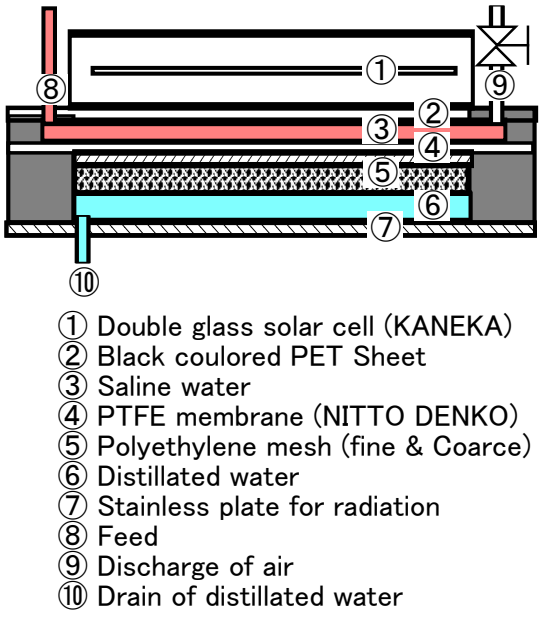

Figure 1. A schematic cross section hybrid solar distillator

Figure 1 schematically shows the cross section of a flat-type hybrid solar distillator combined with a solar cell. The double glass solar sell (manufactured by KANEKA Co.Ltd, Amorphous Si, 1.1cm in thickness, 0.98m in length, 0.95m in width) is put on a flat-type membrane distillator. The I-V Curve Tracer (EKO INSTRUMENTS, MP-160) was used to investigate dynamic fundamental characteristics of a cel l, the Open Circuit Voltage, Short Circuit Current, Conversion Efficiency and Fill Factor of solar cell. A flat-type of membrane distillator composed of a solar absorber of black colored PET sheet (1.88mm in thickness), saline water (2mm in thickness), PTFE (Poly Tera Fluoro Ethylene) membrane (NITTO-DENKO Co.Ltd,NTF-5200,1μm in porε diαmεtεr,85μm in thickness and 80% in void fraction), diffusion gap of water vapor supported with fine and coarse types of polyethylene meshes (5mm in thickness)and radiator of stainless plate(2.2mm in thickness). The hybrid distillator was tilted at the lower angle, 2 deg., for the stable water flow and set up at the outdoor situation in JAPAN. The intensity of solar energy measured with a pyranometer (EKO Instruments Co. Ltd. Model MS-42). Distillate productivity and

partitions temperatures obtained with cupper-constantan thermocouples were respectively recorded per one hour and one minute. The water volume heated through the cell was keeping at the constant value without the outlet of water. Each dynamic characteristics of separately solar cell, membrane distillator and the hybrid membrane distillator was independently measured in order to estimate the effectivity of the hybridization at the different weather conditions during the summer season in Japan

The Photovoltaic performance, particularly Conversion efficiency (η), was evaluated by I-V curve tracer (EKO Instruments Co. Ltd. Model MP-160) on the basis of experimental data of Open Circuit Voltage (V_{OC}), Short Circuit Current (I_{SC}), Maximum Power (P_{MAX}), Fill Factor (FF).

3. Numerical simulation

3.1. Heat and mass balances

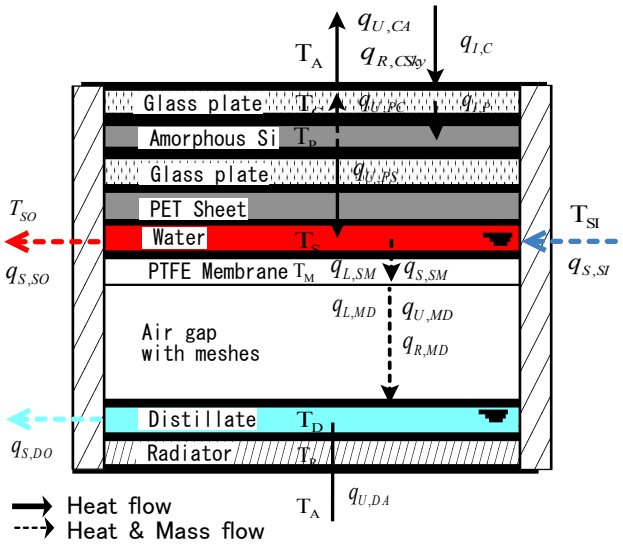

Figure 2. Heat and mass flow of a hybrid distillator

Figure 2 s hows flows of heat and mass transfer for the simulation model of a hybrid solar distillator. This model was constituted on the following assumptions ;

1. Temperature gradients in the flow direction are negligible.
2. Heat transfers with respect to PET sheet, PTFE membrane and radiator are approximated as overall heat transfer coefficients due to only heat conduction.
3. Temperature polarization across the PTFE membrane is negligible.
4. The mesh spacer within the air gap between the PTFE membrane and the radiator has no effect on the heat and mass transfer.

Energy balances for each partition are presented as follow:

Glass cover [T_C] $$:: \rho_C C_{P,C} \ell_C \frac{dT_C}{dt} = q_{I,C} + q_{U,PC} - q_{U,CA} - q_{R,CSky} \quad (1)$$

Amorphous Si [T_P] $$:: \rho_P C_{P,P} \ell_P \frac{dT_P}{dt} = q_{I,P} - q_{U,PC} - q_{U,PS} \quad (2)$$

Saline Water [T_S] $$: \rho_S C_{P,S} \ell_S \left(\frac{dT_S}{dt} + u_S \frac{dT_S}{dx} \right) = q_{U,PS} - q_{S,SM} + q_{S,SI} - q_{S,SO} \quad (3)$$

PTFE Membrane [T_M] $$: \rho_M C_{P,M} \ell_M \frac{dT_M}{dt} = q_{S,SM} - q_{L,MD} - q_{U,MD} - q_{R,MD} \quad (4)$$

Distillated Water [T_D] $: \rho_D C_{P,D} \ell_D \left(\frac{dT_D}{dt} + u_D \frac{dT_D}{dx} \right) = q_{L,MD} + q_{U,MD} + q_{R,MD} - q_{U,DR}$ (5)

Radiator [T_R] $: \rho_R C_{P,R} \ell_R \frac{dT_R}{dt} = q_{U,MR} - q_{U,RA}$ (6)

Distillate productivity is evaluated the following expression [12]

$$D = \Gamma \frac{\pi}{RT_{av}} \frac{1}{\left(\delta / e^{3.6} + z\right)} \frac{P_S - P_D}{P_{BM}}$$

3.2. Numerical analysis

Heat and mass transfer Equations.(1)-(7) were numerically simulated by Runge-Kutta method for estimating dynamic characteristics during one day and compared with experimental data in the open air situation. The temperature gradients along the flow direction may be negligible due to some partitions with high thermal conductivities. The initial or static conditions were estimated by simulated data at the steady state.

4. Results and discussion

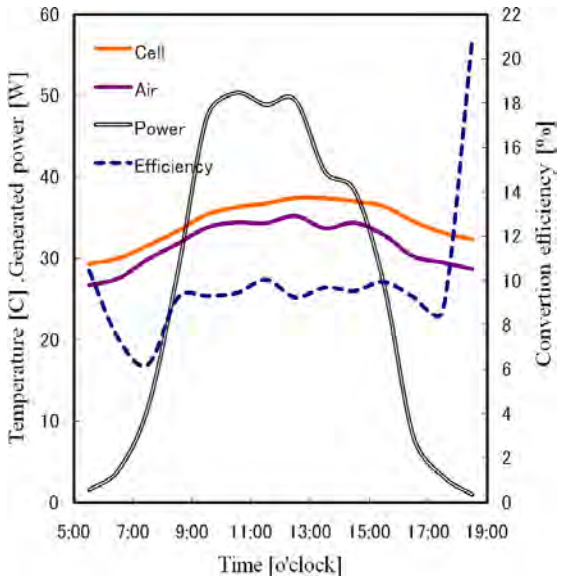
4.1. Dynamic characteristics of solar cell

4.1.1. Effect of hybridization on conversion efficiency (η)

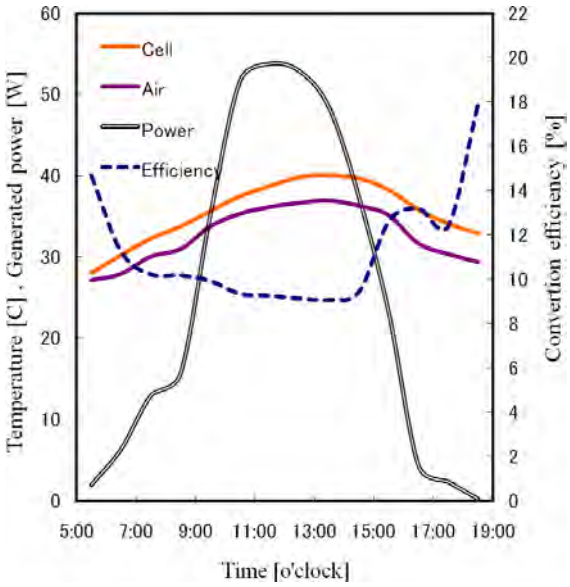
Conversion efficiency of photovoltaic cell (η) can βe estimated by the following expression.

$$\eta = \frac{P_{\max}}{P_{in}} = \frac{V_{OC} I_{SC} FF}{P_{in}} \times 100[\%] \quad (8)$$

Figures 3-(a),(b) show profiles of generated power by a photovoltaic cell and conversion efficiency (η) averaged for one hour in case of (a) exclusive solar cell (11.Augus.2010) and (b) hybridized cell (26.August.2010). In spite of the lower solar intensity per a day Fig. 3(b) shows the higher peak power and average conversion efficiency as shown in Table 1, which is list up each averaged values from 7:00 to 18:00.



(a) Exclusive solar cell
[I=20.4MJ/(m^2·d),11.August.2010]



(b) Hybridized cell
[I=19.0MJ/(m^2·d), 26.August.2010]

Figures 3. Profiles of generated power and conversion efficiency for one day

Table 1 Each characteristic value averaged for 10 hours from 7:00 to 18:00

	Efficiency(η)	Power(P)	$T_{Cell\text{-}terminal}$	T_{Air}
(a) Exclusive solar cell	9.13	32.13	35.36	32.76
(b) Hybridized cell	10.42	30.7	36.85	33.96

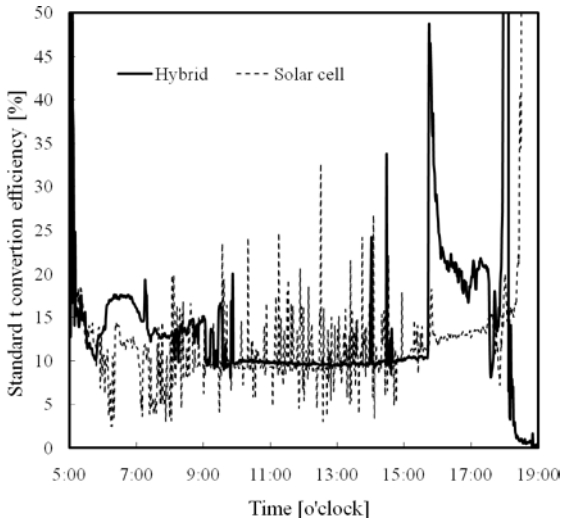


Figure 4. Detailed profiles of standard conversion efficiency

The conversion efficiency at the standard condition of solar irradiation (1kW/m^2) and of cell temperature (25C) is generally available for the public evaluation due to the free dependency of cell temperature. Figure 4 shows detailed profiles of standard conversion efficiency in two cases. Hybridization compresses fluctuation of standard conversion efficiency due to the steady water. In this work water has no flow along the PET sheet and was supplied only for the volume of evaporated water vapor due to the closed outlet of water. Solar intensity inherently has a fluctuated profile due to the presence of variable weather conditions such as cloud, indirect intensity, wind and so on.

4.2. Dynamic characteristics of membrane distillation

4.2.1. Effect of hybridization on temperature profiles of each partition

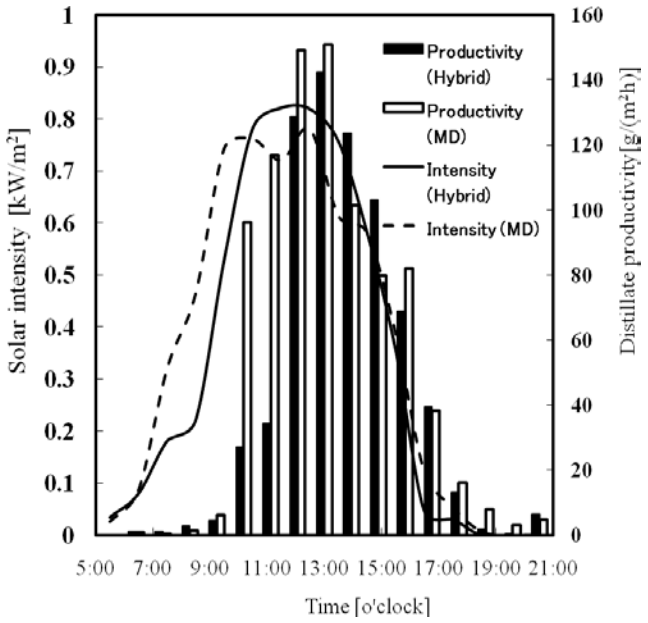

Figure 5. Effect of hybridization on distillate productivity for one hour

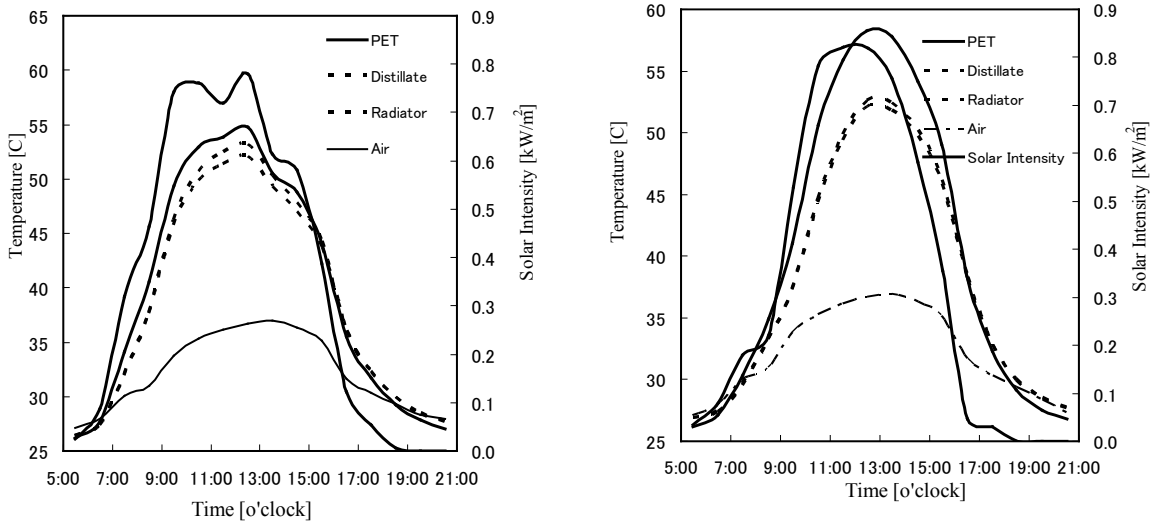
Figure 5 shows profiles of distillate productivity per one hour in two cases of hybrid distillator and membrane distillator without a photovoltaic cell. Table 2 lists up experimental data with total distillate productivity per a day in cases of MD with and without a cell. In spite of the less solar intensity by 20% i, the decrease of distillate productivity n case of the hybridized MD was settled within the less range of 7%.

Figures 6-(a),(b) indicate that hybridization increases the temperature difference between PET sheet and distillate partition. The temperature on PET sheet almost equals to that of evaporated water. The distillate productivity only depends on t he temperature difference between evaporated vapor and condensed water .

Table 2 Total distillate productivity per a day in cases of MD with and without a cell

	Solar intensity [MJ/(m^2・d)]	Distillate productivity[kg/(m^2・d)]
MD without a cell	20.4	0.855
Hybridized cell	19.0	0.691

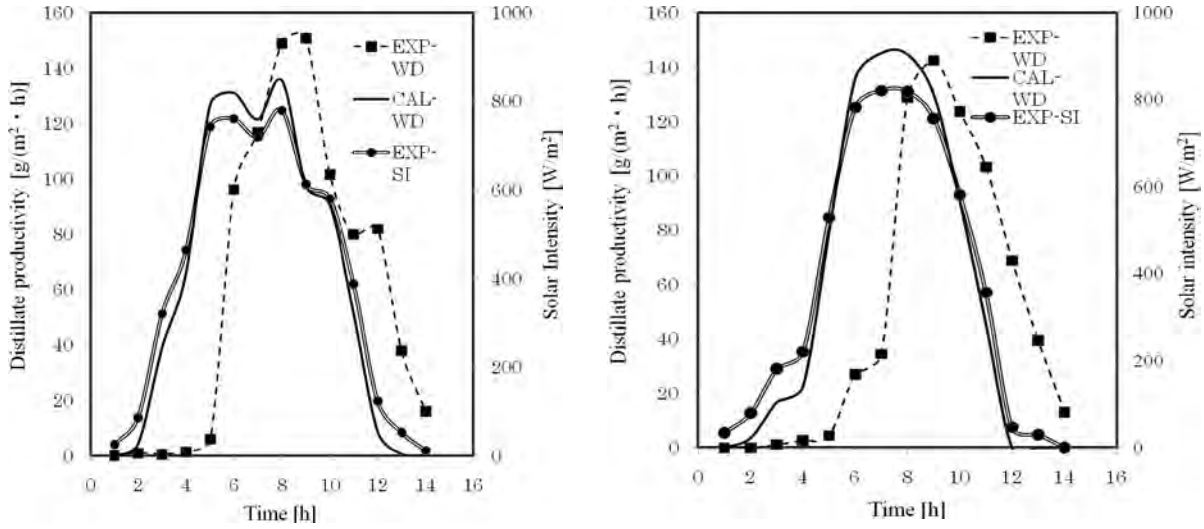


(a) MD without a cell *(b) MD with a cell (Hybrid)*

Figures 6. Temperature distributions in two types of Membrane Distillators (MD)

4.2.2. Numerical results

Figures 7-(a),(b) show profiles of dynamic distillate productivity by numerical simulation in two cases of membrane distillator with and without a photovoltaic cell. Experimental solar intensity and air temperature were used as the weather parameters. The peak value of distillate productivity is underestimated because productivity in Fig.7-(a) was calculated by the hybrid simulation model. Both profiles of productivity in Figs.7-(a),(b) were correspondingly traced by the model. However experimental times at the peak productivity were shifted by two hours from that of solar intensity. The calculated productivity has a response of no time lags for solar intensity due to the negligible temperature gradient along the water flow. The assumption will be invalid in case of operational conditions of water flow. The larger specific heat of water and thickness of spacer mesh than other partitions result in the time lag.



(a) MD without a cell *(b) MD with a cell (Hybrid)*

Figures 7. Numerical prediction of distillate productivity

4.2.3. Effect of hybridization on distillate productivity

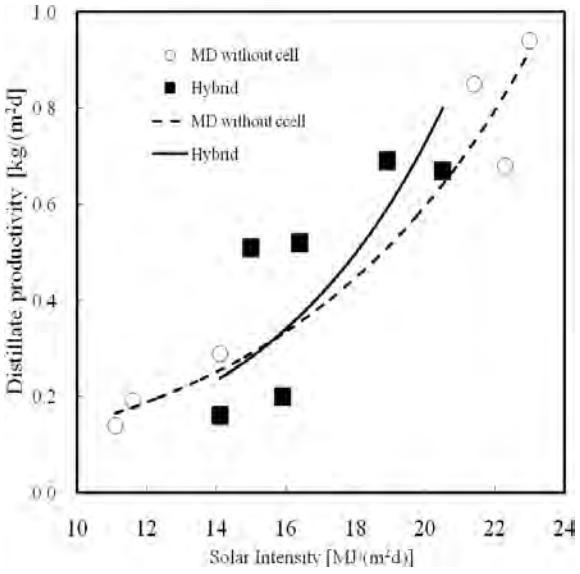


Figure 8. Effect of solar intensity on distillate productivity

Figure 8 shows the effect of solar intensity on distillate productivity for one day. Experimental data were intensively obtained at the summer season in Japan due to the less solar intensity than other arid lands. Approximated curves with experimental relationship between solar intensity and distillate productivity for membrane distillators even if with or without a photovoltaic cell were almost identifiable. The results indicate the effectivity of a hybrid solar membrane distillator directly with a photovoltaic cell even if for the increasing thermal resistances. The productivity is not necessarily desirable in comparison with our previous report [8]. The improvements of hybridization and process flow of water are required.

5. Conclusions

A solar membrane distillator hybridized with a photovoltaic cell supplies with both water and energy which are indispensable for human life and industry and contribute to effective utilization of renewable energy. The effectivity of a hybrid solar membrane distillator was experimentally and numerically verified.

The dependence of cell temperature on conversion efficiency was unrecognized in this work because of an amorphous Si module. However the hybrid solar distillator contributed to the stable standard conversion efficiency of a cell. An amorphous Si module is suitable for the comparatively higher temperature condition.

Relationship between solar intensity and distillate productivity is almost identifiably approximated for the membrane distillator even if with or without a photovoltaic cell. .The performance of distillate productivity is not necessarily desirable. The improvements of hybridization and process flow of water should be required.

Abstract: In this communication, a comparative energy and exergy analysis of various conventional solar distillation systems has been presented. The study includes passive solar distillation systems such as single and double slope solar stills. In a single slope solar still category, three solar stills with inclination angles 15º, 30º and 45º and a 15º inclined single slope multi wick solar still have been considered. Whereas one double slope solar stills and one double slope multi wick solar still, both inclined at 15º with east-west orientation, have been considered in double slope solar still category. The embodied energy is an important factor which depends on locally available materials and their manufacturing technologies. Materials like concrete, wood, steel etc are considered to calculate the embodied energy for the solar still equivalent to the fibre reinforced plastic after deriving the formulae. It has been found that the energy, exergy and embodied energy of single slope solar still are found higher than that of double slope solar still. Those materials which have lower thermal conductivity and low embodied energy than that of FRP such as concrete, PVC, wood can replace the FRP to save the embodied energy for similar performance. The metals have high embodied energy hence these can not be considered in terms of embodied energy despite the use of insulation.

1. Introduction

A solar distillation is a water purification technology. Saline/brackish water can be purified using solar energy. This technology works on the principles of greenhouse effect and hydrological cycle. The use of solar energy to produce potable water is a key factor in context of water & air pollution, global warming, energy security and climate change because most of other water purification technologies use conventional sources of energy such as coal, oil, gas etc [1]. A solar still is a device used for solar distillation in which impure or saline water is fed to obtain distilled water. It is a box type structure made of some materials such as fibre reinforced plastic (FRP), wood, concrete, or steel with insulation. It is covered with a simple window glass through which the solar radiation passes to incident on the water surface. A small amount of reflection heat losses and absorption take place at the glass cover and the water. A major part of incident solar radiation is absorbed by the basin liner. This heat is transferred to the saline water by convection as top heat loss and to the ambient as bottom heat loss. Heat transfer from the water to the glass cover take place by three mechanisms: evaporation, convection and radiation. Vapour leaves most of contaminants and microbes

through thermal diffusion on the basin liner. Further the vapour undergoes film type condensation at the inner surface of the glass cover because of inclination of glass cover, adhesion, cohesion between condensed water molecules, and gravity. The condensed water trickles down to a trough which guides it into a container placed otuside [2]. Researchers have worked to improve the performances of solar stills by suggesting its various designs, materials and operating conditions for different weather conditions. Tiwari and Tiwari [3] have reported that the yield from a single slope passive solar still may vary from 0.5 to 1.2 kg/m^2/day (in winter) and 1.0 to 2.5 kg/m^2/day (in summer) for Delhi, India. Tiwari [4] has found the efficiency of the single slope solar still 25.8, 19.7, 22.8 % at glass cover inclinations 15°, 30° and 45° respectively for the summer climatic condition of Delhi, India. Malik et al. [2] have shown that overall efficiency of a passive solar still is achieved with least water mass in the basin.

Energy and exergy analysis of solar stills have been presented by various researcher such as Dunkle [5], Cooper [6], Tsilingiris [7], and Dwivedi [8, 9] etc. A group of improved heat and mass transfer correlations in basin type solar stills has been developed by Hongfei et. al. [10]. Torchia- Núñez et al. [11] have found that for same exergy input a basin, brine and passive solar still have exergy efficiencies of 12.9%, 6%, and 5% respectively. Dev and Tiwari [12, 13] developed the characteristic equation for single and double slope passive solar stills. In ideal solar still, the instantaneous loss efficiency is minimum (for zero depth of water mass) as analyzed by Cooper [6]. Rubio et al. [14, 15] have studied asymmetries in various temperatures and amount of distillate for a double slope passive solar still (DSPSS) and proposed mathematical models, one in terms of lumped parameters and another for controlled temperatures of glass cover and basin. Dwivedi and Tiwari [8, 9] have reported that the thermal efficiency for single and double slope solar still varies from 22.6% to 31.3% and 25.4% to 34.3% respectively at 0.01 m water depth. Similarly, the average exergy efficiency for single and double slope solar still is 0.65% and 0.82% respectively. The exergy efficiency of single and double slope solar still varies from 0.18 to 1.25% and 0.13 to 1.16% respectively. Tiwari and Yadav [16] have shown that a single slope distiller gives better performance than a double slope for cold climatic conditions whereas a double slope distiller gives better performance than a single slope for summer climatic conditions irrespective of either basin type or multi-wick type. It has also been reported that the concrete basin solar still gives better performance than the FRP single and double slope stills because of the probability of leakage of vapour in the FRP stills was more than for the concrete still. Sakthivel and Shanmugasundaram [17] have shown that the efficiency of single slope solar still using the black granite gravel reaches up to 52% maximum which is 8% higher than the conventional single slope solar still. Singh and Tiwari [18] have studied double effect multi-wick solar stills to increase the still efficiency by utilizing the latent heat released by the vapor at first effect. Kumar and Anand [19] have studied shown that a tubular multiwick solar still gives distillate output of about 8%, 13%, and 18% more than tubular, simple multi-wick and conventional basin type solar stills respectively.

The embodied energy is an important factor which depends on locally available materials and their manufacturing technologies. Hence, on the basis of literature survey the performance of the solar stills on the basis of energy, exergy and materials have been analyzed in this paper.

2. Solar distillation systems

Passive solar distillation systems such as single and double slope solar stills have been taken. In a single slope solar still category, three solar stills with inclination angles 15º, 30º and 45º

(Fig. 1a, 1b) and a 15º inclined single slope multi wick solar still have been considered. Whereas one double slope solar stills and one double slope multi wick solar still both inclined at 15º with east-west orientation, have been considered in double slope solar still category (Fig. 1c, 1d). All these experimental setup have been installed at Solar Energy Park, I.I.T. Delhi, New Delhi, India (28°35´ N, 77°12´ E, altitude 216 m from mean sea level). The single slope solar still works on same principle as given above.

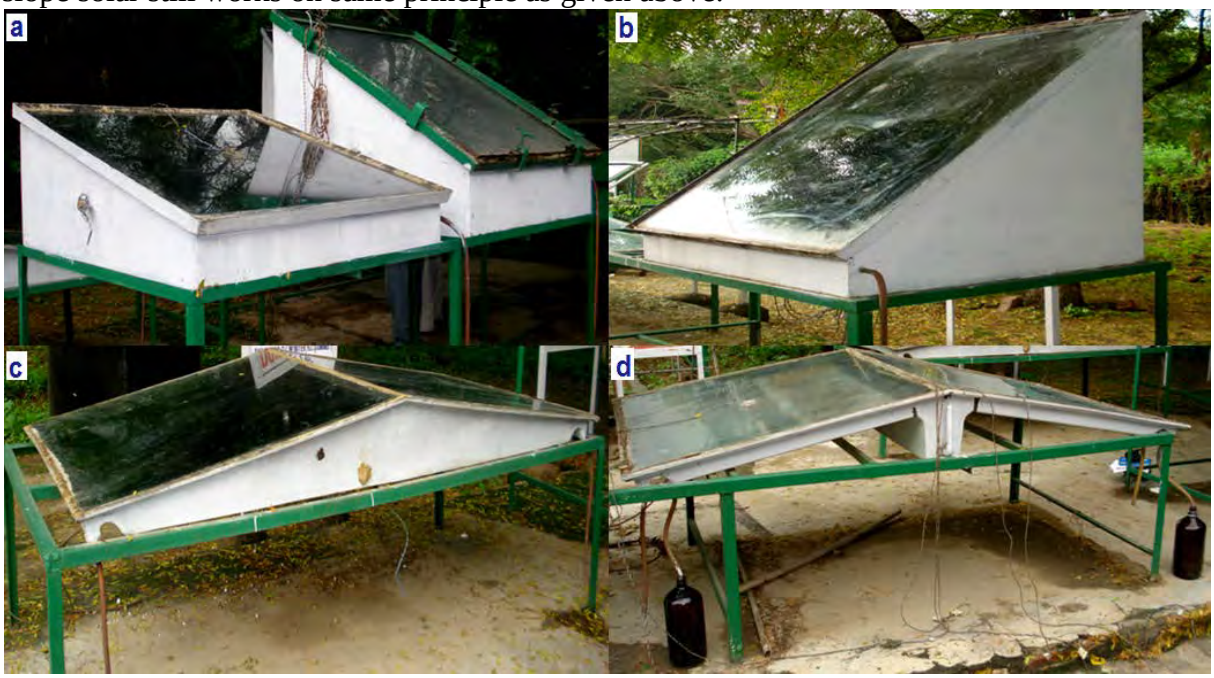

Fig. 1 Various solar stills: (a) Single slope solar still inclined at 15º and 30º with orientation towards south, (b) Single slope solar still inclined at 45º with orientation towards south, (c) Double slope solar still inclined at 15º with orientation towards east-west, (d) Double slope multi-wick solar still inclined at 15º with orientation towards east-west.

A schematic diagram of double slope passive solar still has been shown in Fig. 1c. Two simple window glasses have been placed over the walls of the solar still at inclination angle 15° facing east and west directions. To absorb higher amount of solar radiation, an inside surface of the solar still has been painted black in color. An inlet through the rear wall has been provided to feed the brackish/underground water in to the basin of the solar still. And two troughs are provided at inside of each short wall of the solar still to collect the distilled water. The orientation of the solar still has been kept east-west to receive solar radiation for maximum hours of sunshine. When the sun lies in the east direction then higher temperature difference occur at west side due to low glass temperature which yield higher amount of distillate at this side and vice versa except at the time of noon when both the glass covers have almost the same temperature.

In the single and double slope multi-wick solar still, water is fed from water reservoir through the multiple porous absorbers (black jute cloth) at a slow rate for fast evaporation. The saline water goes upwards due to capillary action in the jute cloths and forms a thin water layer. The solar radiation, after transmission through the glass covers, strikes this water film and heats the water. The water evaporates and condenses at the inner surface of the glass cover by releasing latent heat of vaporization. The condensed water is collected through the drainages for distilled water. A double slope multi-wick solar still, as shown in Fig. 1d, is a

development over the single slope multi-wick solar still similar to double slope solar still, Malik et al. [2]. The specifications of these solar stills are given in Table 1.

Table 1. Design specifications of solar stills which are installed at Solar Energy Park, Centre for Energy Studies, IIT Delhi, New Delhi, India.

Sr. No.	Specifications	Single slope solar still			
		Conventional			Multi-wick
		Type 1	Type 2	Type 3	Type 4
1	Area of basin (m^2)	1 × 1	1 × 1	1 × 1	1.1 × 1.14
2	Height of south wall (m)	0.06	0.15	0.15	0.06

3. Mathematical expressions

Following are the mathematical expression used for the analysis of energy and exergy of considered solar still systems.
The thermal efficiency of a passive solar still can be calculated by the following formula [1]:

$$\eta_i = \frac{\dot{m}_{ew} \times L}{A_s \times I(t) \times 3600} \times 100 \qquad (1)$$

Exergy efficiency of a passive solar still can be calculated by the following formula [20]:

$$\eta_{EX} = \frac{\dot{E}x_{evap}}{\dot{E}x_{in}} \times 100 \qquad (2)$$

where,

$$\dot{E}x_{evap} = \sum_{i=1}^{24}\left(1 - \frac{T_a}{T_w}\right) \times \dot{q}_{ew} \quad ; \quad \dot{q}_{ew} = A_s.h_{ew}.\left(T_w - T_{gi}\right)$$

and

$$\dot{E}x_{in} = \dot{E}x_{sun} = A_s \times I(t) \times \left[1 - \frac{4}{3} \times \left(\frac{T_a}{T_s}\right) + \frac{1}{3} \times \left(\frac{T_a}{T_s}\right)^4\right]$$

Equivalent thickness of materials for same performance as FRP has in case of solar still:

$$l_{material} = \frac{K_{material}}{K_{FRP}} \times l_{FRP} \qquad (3)$$

Thickness of Styrofoam for insulation (when solar still is made of any metal and overall thermal conductivity is equivalent to FRP):

$$l_{Styrofoam} = \frac{K_{Styrofoam}.\left(K_{Metal}.l_{FRP} - K_{FRP}.l_{Metal}\right)}{K_{Metal}.K_{FRP}} \qquad (4)$$

4. Results and discussion

On the basis of literature survey and Eqs. (1, 2) it has been observed that energy, exergy efficiencies and embodied energy of single slope solar still remain higher in comparison to that of the double slope solar still. Dev and Tiwari [12,13] have found better performances at water depth 0.01 m and an inclination angle 30º for single slope passive solar still. They have also developed the characteristic equation of single and double slope passive solar still and suggested the sum of instantaneous gain and loss efficiencies ($\eta=\eta_i + \eta_{iL}$) remain lower than maximum efficiency under ideal i.e. 60%. Although, it can be seen that the energy efficiency can reach up to 60% maximum but because of several factor such as heat loss through vapor leakage and improper insulation, time lag in production, inclination angle, water depth etc, it does not attain such value. Similarly, the exergy efficiency which is measured for the source temperature i.e. sun temperature 6000 K , remain always very much lower than the energy efficiency because of the energy input by the sun is not fully utilized in evaporation process of the water in the solar still.

The design specifications (Table 1), properties of various materials (Table 2 which consists of probable materials for solar still), Eqs. (3) and (4) have been used to get total embodied energy for the solar still by considering metals, concrete, PVC, wood etc. equivalent to that of

FRP (i.e. to keep the productivity of the solar still same as of FRP). The metals have been found large thickness due to their conductivities but these metals (thickness 1 mm) can be considered with insulation of Styrofoam as shown in Table 2. One can see that steel which is very high energy intensive material can not be recommended as a material to make the solar still despite the use of insulation. The thicknesses of materials such as concrete, wood, and PVC have been found very near to the thickness of the FRP. Materials such as glass window and country fired bricks have more thickness which can not be considered.

Table 2. Various manufacturing materials of solar still, their thermal conductivities, embodied energy, density and thickness with and without insulation material.

Material	**Conductivity at 25 °C** (W/mK)	**Embodied energy** (MJ/kg) **(In India)**	**Density** (kg/m^3)	**Thickness of material without insulation** (m)	**Thickness of insulation** $l_{styrofoam}$ (m) **(for l_{metal}=1 mm)**

Note: Embodied energy values based on several international-local sources may vary.

The embodied energies of conventional single slope solar stills made of FRP, concrete, PVC, and wood are found and given in Table (3). The percentage increase in the embodied energy compared of other solar stills compared to that of single slope solar still inclined at 15°, with south wall height 0.06 m has also been given in same table which changes similarly irrespective of material used. The embodied energy double slope solar still, and double slope multi-wick solar still have been found to be 3070 MJ and 2323 MJ respectively when only FRP is considered. On the basis of this one can observe that the embodied energy of double slope solar stills including the multi-wick solar still are less energy intensive in comparisons to single slope solar stills (1361 MJ) and single multi-wick solar still (1495 MJ). One can see in Table 3, wood is found most suitable in terms of embodied energy but it degrades soon in comparison to other materials in terms of life. The PVC can be a better option over FRP in

terms of embodied energy and weight. According to previous studies [3, 4], single slope solar still inclined at 30° is suitable as per the latitude of Delhi. The total embodied energy for this solar still including glass, paint has been found 2587 MJ (FRP), 369 MJ (concrete), 1498 MJ (PVC), 292 MJ (wood). Similarly for double slope multi-wick solar still inclined at 15°, total embodied energy including glass, paint and fabric have been found 2875 MJ (FRP), 640 MJ (concrete), 1773 MJ (PVC), 562 MJ (wood).

Table 3. Embodied energy of single slope solar still for different materials such as FRP, Concrete, Steel, Wood.

Solar still	Specifications	Embodied energy (MJ)							
		FRP	Concrete	PVC	Wood	% increase	Glass	Paint	Fabric
Single slope	15°, with south wall height = 0.06 m	1361	52	718	6	----	168	28	----
	15°, with south wall height = 0.15 m	1776	68	937	8	30	168	45	----
	30°	2306	88	1217	11	70	208	73	----
	45°	2987	114	1576	14	120	245	90	----
	15°, Multi-wick	1495	57	790	6.6	10	226	45	27.5
Double slope	15°	3070	117	1615	13.5	125	345	90	----
	15°, Multi-wick	2323	88	1221	10.2	70	407	90	55

5. Conclusions

1. On the basis of above analysis and literature survey, the energy, exergy and embodied energy of single slope solar still are found higher than that of double slope solar still.
2. Those materials which have lower thermal conductivity and low embodied energy than that of FRP such as concrete, PVC, wood can replace the FRP to save the embodied energy for similar performance.
3. The metals have high embodied energy hence these can not be considered in terms of embodied energy despite the use of insulation.
4. PVC material has been found to be better in terms of embodied energy in comparison to other materials.

On the basis of above study, the similar analysis can be recommended for other materials such as glass, steel, aluminum, copper, bricks, and other advance materials, as the research in the field of materials science is progressing, to have a material of less embodied energy, light in weight, good insulator and portable in comparison to FRP as well which should be easily available in less price.

Abstract: In conventional collector systems for the supply of domestic hot water and space heating the collectors come to a standstill during summer whenever the maximum temperature in the storage tank is reached. The resulting excess heat can be harnessed by a combined heat pump-Organic Rankine Cycle-system. The aim of this work is to simulate such a system in order to determine the optimum operating conditions and impacts on power requirement and cost. For this purpose models for collector, storage tank, heat pump and geothermal heat exchanger are implemented. First results indicate that the isentropic efficiency of the scroll expander has the largest influence on the ORC-revenue. For a system consisting of 12 m² flat-plate collector area with an expansion efficiency of $\eta_{s,\exp} = 0.7$ the power requirement for space heating and domestic hot water is reduced by 3.6%, whereas the costs decrease by 42 € or 12.3% respectively compared to a conventional system. The results suggest that an installation is more reasonable in larger dwelling units like hotels, senior citizens' homes and multiple family dwellings.

G_d	diffuse radiation	W/m²	
h	enthalpy	kJ/kg	
K_θ	incidence angle modifier		
$\dot{m}_{ex}$	external mass flow	kg/s	
$\dot{m}_{ex}$	mass flow between nodes	kg/s	
n_{ser}	number of collectors in series		
$\dot{q}$	specific heat flow	W/m²	
q_{cond}	specific heat of condensation	kJ/kg	
q_{in}	supplied specific heat	kJ/kg	
$\dot{Q}_{DHW}$	heat transferred to the generation of domestic hot water	W	
$\dot{Q}_{Loss}$	heat loss of a node	W	
$\dot{Q}_\lambda$	conductive heat flow across nodes	W	
t_{ORC}	operating time in ORC mode	h	
T_a	ambient temperature	°C	
T_{ground}	temperature of the ground	°C	
T_{DHW}	temperature of domestic hot water	°C	
T_{SH}	space heating flow temperature	°C	
T_{in}	collector inlet temperature	°C	
T_m	mean collector temperature	°C	
T_{ORC}	scroll expander inlet temperature	°C	
T_{out}	collector outlet temperature	°C	
$w_{t,comp}$	specific work for compression	kJ/kg	
$w_{t,exp}$	specific work of expansion	kJ/kg	
$\dot{V}$	volume flow	l/h	
$\dot{V}_{str}$	volume flow per collector string	l/h	
β	collector slope		
$\eta_{s,c}$	isentropic compression efficiency		
$\eta_{s,p}$	isentropic pump efficiency		
$\eta_{s,exp}$	isentropic expansion efficiency		
ρ_{CF}	density of the collector fluid	kg/m³	
$(\tau\alpha)_n$	normal transmittance absorptance product		

1. Introduction

The application of ground coupled heat pumps and solar combisystems providing both space heating and domestic hot water is a proven technology. In these conventional systems the collectors come to a standstill whenever the maximum temperature in the storage tank is

reached. However The resulting excess heat can be harnessed in an Organic Rankine Cycle (ORC). The domestic application of an ORC driven by solar heat has been a topic of interest in recent years [1]-[5]. In contrast in this study a scroll expander is applied as expansion device. Advantages of the use of a scroll expander are that no valves have to be used and that their low costs are low because of mass production. The performance of a scroll expander as the expansion device of a Rankine cycle has been investigated by [6]-[8]. In the ORC the working fluid of the heat pump is evaporated by solar heat and is afterwards expanded through the scroll compressor of the heat pump which in this case operates as a scroll expander. When the fluid condenses heat is recharged into the ground increasing the coefficient of performance of the heat pump and potentially reducing the necessary borehole depth. Upgraded controls and a pump for the ORC are the only additionally required investments compared to conventional systems. A schematic drawing of the combined heat pump-ORC system is given in Fig. 1.

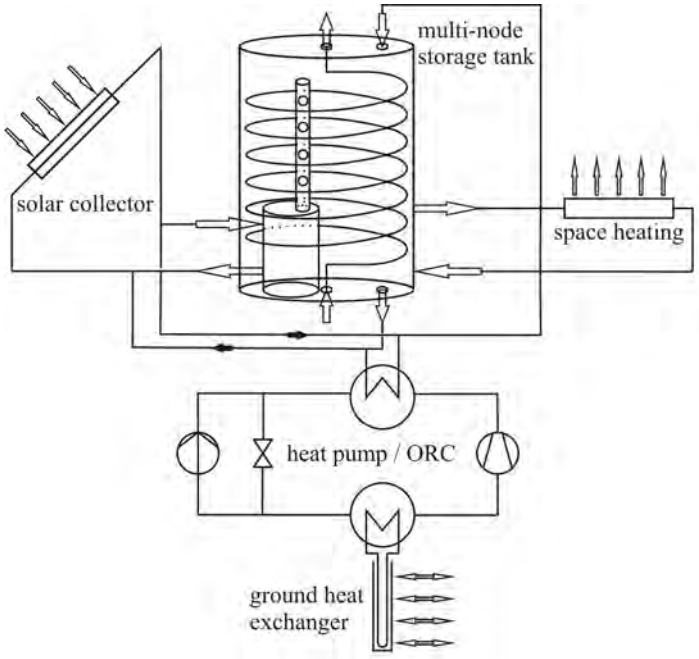

Fig. 1. Schematic drawing of the combined heat pump-ORC system.

2. Modelling of the components of the combined system

In order to simulate a combined system models for the solar collector, storage tank, heat pump, Organic Rankine Cycle and geothermal heat exchanger are required. The flat-plate collector has been modelled dynamically by use of a one-node model which is given in the European norm EN 12975 [9]. Dynamic modelling is necessary because the heat capacity of the collector strongly influences the ORC-revenues due to varying heating-up periods for different operating temperatures. The following differential equation Eq. (1) describes the thermal behaviour of a flat-plate collector.

$$\dot{q} = F'(\tau\alpha)_{en} K_{\theta b}(\theta) G_b + F'(\tau\alpha)_{en} K_{\theta d}(\theta) G_d - c_1 (T_m - T_a) - c_2 (T_m - T_a)^2 - c_5 dT_m/dt \quad (1)$$

The beam and diffuse radiation on the sloped collector have been calculated by means of the algorithms of the European Solar Radiation Atlas [10]. If the collector is feeding the storage tank the volume flow is fixed to a constant value. However if it is operating in ORC mode the volume flow is adjusted to keep a constant temperature. In this case the differential term in

Eq. (1) is zero and for hourly irradiation data the process can be considered stationary. The resulting volume flow can be calculated by equating Eq. (1) and Eq. (2).

$$\dot{q} = \rho_{CF} \cdot c_{p,CF} \cdot \dot{V} \cdot \left(T_{out} - T_{in}\right) / A_C \tag{2}$$

The storage tank installed in the combined system is a multi-node storage tank with stratification device. The stratification system ensures the layering of solar heated water at different temperatures which allows for the use of low-temperature solar heat in a solar combisystem. For each time step a mass and an energy balance have to be solved. It has to be considered that a mass flow also accounts for an energy flow throughout via mixing. The mass and energy flows in a node are depicted in Fig. 2.

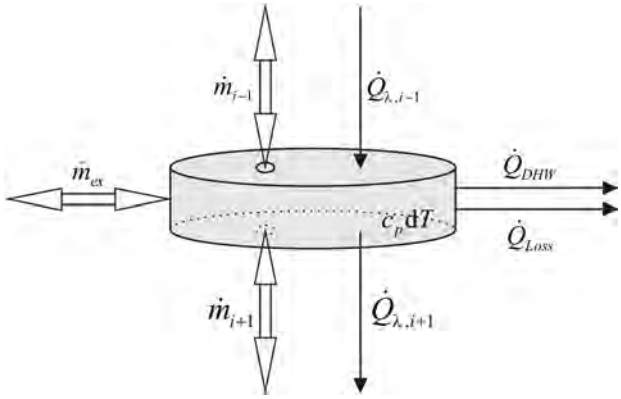

Fig. 2. Mass and energy flow in a node.

Mass flows between adjacent nodes ($\dot{m}_{i-1}, \dot{m}_{i+1}$) result from external flows ($\dot{m}_{ex}$) of the collector, heat pump or floor heating which are either supplied or removed. The terms $\dot{Q}_{\lambda,i-1}$ and $\dot{Q}_{\lambda,i+1}$ describe the heat conduction between adjacent nodes whereas $\dot{Q}_{DHW}$ marks the heat flow from the node to the coiled tube heat exchanger in which the domestic hot water is generated. $\dot{Q}_{Loss}$ indicates the heat loss from the storage tank to the ambient. The mass flows are first converted into equivalent heat flows, afterwards the set of differential equations is solved for each node.

All thermodynamic properties required for the simulation of the ORC and the heat pump are calculated with the software Refprop [11]. The terminal temperature differences in heat exchangers are set to 5 K. For the calculation of the COP of the heat pump the upper and lower pressure are the saturation pressures belonging to the temperatures T_{ground} and T_{SH} in case of floor heating or T_{DHW} in case of the generation of domestic hot water. The suction gas is overheated by 3 K (1a) and afterwards compressed (2a). The compression is assumed to be adiabatic with an isentropic efficiency of $\eta_{s,c} = 0.6$. Subsequently the refrigerant condenses (3a) and transfers heat to the floor or water heating system. The refrigerant leaves the condenser as saturated liquid so no subcooling is performed. To complete the cycle the pressure is relieved by an expansion valve (4a). The COP of the described process can be calculated with Eq. (3).

$$COP = \frac{q_{cond}}{w_{t,comp}} = \frac{\left|h_{3a} - h_{2a}\right|}{h_{2a} - h_{1a}} \tag{3}$$

For the calculation of the thermal efficiency of the ORC the pressure levels are given through the temperatures T_{ground} and T_{ORC}. The fluid is compressed by a pump with an isentropic

efficiency of $\eta_{s,p} = 0.6$ (2b). Afterwards the fluid is evaporated by heat transfer from the collector fluid (3b). The saturated vapour is expanded in the scroll expander (4b). By default the isentropic efficiency of the expansion is set to $\eta_{s,\exp} = 0.5$ which is in good agreement with Peterson et al. [6]. Downstream of the expander the refrigerant is condensed and subcooled by 2 K (1b). The thermal efficiency of this cycle can be calculated as

$$\eta_{ORC} = \frac{w_{t,\exp}}{q_{in}} = \frac{|h_{4b} - h_{3b}|}{h_{2b} - h_{1b}}. \quad (4)$$

To model the ground heat exchanger a short time step model is required because the thermal response of the ground is critical for the description of condensation in ORC mode. With the analytical approach of Lamarche and Beauchamp [12] an hourly calculation, which is in good agreement with the short time-step g functions developed numerically by Yavuzturk and Spitler [13], is achieved.

3. Simulation and optimisation of the combined system

In this work a combined heat pump-ORC system has been simulated which is installed in a single family house. The house has a total floor space of 167 m² and a transmission heat loss of 148.2 W/K. Both values are characteristically for a l ow-energy consumption house fulfilling the German KfW 70 standard. For this type of building a heat pump with a heating output of 5 kW is sufficient. The simulations were carried out with the refrigerant R134a as working fluid of heat pump and ORC. The simulated system comprises a multi-node storage tank with a volume of 700 l. Six south orientated flat-plate collectors with an aperture area of 2 m² each are installed in the system. The working fluid of the collectors is a 20/80 propylene glycol-water mixture. The characteristics of both storage tank and collector represent those of commercially available products. Hourly data for the ambient temperature and solar radiation for the climatological station Weihenstephan (48° 24' N, 11° 42' E) are taken from the European Solar Radiation Atlas [10]. It is assumed that at 6:30, 7:30, 18:30 and 19:30 in each case 50 l of hot water with a temperature of 45 °C are generated in the coiled tube heat exchanger passing through the storage tank.

The aim of the simulation is to find the optimum configuration of the combined system. For the optimisation the number of collectors in series, the volume flow per string of collectors, the collector slope and the expander inlet temperature of the ORC are varied. The range of these parameters is given in Table 1.

Table 1. Modified parameters for the optimization of the combined system and their range of values.

Parameter	Range of simulated values
Number of collectors in series n_{ser}	1 – 3
Volume flow per string of collectors $\dot{V}_{str}$	20 – 80 l/h
Collector slope β	15 – 55 °
Expander inlet temperature T_{ORC}	60 – 90 °C

Chen et al. [5] simulated a small scale solar-driven carbon dioxide power system and mention the importance of the expansion efficiency as the power output decreases by 60% for an isentropic efficiency of 50% instead of 85%. Wang et al. [7] managed to increase the expansion efficiency from 50% to 70% by using a compliant expander instead of a kinematically constrained one. In this work it is therefore investigated in how far the efficiency of the expansion influences the ORC output and the overall performance of the

combined system. For this purpose additional simulations have been done with efficiencies of $\eta_{s,\exp} = 0.6$ and $\eta_{s,\exp} = 0.7$ instead of the default value of $\eta_{s,\exp} = 0.5$.

The output values of the simulation are the electricity consumption of the heat pump for space heating and domestic hot water as well as the power generated in the scroll expander and the power consumption of the pump of the ground loop in the ORC. The power input of the ground loop pump is assumed to be 60 W and has to be subtracted from the power output of the scroll expander. For the financial evaluation electricity costs are set to 0.2 €/kWh whereas the generated power yields 0.3301 €/kWh under the current German feed-in tariff. All components have been simulated for one year with a time step of one minute except for the ground heat exchanger, which has been calculated on hourly basis. All simulations were performed using Microsoft Visual Basic for Applications scripts

4. Results

The results of the simulation show that the energetic optimum of the combined system is reached for collector slopes between 25° and 35°. The optimum is therefore found for slopes up to 23.4° lower than the rule of thumb of Duffie and Beckmann [14] proposing surface slopes equal to the latitude. This effect can be explained with the fact that in summer the total irradiation on slopes which are tilted to a lesser extent is higher. This relation which favours the ORC together with the influence of the volume flow on the power output of the ORC and the operating time in ORC mode are displayed in Fig. 3 for a connection of three collectors in series and an expander inlet temperature of 70 °C. The decrease of the ORC power output with increasing volume flow per collector string is due to the shorter operating time in ORC mode. With increasing volume flow lower collector outlet temperatures are achieved and thus the ORC starting temperature is reached less often.

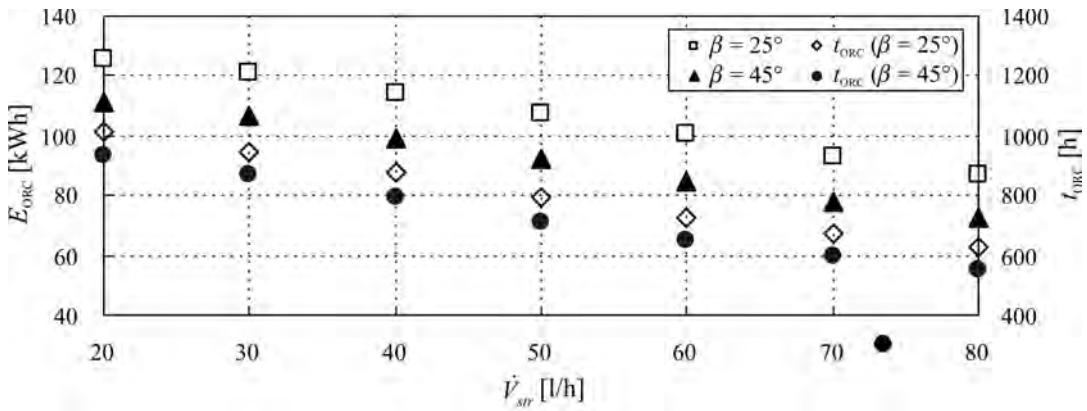

Fig. 3. Influence of the operating time in ORC mode t_{ORC}, the volume flow per collector string $\dot{V}_{str}$ and the collector slope β on the ORC power output E_{ORC} for a connection of three collectors in series and an expander inlet temperature of 70 °C.

The influence of the array configuration, either parallel connection or connection in series, and the specific volume flow per m² aperture area on the system performance is outlined in Table 2 for a collector slope of 25° and an expander inlet temperature of 70 °C. Different array configurations (A, B, C) with the same specific volume yield similar output values. The ORC power output is an exception because it decreases with the number of collectors connected in series. The total electricity demand of the combined system however is almost constant. If the volume flow per collector string is held constant and the number of collectors in series is increased (A, D, E) the electricity consumption of the heat pump for space heating $E_{HP,SH}$ rises. To reach T_{SH} a rather low irradiance is required and the operating time in space

heating mode is quite high. As a consequence the operating time is rising to a lesser extent than the solar gain is dropping because of the lower volume flow. In contrast the electricity consumption of the heat pump for the generation of domestic hot water is reduced and the ORC power output is increased because higher operating temperatures are reached more often and faster for smaller specific volume flows.

Table 2. The effect of the array configuration and the specific volume flow per m² aperture area on the annual electricity consumption of the heat pump for space heating $E_{HP,SH}$ and domestic hot water $E_{HP,DHW}$ as well as the ORC power output E_{ORC} and the total power consumption E_{tot} for a collector slope of 25° and an expander inlet temperature of 70 °C.

Case	n_{ser}	$\dot{V}_{str}$ [l/h]	$\dot{V}_{str}/(n_{ser}\cdot A_c)$ [l/m²h]	$E_{HP,SH}$ [kWh]	$E_{HP,DHW}$ [kWh]	E_{ORC} [kWh]	E_{tot} [kWh]
A	1	20	10	1261.6	611.2	113.4	1759.4
B	2	40	10	1260.1	612.4	102.8	1769.7
C	3	60	10	1258.7	599.2	100.3	1757.6
D	2	20	5	1303.6	598.0	123.5	1778.1
E	3	20	3.33	1354.1	536.5	125.9	1764.7

For the cases A, B and C given in Table 2 the influence of the isentropic expansion efficiency on the expander power output has been investigated. The results are illustrated in Fig. 4 together with the thermal efficiency of an Organic Rankine Cycle with the assumptions made in section 3, an evaporation temperature of 70 °C and a condensing temperature of 20 °C. If the power consumed by the ground loop pump is subtracted from the values depicted in Fig. 4 the same values for the power output of the ORC as in Table 2 are obtained for $\eta_{s,\exp} = 0.5$.

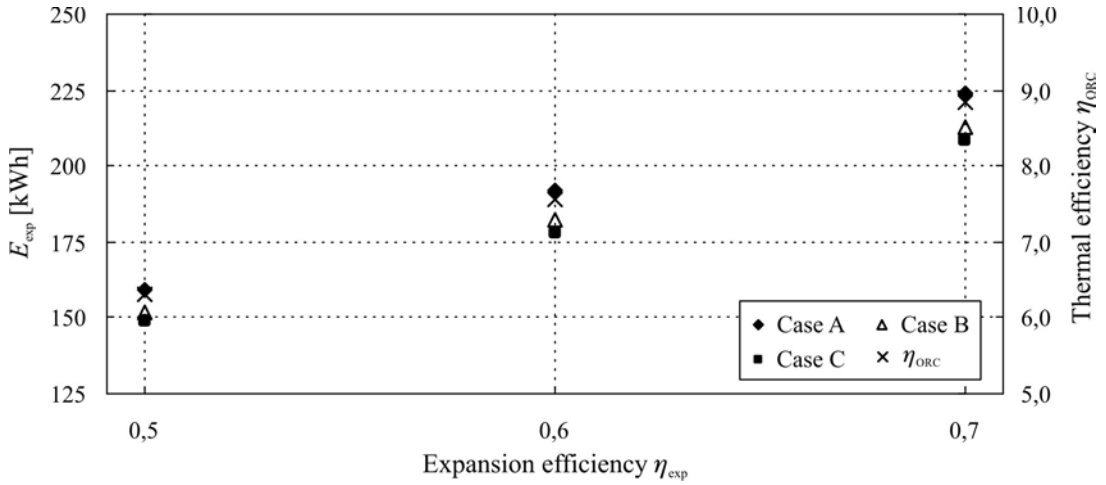

Fig. 4. Influence of the expansion efficiency $\eta_{s,exp}$ on the thermal efficiency of the ORC η_{ORC} and the expander power output E_{exp} for different array configurations with the same specific volume flow.

Fig. 4 shows that the thermal efficiency of the ORC η_{ORC} is the only variable influencing the expander output power. If the efficiency of the expansion is increased by ten percentage points the expander output power and η_{ORC} grow by about 20%. This result is in agreement with the course determined by Chen et al. [5]. With rising thermal efficiency a negligible lower amount of heat is recharged into the ground which would influence the electricity consumption of the heat pump. As the thermal efficiency has no effect on the operating time of the ORC, the power consumption of the ground loop pump remains constant. The results of the simulation reveal that all output values except for the power output remain almost unaffected by the expansion efficiency which has been expected.

Finally the optimised system configurations for each expander efficiency are compared with a conventional system from an energetic and financial point of view. The conventional system is simulated using the methods and assumptions presented in section 2 and section 3 just without the ORC mode. The simulation results for each optimised system and the conventional system are outlined in Table 3.

Table 3. Comparison of the electricity consumption and cost of a conventional solar combisystem and optimised system configurations of the combined heat pump-ORC system for different isentropic scroll expander efficiencies.

$\eta_{s,exp}$	n_{ser}	$\dot{V}_{str}$ [l/h]	β [°]	T_{ORC} [°C]	E_{tot} [kWh]	ΔE_{tot} [%]	ORC-revenue [€]	Total costs C_{tot} [€]	ΔC_{tot} [%]
-	2	30	35	-	1729.3	-	-	346.1	-
0.5	1	40	35	60	1717.4	-0.7	30.2	328.6	-5.1
0.6	1	40	25	60	1693.0	-2.1	41.2	319.1	-7.8
0.7	1	30	25	60	1665.1	-3.6	53.7	308.6	-10.8
0.5	1	30	25	60	1719.5	-0.6	35.8	326.3	-5.7
0.6	3	20	25	70	1727.3	-0.1	61.9	316.3	-8.6
0.7	3	20	25	70	1689.9	-2.3	74.2	303.9	-12.3

The results indicate that the energetic and financial optima are reached for different system configurations. The relative cost savings exceed the energy savings which is due to the fact that 1 kWh generated electricity equals 1.65 kWh consumed electricity because of the feed-in tariff. The energetic optima are reached for a parallel connection of collectors. The rather low energy savings can be explained with the fact that in the combined system the storage tank is charged with less solar heat than in a conventional system. However the combined system is still superior in comparison. For higher expansion efficiencies the array configurations with the lowest specific volume flow become attractive from a financial standpoint as a consequence of the greater ORC revenues.

5. Conclusion

In this work annual simulations of a solar assisted combined heat-pump ORC system have been performed. The results indicate that this system is superior to a conventional solar combisystem from an energetic and financial standpoint. The annual savings strongly depend on the efficiency of the expansion. For a small combined system with a flat-plate collector area of 12 m² the relative energetic savings range from 0.7% ($\eta_{s,exp} = 0.5$) to 3.6% ($\eta_{s,exp} = 0.7$). The absolute monetary savings are about 20 € for $\eta_{s,exp} = 0.5$. They rise to 42 € for an increased efficiency of $\eta_{s,exp} = 0.7$. It therefore seems possible to cover the additional costs that arise from an ORC pump and advanced controls. As the costs for the controls are independent of the system size an application of the combined system is more reasonable in larger dwelling units like hotels, senior citizens' homes and multiple dwelling houses. Experimental studies to evaluate the efficiency of the scroll compressor in expansion mode are required. The results of this study concerning collector slope and volume flow can also be transferred to future works regarding solar-driven Organic Rankine Cycles.

Abstract: This paper presents results of theoretical investigations on the determination of optimal design parameters of a Low Temperature Difference (LTD) Solar Stirling Engine using optimisation method based on Genetic algorithms. The developed thermodynamic mathematical model of the engine takes into account hydraulic and mechanical losses in the engine's working process and this model was coupled to the optimisation algorithm. A set of such design parameters as the stroke of the displacer and diameter and stroke of the power piston and the thickness of the regenerator placed in the displacer have been considered as variables. The engine's performance parameter such as the brake power is used as the objective function of the optimisation algorithm. The GA code is implemented in MATLAB. The accuracy of the optimal design engine's performance is examined using 3D CFD modelling of the working process of the engine. The set of design parameters obtained from the optimisation procedure provides the noticeable improvement of the engine's performance compared with the performance of the original LTD Solar Stilring engine with the same operating condition.

1. Indroduction

Low Temperature Difference (LTD) Stirling engines, though provide low electricity production, can be used as solar energy and waste heat recovery system due to their simple design and low cost production [1]. There is an interest towards development of LTD Stirling engines for deployment in rural areas of developing countries for production of power on the small scale. Because of this reason, numerous studies have been conducted for determination of optimal design parameters of LTD Stirling engines. Several thermodynamic mathematical models have been used for the determination of the optimum power and efficiency of such engines [2-7]. Furthermore, a considerable work was done on the development of optimisation algorithms for conventional high temperature engines [8, 9]. The search method which uses the Genetic algorithm (GA) code coupled to the mathematical model accounting for heat and mechanical losses using the theorem of forced work was presented by Altman in [9]. This work presents the determination of optimal design parameters of a LTD Stirling engine using GA optimization method, coupled to the second-order model of the engine, which takes into account hydraulic and mechanical losses, developed by Kraitong and Mahkamov [10]. Additionally, 3D CFD simulations using CFD FLUENT software were performed to calibrate results of the optimization calculations.

2. Physical model

Figure 1a represents a schematic diagram of the kinematical gamma LTD Stirling engine. The main components of the LTD Stirling engine are the power piston and displacer with corresponding cylinders, the hot and cold plates, , the regenerator placed inside the displacer and the drive mechanism with the flywheel. In this paper, a twin-power piston LTD Stirling engine, see Fig. 1b, manufactured by Kongtragool and Wongwises [11] is used in numerical investigations. This engine consists of two power pistons and one displacer with the built-in regenerator. The regenerator is made of coarse stainless steel mesh placed in the casing perforated at its top and bottom. Table 1 presents data on the physical dimensions of this Stirling engine.

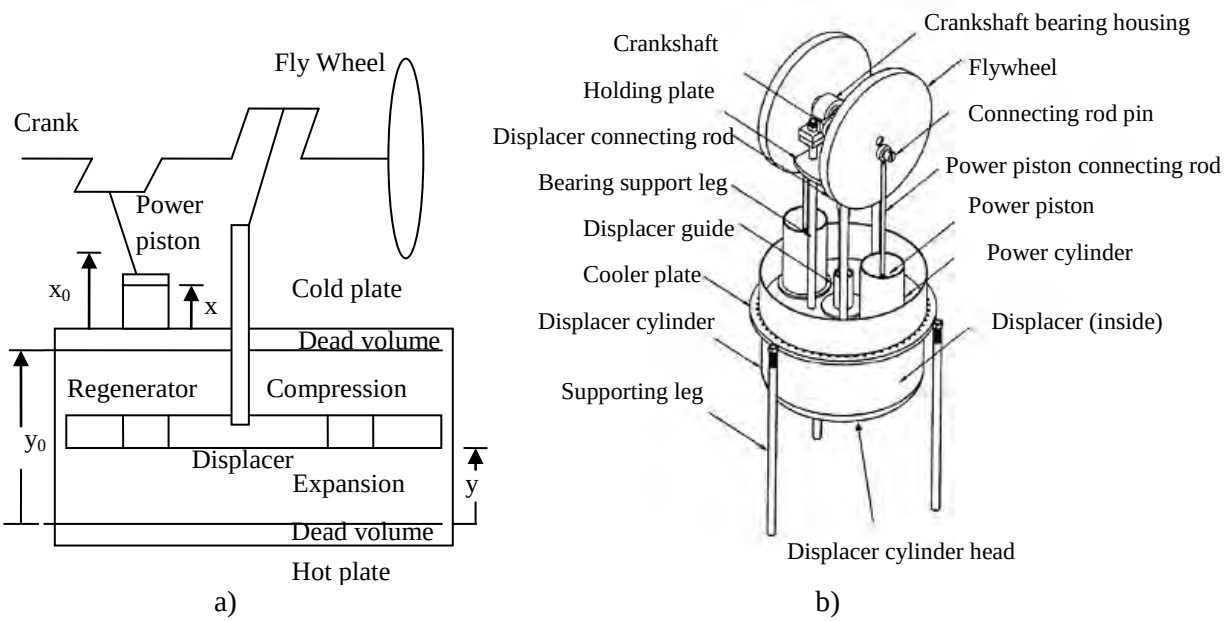

Fig. 1. a) A Schematic diagram of the kinematic gamma LTD Stirling engine and b) The physical characteristic of the twin power piston LTD Stirling from Kongtragool and Wongwises [11].

Table 1. Dimensions of the LTD Stirling engine manufactured by Kongtragool and Wongwises [11]

The geometric data of a twin power piston LTD Stirling engine	Value
working piston stroke (m)	0.0826
working piston diameter(m)	0.083
working piston swept volume (m^3)	893.8×10^{-6}
displacer piston stroke (m)	0.0795
displacer piston diameter (m)	0.32
displacer piston swept volume (m^3)	6393.8×10^{-6}
swept volume ratio	7.15
displacement phase angle of the pistons (°)	90

3. Modelling Procedure

3.1. Thermodynamic modelling

The second-order mathematical model taking into account the pressure drop and the mechanical losses developed by Kraitong and Mahkamov [10] was used for the performance prediction of the engine. This model is the modification of that developed by Timoumi et al. [7] and Urieli [12]. The equations of energy and mass conservation for each control volume are expressed as follows:

$$C_v \frac{d(mT)}{dt} = dQ - \frac{dW}{dt} - \dot{m}_o C_p T_o + \dot{m}_i C_p T_i \quad (1)$$

$$\frac{dm}{dt} = \dot{m}_o - \dot{m}_i \quad (2)$$

Work done by the working gas inside the compression space and the expansion space can be calculated as $\frac{dW_c}{dt} = P_c \frac{dV_c}{dt}$ and $\frac{dW_e}{dt} = P_e \frac{dV_e}{dt}$, respectively.

Volumes of the compression and expansion spaces are expressed as

$$V_c = V_{dc} + \frac{V_{SP}}{2}\left(1 + \cos(\theta - \varphi)\right) + \frac{V_{SD}}{2}\left(1 - \cos\theta\right) \quad (3)$$

$$V_e = V_{de} + \frac{V_{SD}}{2}\left(1 + \cos\theta\right) \quad (4)$$

where $V_{SP} = \pi \frac{D_p^2}{4} Z_p$ and $V_{SD} = \pi \frac{D_D^2}{4} Z_D$.

In order to determine the brake cyclic power, the kinetic motion equations of the mechanical transmission system of the reciprocating engine proposed by Guzzomi et al. [13,14] were used. The determination of the frictional forces in the sealing rings of the displacer rod is carried out using methodology described in [15]. These results were used to calculate the torque induced by the pistons (T_p). The brake cyclic work and the brake cyclic power, therefore, are calculated as

$$T = \Sigma T_p \tag{5}$$

$$W_b = \oint \left(\frac{dW_b}{dt} \right) dt = \int_0^{\tau} \left((T - T_b) \frac{d\theta}{dt} \right) dt \tag{6}$$

$$P_b = W_b f \tag{7}$$

For numerical calculations, the cycle was split into 1000 time-steps and calculations were performed until the pressure and temperature curves converged and the overall heat balance in the system was reached.

3.2. CFD modelling

To achieve better understanding of the working process of the LTD Stirling engine and obtain more accuracy in the performance prediction, 3D CFD modeling using the standard k-ε turbulence model for a compressible flow was carried out to investigate the work of the engine. Commercial CFD software, FLUENT was used to perform CFD simulations of the working process of the engine. During the simulations the movement of pistons was taken into account and the regenerator of the engine was treated as a homogeneous porous medium. The subroutines describing displacements of the pistons and the displacer were written and then connected to the main body of the programme. The cycle was divided into equal 500 time-steps and calculations were performed using a high performance computer. The average gas temperature and pressure in each engine's working space were monitored during calculations in order to determine whether the steady-state condition was reached in the simulated operation of the engine.

3.3. Optimisation modelling

Genetics algorithm is a stochastic optimisation method based on the mechanism of natural selection for survival as the procedure in order to obtain optimal results [16]. The real-valued GA or the continuous GA is applied in this work for the quantitative limitation and the reduction of the computing time [17]. The structure of the continuous GA of the LTD Stirling engine is represented in Fig. 2.

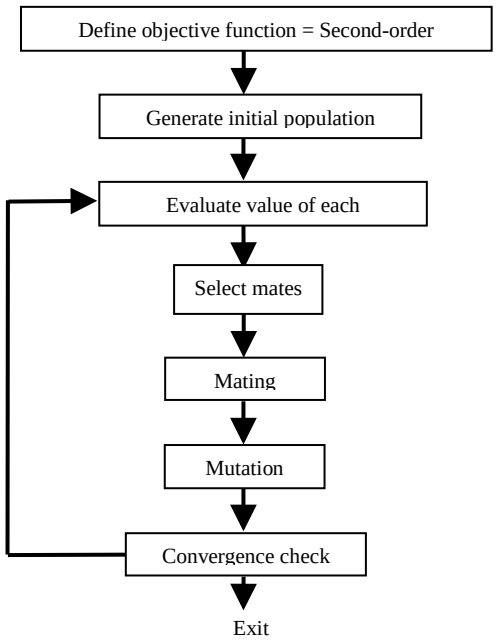

Fig. 2. The structure of the continuous GA of the LTD Stirling engine.

Several original engine design and operational parameters, namely the diameter of the displacer of 0.32 m, the engine speed of 46.5 rpm, the solar irradiation of 5097 W/m^2 created using a solar simulator and the cooler surface temperature of 307 K, are accepted to be fixed as constant values in this work. There are only four engine design parameters are defined as variables. These are the diameter and the stroke of the power piston, the stroke the displacer and the thickness of the regenerator:

$$Chromosome = (D_p; Z_p; Z_D; H_d) \quad (6)$$

The upper and the lower bound of each variable are as follows;
$0.02 < D_p < 0.13$; D_p is diameter of piston (m)
$0.04 < Z_p < 0.3$; Z_p is stroke of piston (m)
$0.04 < Z_D < 0.3$; Z_D is stroke of displacer (m)
$0.01 < H_d < 0.2$; H_d is thickness of regenerator (m)

The above boundaries are defined based on the practical manufacturing and design considerations. The maximum diameter of the piston is limited by the diameter of the cold plate which is equal to the fixed displacer diameter. The range of the displacer stroke to be investigated is typical for displacers of LTD Stirling engines [18]. Only one of the engine's performances, namely the brake power, is defined to be the chromosome value because the heat source is solar energy which is assumed to be cost-free. The the brake power of the engine obtained using the developed second-order mathematical model is used as the objective function:

$$Brakepower = f(chromosome) = f(D_p; Z_p; Z_D; H_d) \quad (7)$$

In GA, there is no effect of the guessed initial chromosomes on the convergence of the solution, thus the initial population is created by using the absolutely random procedure. A generated initial population is in the matrix formation of various chromosomes. The size of the population effects the convergence in the optimization procedure. The number of chromosomes between 30 and 100 is the typical size to operate GA [19]. In this study, the number of chromosomes in a generation of 30 is used. The chromosome value which is the brake power is evaluated by the fitness function for locating in the value map of each generation [20]:

$$Fitnessvalue = \frac{1}{1 + maxvalue - value} \quad (8)$$

The fitness value of each chromosome is descending order to determine survival chromosomes for the next generation. The number of survival chromosomes is defined by the selection rate of 0.5 from the weighted random pairing selection and the rank weighting technique [17]. The single point crossover is used for the mating process that the parents are operated by the reproduction operator to produce some offsprings for the next generation. Fittest chromosomes of the ranking are randomly selected to be the parents for the reproduction operation. The second operator of the reproduction called the mutation is used as a tool to avoid finding only the local solution. The mutation rate of 0.2, though probably is high, results in the gradual convergence and ensures that the global maximum is not missed out in during simulations [17].

Finally, the new generation is produced and the population of new design parameters in this generation is then evaluated by the developed thermodynamic model and the fitness function is checked for the ranking until the solution found satisfying the termination condition. The maximum number of generation in the computing process of 80 is defined to obtain the convergence of this algorithm. The optimisation code was modified from [19] and implemented in MATLAB. In this case, the continuous GA was used to obtain the optimal design parameters for the performance's improvement of an original LTD Stirling engine. Simulations were, thus, conducted for the same operating condition. A set of optimal design parameters from the numerical simulations was then used to create the engine mesh for the 3D CFD simulation to more accurately predict the engine power.

4. Results from optimisation cacluations

The modelling of the engine with the SM15-matrix regenerator was performed for the constant solar flux of 5097 W/m^2, the cooler surface temperature of 307 K, the engine speed of 46.5 rpm with air at 1 bar pressure used as a working fluid. Figure 3 represents the best brake power for each generation. The best brake power first sharply increases and then gradually reaches the convergence with its value of 1.515 W. The design parameters of this generation are presented in Table 2. The corresponding indicated power is 1.668 W.

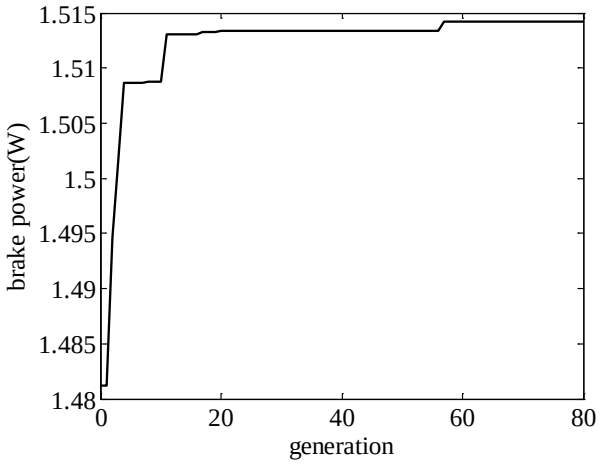

Fig. 3. The best brake power of each generation as the function of generations.

Table 2. The first set of optimal engine design parameters obtained from optimisation simulation.

Optimal engine design parameters	Value
working piston stroke (m)	0.228
working piston diameter(m)	0.065
displacer piston stroke (m)	0.074
displacer thickness (m)	0.056

However, it could be seen that the stroke of the power piston of 0.228 m which is much longer than the stroke of the displacer of 0.074 m. This may be unsuitable for the practical engine. Thus, the power piston and displacer strokes were fixed at 0.1 m and a new set the optimisation simulations with two variables were run. Optimal engine parameters from the second run are presented in Table 3 and the maximum brake and indicated power is 1.346 W and 1.47 W, respectively. There is only 11% reduction in power when compared with the results of the first optimization run.

Table 3. The second set of optimal engine design parameters is obtained from optimisation simulation.

Optimal engine design parameters	Value
working piston stroke (m)	0.1
working piston diameter(m)	0.1
displacer piston stroke (m)	0.095
displacer thickness (m)	0.058

Finally, two engines with optimal engine parameters shown in Tables 2 and 3 were modelled using 3D CFD simulation. The indicated power of the first and the second engine calculated from P-V diagrams which are shown in Fig. 4a and Fig. 4b are 1.427 W and 1.352 W, respectively. 3D CFD modelling results demonstrate that the second-order thermodynamic model used in oprimisation procedure has an adequate accuracy in the prediction of the engine performance.

5. Conclusion

The developed second-order mathematical model of the LTD Stirling engine was developed which accounts for hydraulic and heat losses in the working process and mechanical losses in the engine. This model was used with GA optimisation code. As a result of optimization simulations a set of design parameters for the engine was obtained which provides a considerable improvement in the performance. Results obtained using the developed second-order thermodynamic model were calibrated using 3D CFD modeling technique. The optimisation procedure developed in his work can be applied to improve the design of a wide range of Stirling engines, including high temperature ones.

Abstract: In a liquid desiccant air conditioner developed at Materials & Energy Research Centre (MERC), dehumidification of the outside air is achieved through a packed-bed heat and mass exchanger, using lithium chloride solution as the desiccant. The dry air thus obtained is evaporative cooled inside a cooling pad and directed into the conditioned space. The dilute solution from the dehumidification process is concentrated in a scavenger air regenerator using hot water from flat plate solar collectors. Carryover of the desiccant particles has been avoided by using eliminators, such as demister or filter.

In this paper the experimental results obtained from testing the prototype of the liquid desiccant absorber unit in a simulated Persian Gulf summer has been presented and compared with a previously developed model for the packed-bed. The comparison reveals that good agreement exists between the experiments and model predictions. The inaccuracies are well within the measuring errors of the temperature, humidity and the air and solution flow rates. The above tests further reveal that the unit would have a satisfactory performance in controlling the air temperature and humidity if installed on a commercial site of about 200 m^2 area in a hot and humid climate.

A commercialization study was performed for the solar operated liquid desiccant air conditioner (LDAC) and compared with the conventional vapour compression system. The study reveals that the operating cost of an LDAC is significantly lower than its conventional counterpart. The costs would further reduce if a storage system was used to store the concentrated solution of liquid desiccant. A simple payback of five years was determined for the solar components of the liquid desiccant system in this study.

Keywords: *Liquid desiccant, Dehumidification, Packed-bed, Solar regeneration.*

1. Introduction

Much work has so far been conducted in the area of air dehumidification using liquid desiccant and a cross-flow or a packed-bed type heat and mass exchanger, as the dehumidifier [1]. The use of the solar liquid desiccant air dehumidification / cooling system appears to be promising in hot and humid locations of Iran, such as the Persian Gulf region, due to high availability of solar energy. Figure 1 shows a schematic diagram of the solar air conditioner.

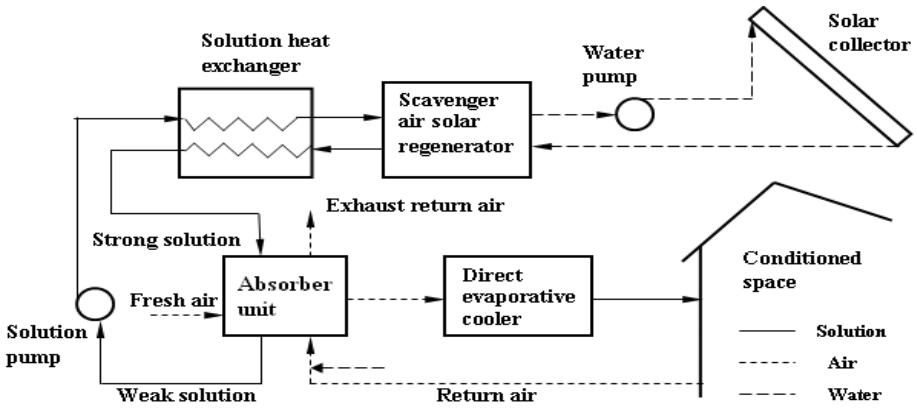

Figure 1. schematic diagram of a liquid desiccant solar air conditioner

Outside air is dehumidified in the absorber unit using a strong solution of lithium chloride and cooled within a direct evaporative cooler before it is introduced into the conditioned space. The dilute solution thus obtained is concentrated in a scavenger air solar regenerator using hot water from flat plate solar collectors. A solution heat exchanger, as indicated in the figure, is used for heat recovery between the strong and weak solutions. Return air from conditioned space has also been used to take some heat out of the outside air as shown in Figure 1.

Considerable laboratory experiments, computational analysis and design work has been carried out on a liquid desiccant system at the Sustainable Energy Centre of the University of South Australia [2-6], and the Queensland University of Technology [7, 8]. These involved modelling and experimental work on both cross flow and packed-bed dehumidifier as the absorber unit as well as the solar regenerator [9]. In the packed-bed system used in this study, different packing materials are considered, which include the polymer type usually used in cooling tower applications and the counter flow type with a layer of wick applied to the heat exchanger surfaces to reduce the carry over of the desiccant particles into the conditioned space, as well as to increase the dehumidification efficiency of the air conditioning unit.

In a solar liquid desiccant system the weak desiccant can be concentrated, stored and used at a later time; therefore, energy is stored as concentrated solution in the system rather than thermal. The system provides the options of using the solar LDAC either as a packaged roof top air conditioner for domestic or commercial use or as an air handler unit in commercial applications such as conditioning large volumes of ventilation air. The LDAC could also be used for space heating in winter due to the property of desiccants to provide heat when wetted and, thereby, indirectly heat the supply air.

2. Testing the conditioner prototype

In the experimental tests carried out on the developed LDAC, dehumidification and cooling are both achieved within the absorber unit by using liquid desiccant and the cool air from the conditioned space, respectively. A photograph of the absorber unit showing the system main components is demonstrated in Figure 2.

Figure 2. The LDAC packed-bed dehumidification unit as viewed from the MERC Energy Laboratory.

This 20 kW unit has an overall dimensions of approximately 1.3 × 1.5 × 1.8 m. The conditioner casing is made from an insulating material to protect the system from heat transfer with the environment. The packing material is incorporated vertically inside the dehumidification tower with the weak solution container at the bottom. The conditioner prototype was optimized for the air and solution flow rates, further reducing electrical power consumed by the unit.

Preliminary tests have been carried out on the system with water to ensure a smooth operation of the unit. These involved running the air conditioner at variable fan speeds by reducing the applied voltage from 220 to 110 V. The air velocity on the supply and exhaust sides of the conditioner and on a face area of approximately 0.15 m^2 was measured. The power consumed by the fan during the system operation was also measured and recorded.

Two sets of experiments were carried out with liquid desiccant. In the first set of the experiments, the absorber unit was tested with desiccant only sprayed into the outside air, while the direct evaporative cooler was inactivated. The experiments were aimed to investigate the air temperature rise due to condensation of the air moisture content, and reduction in the air relative humidity. The process of dehumidification / cooling of the outside air for these two experiments are shown on the psychrometric chart in Figure 3. The dashed line on this figure represents the test with desiccant only.

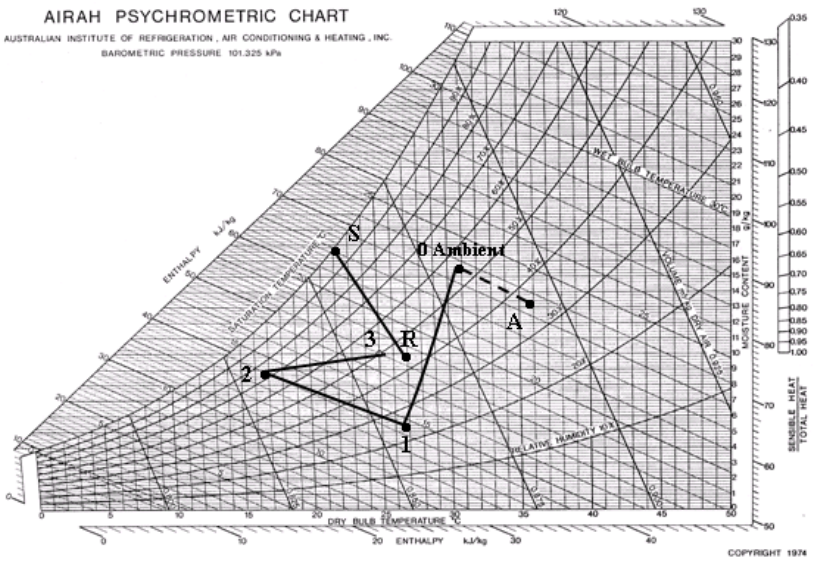

Figure 3. Psychrometric paths for the tests with: (a) desiccant only (dashed line); and (b) desiccant followed by evaporating cooling of the air. (Supply air: 0-1-2-3; Return air: R-S)

In the second set, the system was operated with the evaporative cooler activated, while lithium chloride solution was sprayed into the outside air. The test was to investigate the effect of dehumidification and direct evaporative cooling on the supply air. The process of dehumidification / cooling of the outside air for the above two experiments are shown on the psychrometric chart in Figure 3. The dashed line on this figure represents the test with desiccant only.

Following each set of experiments with liquid desiccant, the concentration of the dilute solution was measured, using a conductivity meter. A plot of conductivity-concentration as

indicated in Figure 4 was then produced for diluted samples and for several conductivity measurements. The plot was used to determine the subsequent values of concentration for new desiccant solutions, using a correction factor to be accounted for higher concentration values. The weak solution obtained from the dehumidification process in the above experiments was regenerated in a scavenger air solar regenerator. This will be described in section 4.

In Figure 5, the effect of air flow rate on the air temperature and relative humidity of the outside air has been studied. The air temperature and relative humidity on this figure are denoted by T_{bp} and H_{bp}, respectively, which are the air conditions before entering the packed-bed column. As seen from the figure a substantial reduction in the air relative humidity is achieved after it passes through the packed-bed column, which is due to the spray of the desiccant solution over the packing material. In Figure 5, values of the air temperature and relative humidity, following the dehumidification process, are denoted as T_{ap} and H_{ap}, respectively.

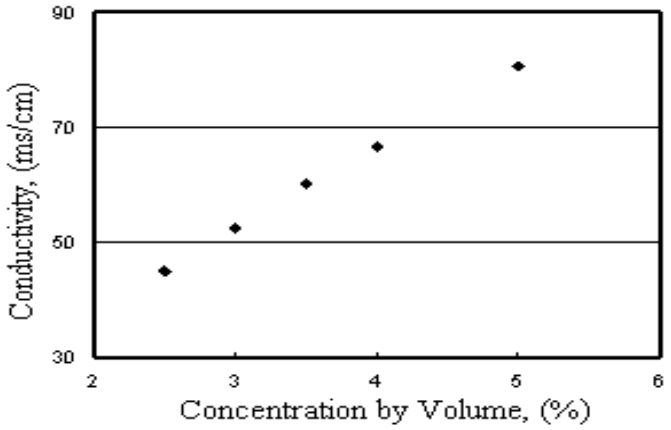

Figure 4. Conductivity-concentration chart for the lithium chloride solution.

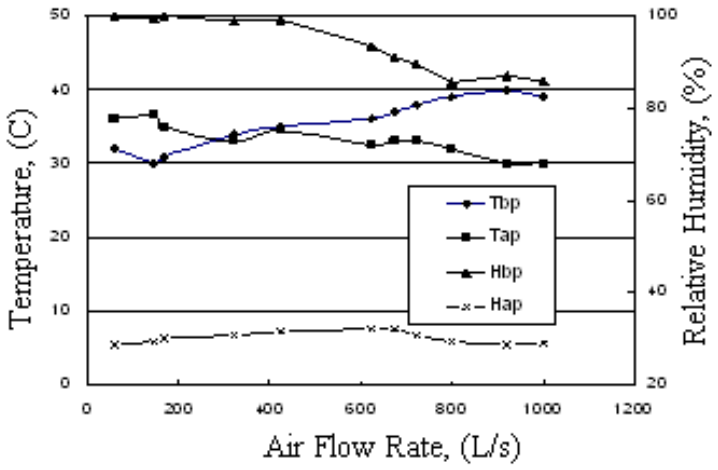

Figure 5. The effect of air flow rate on dehumidification process of the outside air.

In Figure 6 the experimental values of the temperature and humidity after the packing are compared with the predictions obtained from a developed model for the packed-bed. As can be seen from the figure there is good agreement between the data obtained from theory and experiment.

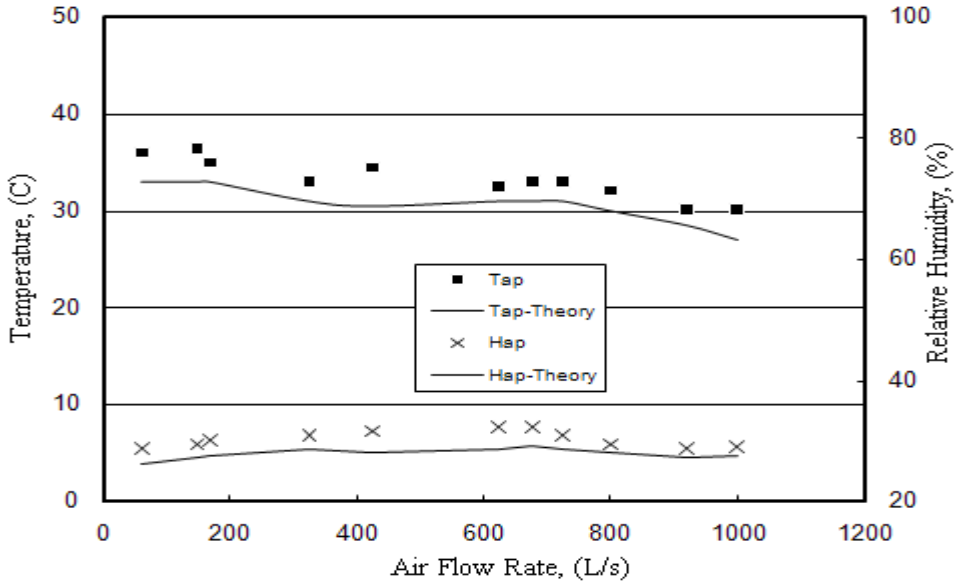

Figure 6. Comparison between the results obtained from the model and experiment.

3. Discussion of the test results

In the tests with desiccant only, the air dehumidification by liquid desiccant is an adiabatic (constant enthalpy) process; therefore, no heat is added or removed from the air during the process. However, according to Figure 3, for an adiabatic dehumidification the air dry bulb temperature increases as the relative humidity reduces. This is due to the heat generated in the process as a result of water vapour condensation in the air. The air wet bulb temperature as seen in Figure 3, remains constant.

The results from the tests with evaporative cooler and desiccant prove a satisfactory performance of the unit in a tightly control of the air temperature and humidity if installed on a commercial site of approximately 200 m^2 area in a hot and humid climate. This will maintain the building air conditions within the comfort zone (dry bulb temperature of about 25 °C and 50% relative humidity). The results of the tests further reveal that there are optimum values of air and solution flow rates, where the conditioner performance is enhanced.

To quantify the confidence level of the experimental data, the results of an uncertainty analysis are presented in Table 1 for the experimental values obtained from testing the conditioner prototype. In this analysis, the fixed errors are assumed to be calculated and accounted for via calibration against known standards. Hence, the remaining error is solely due to the precision error. The precision errors were determined by statistical means or from data provided by equipment manufacturers or by the best estimate based on experimental observations. Since the prototype testing of the absorber unit was under many uncontrolled environmental conditions, the results are quite acceptable.

The results obtained from the demonstration system in this study have been used in a solar liquid desiccant pilot plant project currently ongoing at MERC. The system was built and installed within the Fluid Mechanics Laboratory at Babol University of Technology, a hot and humid location on the Caspian Sea in the north of Iran. The system, which is also used for heating during the winter, is now being tested and monitored for a full year operation. Similar

equipment will also be installed and tested on the Persian Gulf region in southern part of the country, where the temperature and humidity are very high during most of the year.

Table 1. Experimental results obtained from the conditioner test and the uncertainty values.

Conditioner performance parameters	Measured values	Precision errors	Uncertainty values %
Supply and return air flow rates, L/s	1000	100	10
supply air temperature °*C*	15.2	1	6.7
supply air humidity ratio, kg/kg	0.0094	0.0005	5.3
Solution flow rate, L/min	3	0.2	6.8
Exit solution concentration, (*wt* %)	0.412	0.008	2
Effectiveness, %	82	5	6.1
Latent cooling, kW	16.7	0.5	3.3
Sensible cooling, kW	3.3	0.1	3.1
electrical energy used, kW	3	0.1	3.3
Total cooling, kW	20	0.6	3
Electrical COP	7	0.2	2.8

4. Performance of the solar regenerator

The concentration of dilute solution in this study is carried out in a scavenger air regenerator, using hot water from flat plate solar collectors. Both the scavenger air and the weak solution are preheated within the regenerator; however, solution regeneration will be more effective when preheating the air than preheating the solution [9]. It is notable that the lithium chloride desiccant can be concentrated using solar energy or other low grade heat at temperatures as low as 40 °C. The flat plate solar collectors used in this study can produce hot water at about 85 °C in summer.

In a scavenger air regenerator the weak solution is sprayed over a column of packed-bed (see Figure 7). Polymer pall rings, spheres or other polymer based materials are used as a packed-bed to increase the contact area between the solution and the scavenger air, which facilitates the regeneration process. A stream of outside air is passed through the column, using a fan, in a counter current operation to pick up the water evaporated from the solution, and the hot moist air is, subsequently, exhausted from top of the column. A mist eliminator, as shown in Figure 6, is used at the top of the regenerator column to prevent the carryover of the desiccant particles. Gas or electricity could be used as a back up for the regenerator during the peak cooling hours.

Eliminators, such as demister, are used to avoid carryover of desiccant into the environment. Alternative method in preventing the carryover is the use of indirect cooling, in which the supply air does not contact the desiccant [10]. The latter could also be used to produce potable water from the atmospheric air in remote areas when a cross flow plate heat exchanger is used. The water can either be used for human consumption or returned to the conditioner for evaporative cooling of the air.

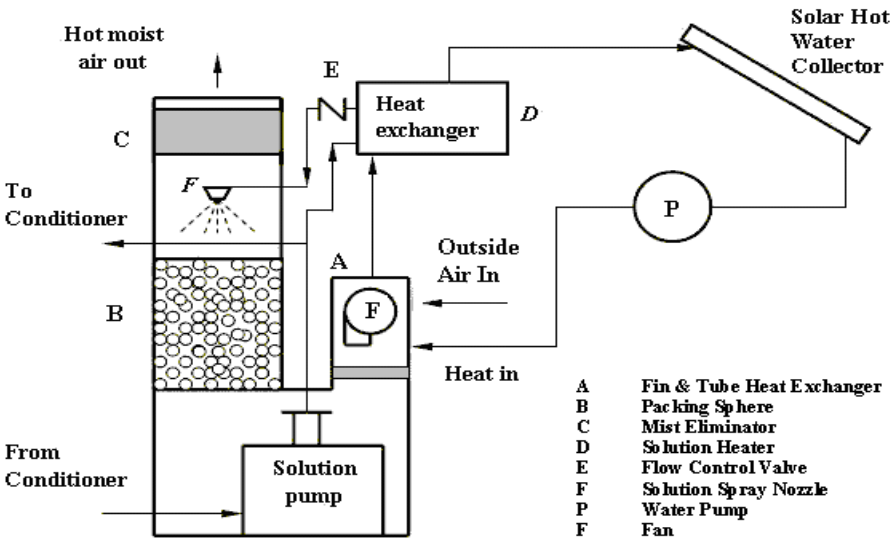

Figure 7. Schematic of the scavenger air solar regenerator.

5. Commercialization strategy for a solar LDAC

An LDAC, in which the carryover of the desiccant has been eliminated, creates new opportunities for solar cooling. A commercialization strategy has been proposed in this study for a solar operated LDAC and compared with conventional vapour compression systems. Based on the computer modelling results obtained from the system simulation for a building in the Persian Gulf region, the operating costs of an LDAC is significantly lower than its conventional counterpart. This study further reveals that using the solar operated LDAC with a storage system for the concentrated solution, will result in considerable savings in operating costs when compared with the equivalent gas-fired liquid desiccant system. A simple payback of five years was determined for solar components of the system in this study.

A 30 kW capacity, packaged roof-top LDAC delivering 1.5 m^3/s of outside air could be used in domestic applications as well as the commercial. The unit uses a storage system and 100 m^2 of flat plate solar collector to dehumidify and cool 500 m^2 of a residential building in the Persian Gulf region. Compared with the conventional unit, an annual saving of $2,500 with a payback of less than 5 years was determined for the solar LDAC in this application.

6. Conclusion

In this paper the performance of a solar LDAC developed at MERC, using packed-bed for air dehumidification, and a scavenger air regenerator was studied. It was found that the solar liquid desiccant system is an efficient and cost effective alternative to the conventional air conditioner. Elimination of carryover of the desiccant particles within the absorber unit in this study was performed through the cooling pad of the direct evaporative cooler, which acts as a filter, as well as evaporative cooling of the supply air. Using the indirect cooling technique, the unit could produce potable water from the atmospheric air in remote areas.

Experimental results obtained from prototype testing of the LDAC absorber unit indicates that the unit has a satisfactory performance in controlling the temperature and humidity when installed on a commercial site of about 200 m^2 area located on the Persian Gulf region. The tests further reveal that the experiments are in good agreement with a previously developed model for the packed-bed and that the conditioner unit can have an effectiveness of about 82% when used with liquid desiccant. The maximum electrical energy utilization of the unit,

which was determined through the above experiments, is 3 kW with an electrical COP of about 7.

For domestic roof-top applications, it was determined that a 30 kW capacity LDAC could dehumidify and cool 500 m^2 of a residential building on the Persian Gulf with an annual saving of $2,500 and a payback of less than 5 years.

Abstract: The effectiveness of solar adsorption system for space conditioning would be enhanced through radiant ceiling cooling, since a higher chilled water temperature can be supplied. In such provision, desiccant dehumidification should be involved in order to cater for the latent cooling load. A solar hybrid adsorption refrigeration system is therefore formulated. In this study, the effect of radiative load ratio *R* of active chilled beams (ACB) and passive chilled beams (PCB) for the solar hybrid adsorption refrigeration system was investigated. Through the year-round dynamic simulation, it was found that the performances, like solar fraction and primary energy consumption, of the system with ACB or PCB would be improved along with the decrease of *R* from 0.3 to 0.1. At the same *R*, the system with PCB would have better performances than that with ACB. With suitable design and control, the solar hybrid adsorption refrigeration system with PCB at low *R* would be more technically feasible for office use in the subtropical climate.

Keywords: *Radiant cooling, Radiative load ratio, Adsorption refrigeration, Solar air-conditioning, High temperature cooling*

1. Introduction

To promote the low energy buildings in the hot and humid places, strategic use of renewable energy in air-conditioning would certainly contribute to sustainable design. Solar air-conditioning is getting popular in the European countries [1,2]. Through the approach of high temperature cooling, the energy performance of chiller can be enhanced by using higher chilled water supply temperature for radiant cooling. As the latent cooling load cannot be effectively handled in such provision, a separate desiccant dehumidification is necessary [3,4]. In fact, it would be effective to hybridize the adsorption refrigeration, radiant cooling and desiccant dehumidification, driven by solar energy for building space conditioning. In the previous study [5], this solar hybrid adsorption refrigeration system would have much less annual primary energy consumption than the conventional vapour compression air-conditioning system for office application. In this study, it is to investigate more deeply about the effect of chilled beams on the performances of the solar hybrid adsorption refrigeration system in the subtropical city.

The common chilled beams include the active chilled beams (ACB) and passive chilled beams (PCB), which are mounted at the ceiling level but not for structural purpose. ACB have finned coils, in which chilled water flows inside. ACB make use of forced convection for cooling through induction, so they are connected with a supply air stream that is mechanically driven. PCB also have finned coils inside, but they rely on natural convection rather than forced convection. Therefore, their performances would be affected by the radiative load ratio, which is the proportion of radiative to total (i.e. radiative and convective) cooling capacity of the chilled beams. In this study, the effect of the radiative load ratio *R* on the year-round performances of the solar hybrid adsorption refrigeration system was evaluated for the office application. Two types of offices were involved, a typical office and a high-tech

office, where the latter is featured with a much higher internal heat gains due to different electrical facilities of information technology and office automation.

Fig. 1 illustrates the design of solar hybrid adsorption refrigeration system with ACB serving an office. Solar energy is collected to supply to the adsorption refrigeration and the desiccant dehumidification through regenerative water and desiccant water respectively. Auxiliary heaters are involved whenever the required driving temperatures are not sufficient. The adsorption chiller provides chilled water to the chilled beams for sensible cooling, it also furnishes the chilled water to the supply air coil for supporting the desiccant dehumidification. The chilled beam valve and the supply air valve are used to control the required chilled water flow rate to the respective equipment. For the system with ACB, supply air fan is needed for induction of indoor air. However for PCB, no supply and return air fans, and the associated air ducts are required.

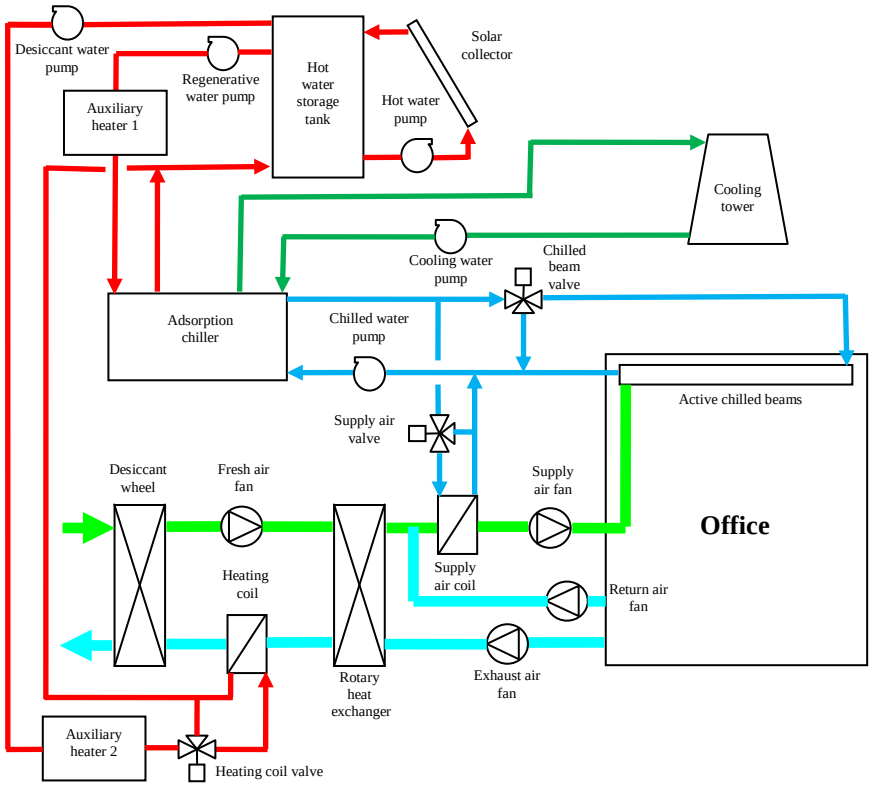

Fig. 1. Solar hybrid adsorption refrigeration system for active chilled beams.

2. Methodology

In this study, year-round dynamic simulation was applied for the solar hybrid adsorption refrigeration system. Generally the entire system model was built on the component-based simulation platform TRNSYS [6], and the validated component models of adsorption chiller [7] and desiccant wheel [8] were used. The models of ACB and PCB were developed from the empirical information of the manufacturers [9,10]. The other system components, including the office building zone, solar collector, storage tank, auxiliary heaters, rotary heat exchanger, water coils, cooling tower, pumps, fans and valves were based on those of TRNSYS and the component library TESS [11]. Different radiative load ratios were adjusted at the TRNSYS multizone building model. The indoor design conditions were set at 25.5°C and 60%RH. The floor area was 196 m^2 with 24 occupants and daily working schedule

between 08:00 to 18:00. The fresh air amount was based on 10 litres/s per occupant. The subtropical city Hong Kong (22.32°N and 114.17°E) was used, and the year-round dynamic simulation was carried out with the typical meteorological year for Hong Kong [12]. The major simulation parameters of the solar hybrid adsorption refrigeration system are summarized in Table 1.

Table 1. Values of major simulation parameters of solar hybrid absorption refrigeration system.

Fresh air stream		
Fresh air mass flow rate ($kg \cdot s^{-1}$)		0.288
Fresh air fan power (kW)		0.277
Exhaust air stream		
Exhaust air mass flow rate ($kg \cdot s^{-1}$)		0.259
Exhaust air fan power (kW)		0.166
Rotary heat exchanger		
Temperature effectiveness of rotary heat exchanger		0.8
Rotary heat exchanger power consumption (kW)		0.1
Desiccant wheel		
Mass per unit length of matrix material in desiccant wheel ($kg \cdot m^{-1}$)		0.003
Mass per unit length of silica gel in desiccant wheel ($kg \cdot m^{-1}$)		0.005
Half height or width of air channel (m)		0.0015
Outer diameter of desiccant wheel (m)		0.6
Effective area ratio of desiccant wheel		0.744
Fraction of wheel area for regeneration		0.5
Length of desiccant wheel (m)		0.2
Desiccant wheel speed (rph)		13
Number of discretization segments along the air channel length		20
Number of time steps for one revolution of the desiccant wheel		360
Desiccant wheel power consumption (kW)		0.1
Adsorption Chiller	**Typical**	**High-tech**
Number of stages per chiller	2	
Mass of metal in adsorption/desorption chamber per stage (kg)	60	80
Mass of silica gel in adsorption/desorption chamber per stage (kg)	30	40
Mass of metal in condenser coil per stage (kg)	75	90
Mass of metal in evaporator coil per stage (kg)	75	90
Maximum adsorbate intake in Freundlich equation	0.552	
Exponent in Freundlich equation	1.6	
Ratio of initial absorbrate intake to maximum abosrbrate intake	0.7	
Adsorption/desorption period (s)	360	

Cooling water system	**Typical**	**High-tech**
Cooling tower air volume flow rate ($m^3 \cdot s^{-1}$)	2.640	3.333

Return air mass flow rate (kg·s-1)	0.72	1.056
Return air fan power (kW)	0.092	0.135

3. Results and discussion

3.1. Performance indicators

A number of performance indicators were used in this study, including solar fraction *SF*, coefficient of performance *COP* and primary energy consumption *PE*, as determined below.

$$SF = \frac{Q_{sol}}{Q_{sol} + (Q_{aux1} + Q_{aux2})} \quad (1)$$

where Q_{sol} is the solar thermal gain, Q_{aux1} and Q_{aux2} are the heat output from Auxiliary Heaters 1 and 2 respectively.

$$COP = \frac{Q_e}{Q_g} \quad (2)$$

where Q_e is the refrigeration effect of absorption chiller and Q_g is the heat input to generator of absorption chiller.

$$PE = PE_p + PE_f + PE_{aux} \quad (3)$$

where PE_p is the primary energy consumption of pumps, PE_f is the primary energy consumption of fans, cooling tower, desiccant wheel and rotary heat exchanger, PE_{aux} is the primary energy consumption of auxiliary heaters.

In addition, the annually averaged room conditions, including zone temperature T_z and zone humidity RH_z, were also examined.

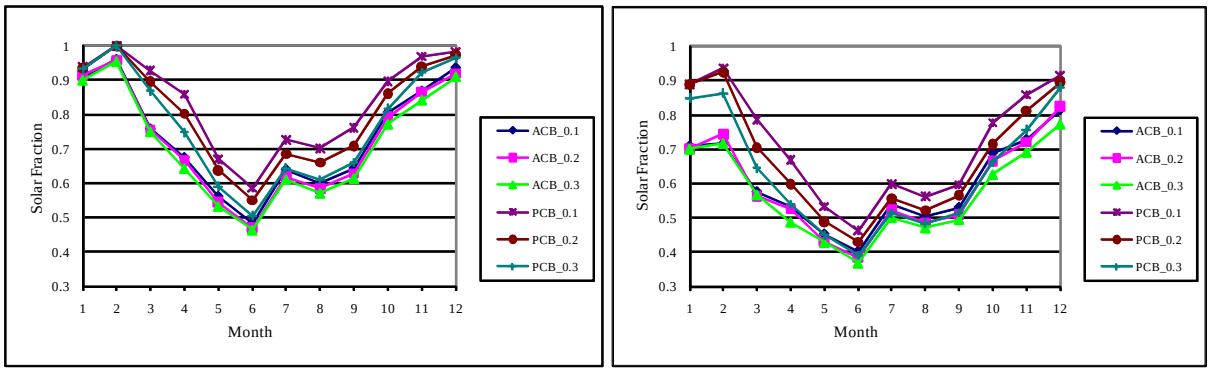
3.2. Solar fraction and coefficient of performance

Table 2 summarizes the annually averaged performances of the solar hybrid adsorption refrigeration system with different types of chilled beams for typical and high-tech offices. Generally the system could maintain satisfactory indoor conditions for both types of offices. The results of the typical office shows that the annually averaged *SF* of the system with PCB would become better, increased by 10.9% along with *R* decreased from 0.3 to 0.1, while that with ACB could be increased by 3.9%. Similarly for the high-tech office, the annually averaged *SF* of the system with PCB was raised by 15.6% for *R* from 0.3 to 0.1, and that with ACB by 6.4%. *SF* decreased with an increase of *R*, it was because the radiative load had less effect in reducing the zone air temperature. Hence, with a higher radiative load ratio, the zone air temperature would drop slower, meaning that the running hour of the chiller would increase. As such, the regenerative heat required was larger and resulted in a lower *SF*. For *COP*, although it was slightly increased with the rise of *R*, the change was minimal for both types of offices. At the same *R*, PCB had higher *COP* than ACB. The main reason was due to a higher chilled water supply temperature would be offered by the PCB, and the regenerative heat demand could be reduced.

Table 2. Annually averaged performance of solar hybrid adsorption refrigeration system.

Office	Chilled beams	*R*	*SF*	*COP*	T_z (°C)	RH_z (%)
Typical	ACB	0.1	0.689	0.548	25.02	53.12
	ACB	0.2	0.675	0.548	25.07	52.94
	ACB	0.3	0.663	0.548	25.13	52.80
	PCB	0.1	0.791	0.557	25.29	53.14
	PCB	0.2	0.754	0.558	25.39	53.09
	PCB	0.3	0.713	0.559	25.51	52.95
High-tech	ACB	0.1	0.568	0.546	25.19	52.51
	ACB	0.2	0.553	0.546	25.25	52.33
	ACB	0.3	0.534	0.547	25.33	52.07
	PCB	0.1	0.659	0.554	25.45	53.00
	PCB	0.2	0.616	0.554	25.56	52.87
	PCB	0.3	0.570	0.557	25.71	52.57

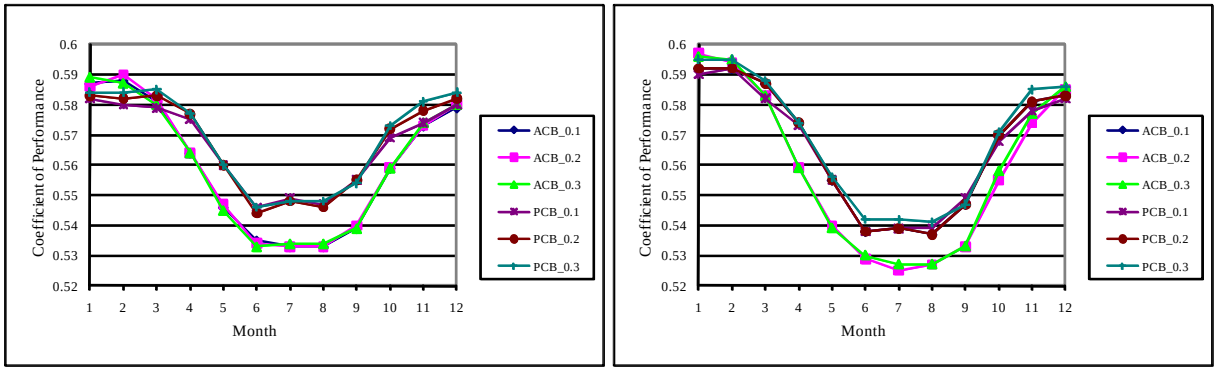
Fig. 2 illustrates the annual profiles of *SF* of the solar hybrid adsorption refrigeration system using ACB and PCB for both typical and high-tech offices at various *R*. The changing patterns were similar, with high *SF* from November to February and low *SF* from May to September. The former period was typical short autumn and winter in subtropical climate, while the latter was typical long summer. As compared between Fig. 2(a) and 2(b), the *SF* profiles of the typical office were generally higher than those of the high-tech offices, since the cooling demand of the typical office was lower and the involvement of auxiliary heaters would be less.



(a) Typical office *(b) High-tech office*

Fig. 2. Annual SF profiles solar hybrid adsorption refrigeration system.

Fig. 3 presents the annual profiles of *COP* of the adsorption chiller for ACB and PCB for typical and high-tech offices at various *R*. Generally the *COP* was higher in the winter months, while lower in the summer months. However the variation range of *COP* was narrow and maintained within about 10% even for different scenarios, since the chiller was supported by auxiliary heating. As compared between the chiller for the typical office and that for the high-tech office, although the latter *COP* was higher in the winter months, it was lower in the summer months. As a whole, the adsorption chiller for the high-tech office had lower annually averaged *COP* already shown in Table 2.



(a) Typical office *(b) High-tech office*

Fig. 3. Annual COP profiles of adsorption chiller of solar hybrid system.

3.3. Primary energy consumption

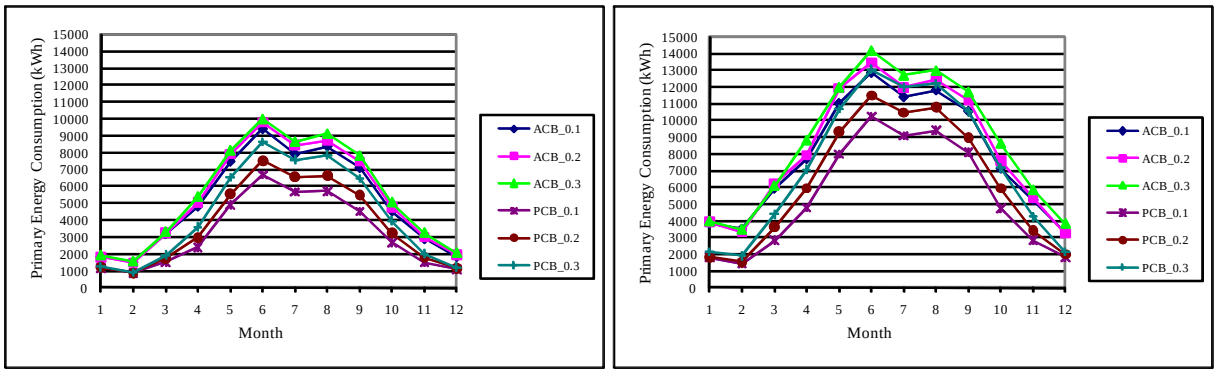
Table 3 summarizes the annual primary energy consumption of the solar hybrid adsorption refrigeration system with ACB and PCB for both typical and high-tech offices. The results of the typical office shows that the *PE* of the system with PCB would become less, reduced by 25.5% along with the decrease of *R* from 0.3 to 0.1, while that with ACB could be reduced by

8.0% only. Similarly for the high-tech office, the *PE* of the system with PCB was trimmed by 25.6% for *R* from 0.3 to 0.1, and that with ACB by 9.6%. These changing patterns were directly related to those of *SF*, since higher *SF* of the solar hybrid adsorption refrigeration system indicated less demand of auxiliary heating, thus leading to lower *PE*. At the same *R*, PCB could have less *PE* than ACB, up to 36.4% and 31.0% for typical office and high-tech office respectively. This was because the *SF* of the system with PCB was better than that with ACB, as discussed in Section 3.2, and the PE_{aux} of the system with PCB was less. In addition, the system with PCB did not have the additional supply and return air fans, so the PE_f of PCB was only about half of that of ACB.

Table 3. Annual energy performance of solar hybrid adsorption refrigeration system.

Office	Chilled beams	*R*	*PE* (kWh)	PE_p (kWh)	PE_f (kWh)	PE_{aux} (kWh)
Typical	ACB	0.1	60,943	19,466	8,232	33,247
	ACB	0.2	63,687	19,910	8,236	35,543
	ACB	0.3	66,212	20,155	8,238	37,820
	PCB	0.1	38,786	15,454	4,355	18,977
	PCB	0.2	44,764	16,588	4,361	23,815
	PCB	0.3	52,024	17,769	4,374	29,882
High-tech	ACB	0.1	94,371	26,124	9,670	58,578
	ACB	0.2	98,591	26,411	9,673	62,507
	ACB	0.3	104,398	26,971	9,676	67,751
	PCB	0.1	65,073	21,423	4,392	39,258
	PCB	0.2	75,309	22,871	4,402	48,036
	PCB	0.3	87,459	24,168	4,410	58,882

Fig. 4 presents the annual profiles of *PE* of the system with ACB and PCB for the two types of offices. Obviously the *PE* variation followed the seasonal change, and the system serving the high-tech office would demand higher *PE*. For the same type of chilled beams, higher *R* would require higher *PE*.



(a) Typical office *(b) High-tech office*

Fig. 4. Annual PE profiles of solar hybrid adsorption refrigeration system.

4. Conclusion

Through the year-round study of the solar hybrid adsorption refrigeration system using the two types of chilled beams, the effect of *R* on the system performances was investigated,

particularly the *SF* and the *PE*. It was found that the system with either ACB or PCB could have higher *SF* and lower *PE* when *R* was decreased from 0.3 to 0.1. Although both ACB and PCB could provide satisfactory indoor conditions for the typical and high-tech offices, the PCB had better annually averaged *SF* and total *PE* at the same *R*. As the conventional *R* of ACB is 0.1 or less, and that of PCB is between 0.1 and 0.2, suitable equipment selection and control provision of the solar hybrid adsorption refrigeration system would be technically feasible for office use in the hot and humid city. Through appropriate system design and year-round evaluation of solar air-conditioning, this would certainly help to determine a solution for reduction of carbon footprint of buildings in the subtropical climate.

Abstract: This paper presents constructive aspects and preliminary experimental results of an adsorptive chiller as part of a 20 kW central air conditioning unit for providing thermal comfort in a set of rooms that comprises an area of 110 m^2. Some simulation results of the air conditioner regeneration system are also presented. The cooling system is basically made up of a cold-water storage tank – supplied by an activated carbon-methanol chiller, and a hot-water storage tank – fed by a field of high efficient solar collectors with complementary heat by natural gas. The adsorber – a compact heat exchanger containing the activated carbon – was conceived and constructed in four modules, in order to allow heat and mass recovery. Other components are the same existing on conventional central air conditioners, as a condenser, an evaporator and a cooling tower. Constructive details of the collector's field, the adsorbers and the regenerating storage component are shown. The solar system is a 120 m^2 collection area field composed by 76 units of a flat plate collector covered with a high efficient transparent insulation. Results obtained from a multi-objective optimization based on a statistic modeling shown that – for a specific cooling power of 120 W/kg of adsorbent – the chiller's COP can reach 0.6. With this COP value, and considering the mean value of the total daily irradiation in João Pessoa (7º8'S, 34º50'WG), we can expected a solar energy cover fraction of 70%, for a typical summer day. This scenario is expected for the following operation temperatures: 30°C for the condenser, 7°C for the evaporator and 105°C at the start of the regeneration process. For an acclimatization period of 8 hours (9 to 17 h), the main dimensioning parameters were: 504 kg of activated carbon, 180 liters of methanol, 7,000 liters of hot water, 10,300 liters of chilled water with its temperature varying in the fan-coil from 1°C to 14°C.

Keywords: *Solar-gas adsorptive chiller, Thermal storage, Numerical simulation.*

1. Introduction

The simplicity of operation and minimal requires of maintenance of the adsorption chiller are certainly the major advantages compared to conventional liquid chiller (vapor compression) and to absorption chiller.

The scope of this technology involves besides the sectors of commerce and service, also the industrial, and it becomes possible the large-scale use of 'trigeneration' (combined heat, power and cooling).

The system consists basically of 3 components: an activated carbon–methanol adsorption chiller (water-cooling unit), a chilled water storage tank and an air–water heat exchanger (fan-coil). The schematic diagram of the system operation is shown in Fig.1.

The adsorption chiller is made up of the following main devices: four adsorbers (heat exchangers porous media/liquid), disposed in a parallel-series arrangement, one hot water storage tank supplied by solar energy and natural gas, two air condensers, one evaporator, and accessories such as valves and circulation pumps.

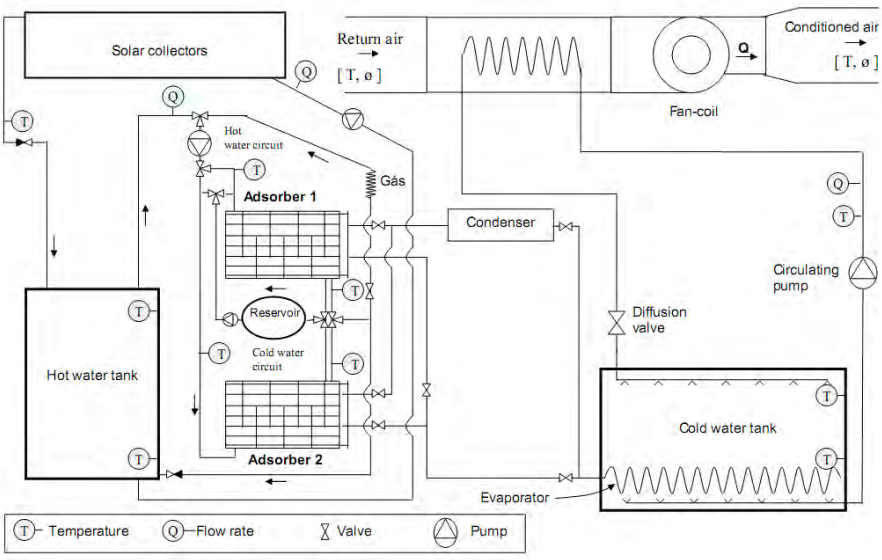

Fig.1. Scheme operation of the adsorption chiller fed by solar energy and natural gas, with thermal storage of chilled water (1).

2. Methodology

For dimensioning the adsorptive air conditioning system, we used a detailed study of individual components by means of a computer simulation program, using initially the analysis of each component and then the entire integrated system.

The computational simulation, called ADSOL, was carried out using the calculation program in the Simulink interface, with functions created in Matlab® to simulate the operation of the solar collectors field connected to the hot water storage tank and the adsorption chiller (2). For the collectors and the chiller, empirical correlations and simple methods of energy balance were used. For the storage tank, the function was based on the finite volume method.

The simulation of the complete system aims to determine the seasonal variations of different operating parameters such as the temperature, the efficiency of solar collectors, the coefficient of performance (COP) and the specific cooling power (SCP). With these data it is possible to adjust the operating times and other parameters of the system operation.

2.1. Solar collectors

For modeling the field of solar collectors it was used the quadratic efficiency collector Eq.(1) (3), which estimates the average efficiency of a solar collector at a given time, from the temperature difference between the collector (T) and the environment (T_{env}) and from the solar radiation (Rad) at that moment. The constants a_0, a_1 and a_2 depend on the characteristics of the collector, as the overall coefficient of thermal loss to the environment and the relationship between the transparent and the total area. It also takes into account the arrangement of the collectors (parellel-series) that was disposed in two sets of 38 collectors each one.

$$\eta = a_0 - a_1 \frac{T - T_{env}}{Rad} - a_2 \frac{(T - T_{env})^2}{Rad} \qquad (1)$$

The Eq.(2) represents a simple energy balance for each collector:

$$T_i = T_{i-1} + \frac{\eta A \cdot Rad}{\dot{V}_{col} c_p \rho} \quad (2)$$

Where, *Ti* is the temperature of the i-th collector in serie, *A* is the transparent area, $\dot{V}_{col}$ is the water flow in each collector in parallel, c_p is the specific heat of the water and ρ is the density of the water (properties taken in the inlet temperature).

2.2. Adsorption chiller

The adsorption chiller operation was simulated using a model developed by Riffel et al. (4). It was investigated statistically the results of the dynamic model of the adsorber in order to obtain the optimum project parameters, taking into account the best operating points and the influence of seven variables (temperature and mass flow of hot water, cycle length, number of tubes, number of fins, fin thickness and material of manufacture) (5). The results showed that all variables are statistically significant and interdependent. In other words, a change in one variable affects directly the other one. This demonstrates the importance of using statistical modeling for this analysis. As a main result, we observed that the COP is highly dependent on the number of fins, the material and the cycle length. The inner surface of the adsorber, exchange heat with water from a hot or cold source, depending on the phase of the cycle. The adsorbent occupies the space delimited by the external wall of the tube and the corrugated fins. The adsorbent bed operates under vacuum for getting the required thermodynamic properties of the working fluid (the methanol). The micropores of the adsorbent medium has a diameter smaller than 2 nm. In the case of specific cooling power (SCP), the most important variables were the number of fins, the number of tubes and the hot water temperature.

The Eq.(3) represents an energy balance for the water that flows in the adsorber. Losses in the pipeline and the delayed response in thermal heat exchanger (adsorber) were not considered.

$$T_{out} = T_{in} - \frac{SCP}{COP} \cdot \frac{m_{ads}}{\dot{V}_{ad} c_p \rho} \quad (3)$$

Where, T_{out} and T_{in} are, respectively, the water temperatures at the exit and entry of the adsorbers, m_{ads} is the total mass of adsorbent (activated carbon), and $\dot{V}_{ad}$ is the water flow in the adsorber.

2.2. Hot water tank

The geometry of the hot water storage tank is cylindrical, with is connected at the bottom and the top, with the solar collectors and the adsorbers. For calculating the heat exchanges in the tank the finite volume method was used and it was considered a stratified tank with one-dimensional heat transfer. The stratification occurs in layers of increasing density and decreasing temperature. This method presents a numerical solution that enables problem solving under any initial conditions and it consists in dividing the tank into a finite number of longitudinal nodes of same temperature and volume. Thus, we obtained the equations of the heat and mass transfers for each volume, applying the respective boundary conditions. The solution of the equations is performed by implicit formulation and the method of matrix inversion. The model of the hot water tank was developed by Riffel (2), by changing only the response of simulation to provide temperature values in both the base and on top of the tank.

3. Description of the central air conditioning unit

The air conditioning system is based on an adsorption cycle with heat recovery, in which the steps of regeneration and production of refrigeration effect occur simultaneously, i.e., the adsorbers (I and II, in Fig. 1) work in alternated way; when one is the adsorbing phase, the other is in the desorbing phase (1). The adsorber model takes into account the geometry of the finned-tube liquid-adsorbent heat exchanger. It is based on the activated carbon-methanol pair and is responsible for cooling the water that is accumulated in the tank. The working fluid is the methanol, which flows through a compact heat exchanger evaporator, where the water is cooled. The conditioned air is obtained by changing heat with the stored chilled water and the air process through a fan-coil, and then it is distributed in the set rooms by a pipelines network. The regeneration is made by solar thermal energy produced by a highly efficient solar collectors field that is stored in a water tank, and, from this main tank to the adsorptive chiller, an additional heat is supplied by the combustion of natural gas.

4. Constructive aspects of the central air conditioning unit

4.1. Regeneration system

The regeneration system comprises a f ield of flat solar collectors with high efficiency**,** coupled to a thermal storage tank. The water previously heated by the solar energy will get the process temperature of 105°C with the help of a small gas heater.

4.1.1. Solar collectors

The solar collectors are flat and static. The outer surface of the collectors is painted nonselective matte black, and a Teflon film is placed between the absorbing surface and the glass cover plate (Fig. 2) (6, 7).

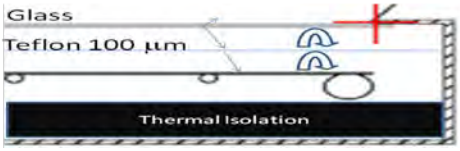

Fig. 2. Scheme of TIM cover.

The field of collectors was installed in a parallel-series arrangement, in two symmetrical blocks, each consisting of 38 units of a commercial flat collectors of 1.58 m^2 each, covering a total collection area of 120 m^2, installed on the roof titled 9^o facing to the South (Fig. 3), which corresponds to the average value for the six hottest months in João Pessoa (7°8′S, 34°50′WG), whose climate is typically hot and humid (8).

Fig. 3. Field of flat plate collectors with TIM coverage installed on the LES/UFPB.

4.1.2. Hot-water storage tank

As showed in a previous article (9), the required cylindrical hot water tank for providing the minimum gas consumption was obtained from simulations to be around 7m^3 of capacity, by comparing the volumes from 1m^3 to 9m^3 during 24 hours. It was built in steel, with 2.074m of diameter and 2.50m of height, insulated with 50mm thick polyurethane foam.

4.1.3. Adsorptive chiller

As result from simulations carried outd by Riffel (4, 5), we have determined the characteristics of the adsorber, as shown in Table 1.

Table 1. Characteristics of the adsorber.

Dimensions	668mm x 330.2mm x 19mm
Number of flat tubes	27
Row number of fins	28
Tube external diameter	12.7mm
Tube internal diameter	10.9mm
Fin width	19mm
Fin thinckness	0.3mm
Fin pitch	1.8mm
Heat transfer area (fin side)	4.175m²

4.1.4. Condenser and evaporator

The equations related to the condenser and evaporator where widely described and experimentally validated on a previous paper (10). They are a finned-tube heat exchanger. From the simulation data, the evaporator must operate continuously (i.e., during the 24 hours a day) to ensure the storage of chilled water required by the heat exchanger air-water (fan-coil) and thus provide the design temperature for the inlet air of the rooms. For the evaporator we selected a compact plate heat exchanger, manufactured by CIAT (French), for a wide power range (2 to 200 kW) (11). The equipment will be adapted for the required operating conditions, to ensure that the outlet methanol is completely superheated.

4.1.5 Natural gas heater

The natural gas heater model GWH 300DE-GN - BOSH, will heat the water from the hot water tank until the temperature of 105°C to ensure the regeneration. The simulation program calculates the total amount of natural gas need to be consumed in one day.

5. Results

For the simulation we have taken some considerations concerning some system parameters. The chilled water temperature is considered constant and equal to 7^{o}C and the cold water temperature is taken 5^{o}C above ambient temperature. The mass of the adsorbent (activated carbon) is considered equal to 116 kg for each adsorber, and the adsorber water flow is equal to 0.1L/s. The simulation results were obtained considering a typical summer day in Joao Pessoa, represented by the data of January 1, 2010 (10).

The water flow in each set of collectors in parallel arrangement was examined for different volumetric flows (0.1L/s, 0.2L/s, 0.3L/s, 0.4L/s and 0.5L/s) to verify which of them provides the lower gas consumption while the system reach a regeneration temperature. They are presented in different response curves generated for periods of 24 hours.

The volumetric rate flow through the solar collectors field was measured to compare this value with those obtained in the simulation. The measure was made with an ultrasonic flow meter, mark FMS, model UFM170. The volumetric flow rate is considered constant and the average of six measured values was about 0.71L/s.

5.1. Figures

The Fig. 5 shows the daily consumption of natural gas, for the water collector flow between 0.1L/s and 0.5L/s.

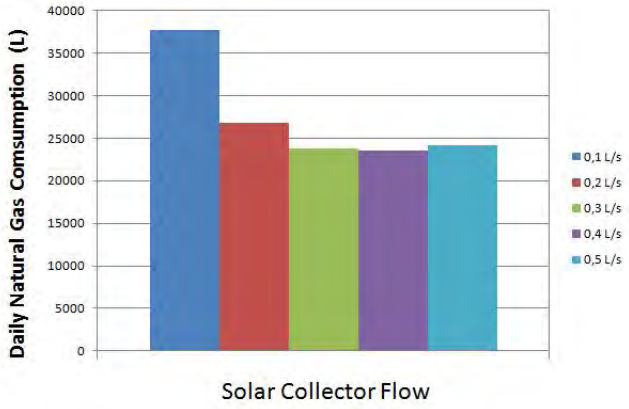

Fig. 5. Daily consumption of natural gas.

Taking into account the simulation results of Fig. 5, we can see that the solar collectors water flow of 0.4L/s gives the minimum consumption of natural gas. Thus, other results based on this flow rate are shown in Figs. 6 and 7.

The Fig. 6 shows the average water temperature in the hot water tank, during a whole day. The curves show that, at around 7am it was obtained the minimum temperature, of 58°C, corresponding to the maximum gas flow of 0.037L/s. The need of gas decreases with the temperature rise. Due to the thermal inertia, until the maximum temperature at 16:10h (86.2°C) the gas flow increases, and then it decreases following the same tendency of the temperature.

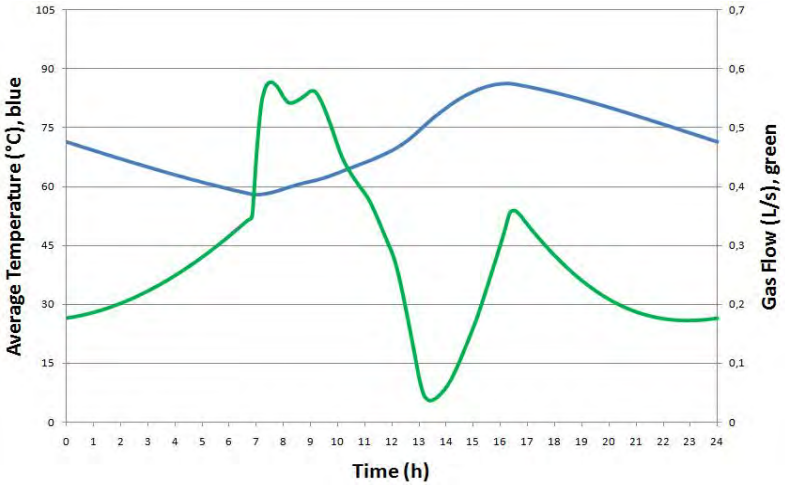

Fig.6 Average hot water temperature and the corresponding natural gas flow for the solar collector flow rate of 0.4L/s, during a day.

The Fig. 7 shows the solar collector temperatures (blue) and the temperatures of the bottom and the top (red and green) of the storage water tank, obtained with a water flow rate of 0.4L/s. We can see that there is an agreement between the temperature curves in the collectors

and on the top and the bottom of the storage tank. Due to the thermal inertia, the temperature at the bottom of the tank remains almost constant until around 8am, when it begins to increase, reaching its maximum at 16:20 and then starts to decrease.

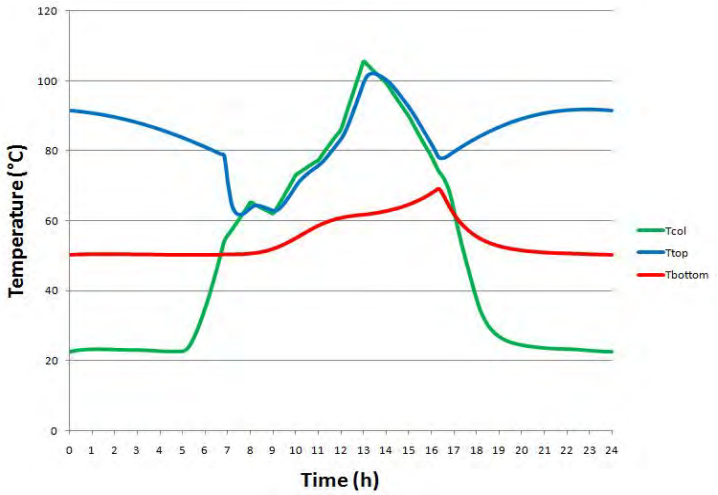

Fig.7. Thermal response of the system to the real situation, for a water flow rate of 0.4L/s, during a day.

6. Conclusion

We have presented the main parameters of a central air conditioning unit based on t he adsorption of methanol in activated carbon and a hybrid regeneration system, projected to provide until 70% of the required heat by solar energy, the complementary heat by natural gas. A simulation program was developed and we have obtained from it an optimal volume of the storage hot water of 7,000 liters. It was found that 0.4L/s is the flow rate through the solar collectors field that gives the minimum consumption of gas, and the water pump should be regulated to obtain the ideal volumetric flow.

6.1. The current stage of the project

The solar collectors are installed and connected to the hot water storage tank; to compensate the thermal inertia of it a small tank of 500 liters was built and connected to the main one for providing the process regeneration temperature (105oC) with aid of the gas heater and. An equipment for analyzing the heat losses from the storage tank was also built.

The 4 adsorber modules were made, and a test bench is now under construction. The chilled water storage tanks were manufactured and their hydraulic connections installed. The air–water heat exchanger unit (fan-coil) and their pipelines network are already installed in a set of rooms.

Abstract: In this study, performance of the solar-thermal assisted air-conditioning system installed in an office building is investigated. In this paper, firstly the results of field measurements in winter (heating) and summer (cooling) are presented. Efficiency and performance of equipments which constitutes a system are investigated. Also the utilization efficiency of solar energy and the solar fraction are estimated for winter/summer season. In addition to analysis of field measurement data, system simulation of performance was conducted in this paper. Simulation program using in this study was developed as the tool for Life Cycle Energy Management of HVAC system. In this paper mathematical model of each equipment are presented as well as how to model total system . Although there are some limitations of solar system simulation with 1 hour time step, the calculation result was well in agreement in an actual measurement.

1. Introduction

Practical use of renewable energy is necessary for CO2 emissions reduction, especially, possibility of energy conversion by using solar thermal is high, and it is considered to be one of the effective means.

Although the solar-thermal-conversion air conditioning system combined with the absorption refrigerating machine was proposed at 1970's in Japan[1)2)], remarkable spread after that was not seen because of solar heat collection at high temperature having been difficult. Also there was not high performance thermal driven chiller (absorption machine) for effective use solar thermal energy.

In this paper, the actual proof examination of the air conditioning system which combined the solar collector and the gas absorption chiller/heater which can use solar heat is presented. The actual proof examination started from Jan. 2010 in Tsu City, Mie for the purpose to demonstrate effectiveness of solar HVAC system. Firstly the outline of building and system was described. Then performance of system in winter and summer season is presented and discussed. Furthermore the system simulation for solar system was intoroduced and possibility to represent the behavior of system is discussed.

2. Outline of Object Building and System

A building is 2,400m2 of total area and 4 stories. The appearance is shown in Fig. 1. The layout of equipments on roof is shown in Fig. 2, and specification of equipments is shown in Table 1. The appearance of two type of collector is shown in Fig.3. The system flow of diagram and outline of control are shown in Fig. 4.

3. Result of Actual Proof Examination

3.1 Thermal efficiency of collector

Fig. 5 shows the change of amount of heat collection Qc and thermal efficiency calculated by following equation.

$$Qc = (Tc,out - Tc,in) * FE \quad (1)$$

$$\eta = Qc/ (J * Ac) \quad (2)$$

Collector	Medium : Water	2.0m^2 x 28
	Tilted angle : 25°	Evacuated tube
	Angle of direcstion : SSW30°	4.1m^2 x 20
Absorption	Three stage	
Machine	Cooling 527kW Heating 290kW	
TES	4.9m^3	

Fig. 6 shows daily solar irradiance and amount of heat collected in March 2010. Total amount of solar insolation was 16,800kWh and total amount of heat collected was 5,870kWh. Thermal efficiency of solar collector in March was 35%.

Thermal efficiency is plotted as a function of {(Tc,out+Tc,in)/2-Ta}/I in Fig.7. At the high collecting temperature (at large value of (Tc,out+Tc,in)/2-Ta), efficiency of flat plate collector decrease while that of evacuate tube type heat pipe stable. It means evacuate tuype heat pipe collector is suitable for "Solar cooling" where absorption machine require relatively high temperature heat source water.

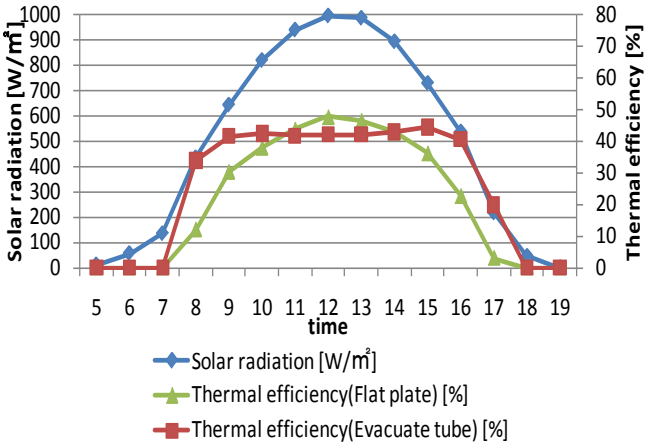

Fig.5 Collected heat and thermal efficiency of collector

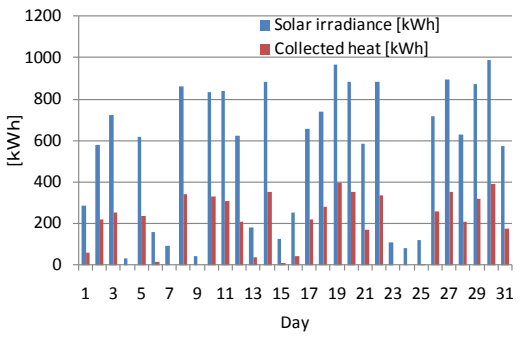

Fig.6 Daily solar irradiance and amount of heat collected (March, 2010)

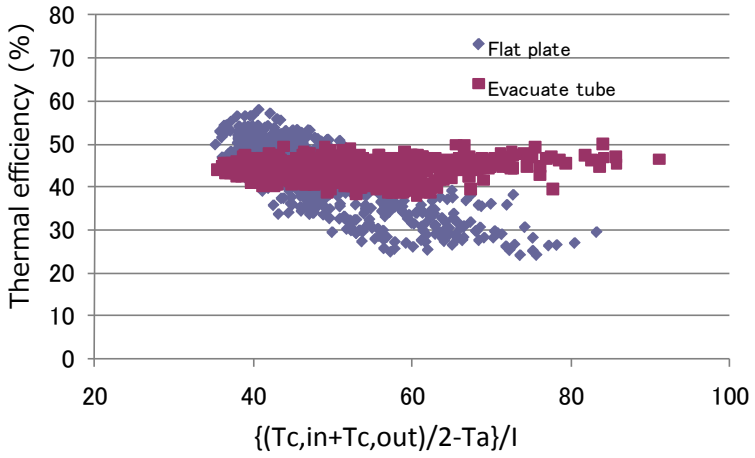

Fig.7 Plot of thermal efficiency as function of {(Tc,in+Tc,out)/2-Ta}/I

3.2 System performance in winter (heating)

Fig. 8 shows daily amount of solar heat and gas energy consumed for heating. Monthly solar fraction calculated by following equation was 19%. Seasonal performance of the system is shown in Table 2. Solar heat utilization efficiency is 72% and solar fraction is 13.1 for heating season. Also ratio of pump energy to amount of collected heat is 12%.

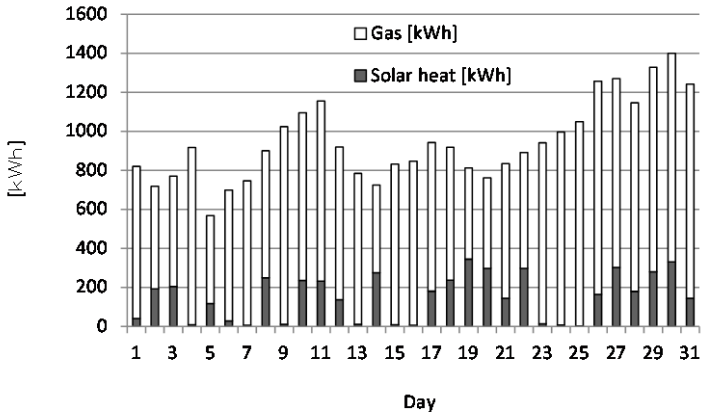

Fig.8 Daily amount of solar heat and gas energy consumed for heating

Table 2 Performance of system in heating season

		Feb.	Mar.	Apr.	Total
Collected heat	kWh	4,543	5,873	3,807	13,223
Heat delivered to heat exchanger	kWh	3,426	4,701	2,155	10,282
Heat loss	kWh	1,117	1,172	1,652	3,941
Pump energy (primary)	kWh	629	786	328	1,743
Solar fraction	%	8.3	16.0	25.5	13.1

3.3 System performance in summer (cooling)

Fig. 9 shows seasonal performance of the system for summer. Solar heat utilization efficiency changes among 78 to 89%. The highest heat utilization efficiency was seen in August. Fig. 10 shows . Monthly solar fraction calculated by following equation changes among 16 to 18%. In August, the coefficient of performance for system (System COP) and the saving rate of gas consumption were 1.4 and 0.1 respectively.

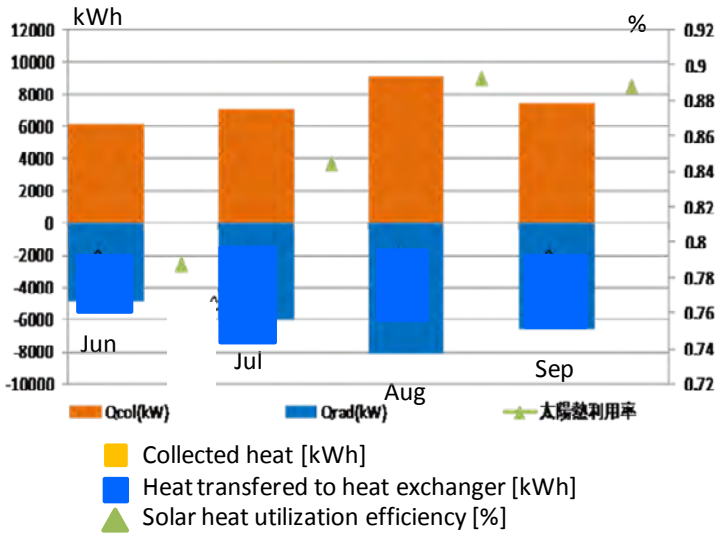

Fig. 9 Heat collected and transferred to absorption machine

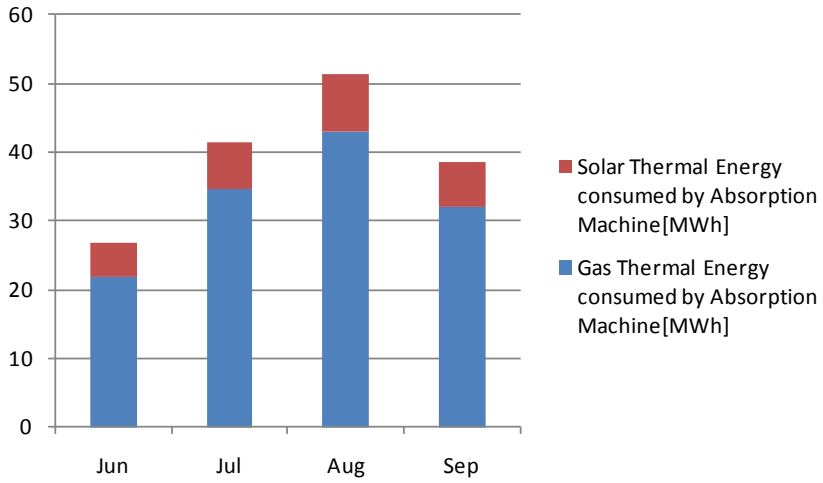

Fig. 10 Monthly amount of solar thermal energy and gas energy consumed for absorption machine

4. Simulation

In this paper, simulation of the performance of system in winter was conducted using LCEM tool. LCEM tool was developed by the basis of editorial supervision of Ministry of Land, Infrastructure and transportation, Japan for life cycle energy management of HVAC system.

4.1 Outline of Analysis Model

A part of LCEM tool Ver.3.02 was improved, and the simulation model was built. It consists of two models of the heat collection system shown in Fig. 11 and the air-conditioning system shown in Fig. 12. Two models are combined via interface.

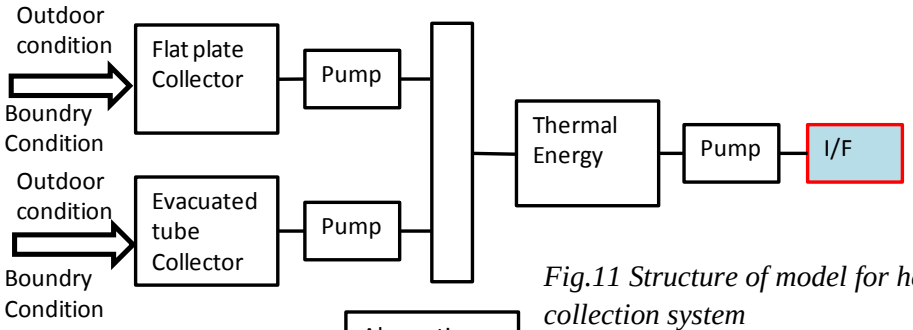

Fig.11 Structure of model for heat collection system

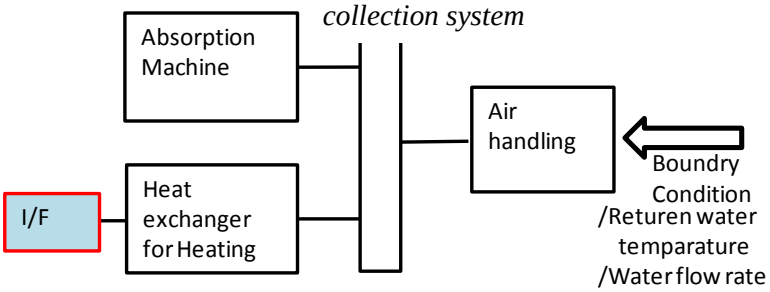

Fig,12 Structure of model for solar air-conditioning system

4.2 Collector Object

Heat collected by solar collector Qc (kW) is calculated by the following equations.

$$Qc = \eta * J * Ac \qquad (3)$$

Moreover, thermal efficiency of solar collector is expressed with the following equations.

$$\eta = \tau*\alpha - U*\triangle t/J$$

$$\triangle t = (Tc,in+Tc,out) / 2 - Ta \qquad (4)$$

The following characteristic were used in this simulation.

$$\text{Flat plate collector: } \eta = 0.578-0.00493\triangle t/J \qquad (5)$$

$$\text{Vacuum-tube type: } \eta = 0.496-0.00156\triangle t/J \qquad (6)$$

4.3 Thermal Storage Tank Object

The characteristic of thermal storage tank was assumed as complete mixed.

4.4 Pump Object

The energy consumed by pump is calculated using pump efficiency, water flow rate and head of piping system. Efficiency of pump is set constant in the object used in his paper. LCEM tool cannot make the model of the differential gap in the ON-OFF control of a pumps.

4.5 Heat Exchanger Object

The heat exchanger object used in this paper are as follows.

$$Qhex = C1* (T1\ in-T1out) = C2* (T2\ out-T2in) = \varepsilon*Qhexmax \qquad (7)$$

$$Qhexmax = Cmin* (T1\ in-T2in) \qquad (8)$$

$$\varepsilon = [1-exp\ \{-N\ (1-C)\}] /[1-Cexp\ \{-N\ (1-C)\}] \qquad (9)$$

$$N = UA/Cmin \quad (10)$$

$$C = Cmin/Cmax \quad (11)$$

$$Cmin = 4.186 * Wmin/60 \quad (12)$$

$$Cmax = 4.186 * Wmax/60 \quad (13)$$

4.6 Absorption Chiller/Heater Object

The amount of gas consumption is assumed as the function of the load factor (q), and was modeled by the following formulas.

In case of 0% <q< 25%

$$G = 1.2 * q/100 * 25.8 \quad (14)$$

In case of 25%<q<40%

$$G = (-0.013 * q + 1.533) * q/100 * 25.8 \quad (15)$$

In case of 40%<q<100%

$$G = q/100 * 25.8 \quad (16)$$

The differential gap in ON-OFF of absorption machine can not be expressed by LCEM tool and the outlet temperature was set to constant value of 55 degrees C.

5. Simulation Result

In this section simulation results for heating operation are shown. Fig. 13 shows the comparison between measurement and simulation for flat plate collector and evacuated heat pipe. Fig. 14 shows the heat collected and delivered to heat exchanger. Also fig.14 shows temperature in thermal storage tank. Fig. 15 shows the change of output of absorption machine. From these figures, it can be concluded that simulation results using LCEM tool shows good agreement with an actual measurement. However there are limitations of simulation as follows.

Time interval of calculation

In this study, 1 hour of time interval for calculation is applied. The system is controlled by the shorter time interval. Therefore, calculation result of collected heat at end of operation (evening) is overestimated. Also output of absorption machine (operate as boiler in heating) is overestimated when heat load is small. In this situation, absorption machine repeats operation and stop at short time step. However, this action cannot be expressed by simulation.

Simplified model

In this study, components in the system are modeled simply, for example heat loss from storage tank was neglected. This kind of simplification effects on the accuracy of simulation.

6. Conclusion

The system performance for the 1st year has been grasped by field measurements. Also system simulation for heating season was conducted by using LCEM tool. The simulation for cooling season will be conducted from now on. Although the system demonstrated good performance, improvement of operation should be conducted based on the results of field

measurements and simulation. Also simulation program will be revised to reduce the limitation which was mentioned in this paper.

Abstract: In this research, black nickel coatings have been deposited on brass, copper and steel substrates by electrodeposition method. The physical properties of solar absorber black nickel coatings on different metallic surfaces have been investigated. The effect of different metallic substrates including brass, copper and steel with presence of bright nickel middle layer and without its presence on optical and structural properties of deposited layers have been studied. These coatings characterized by scanning electron microscopy (SEM), X-ray diffraction (XRD) and energy-dispersive X-ray analysis (EDAX). For investigation of optical properties of deposited layers, UV-VIS-NIR spectrophotometer was used.

Keywords: *Electroplating, Black nickel, Bright nickel*

1. Introduction

The use of selective coatings has been widely established as an industrial application which used to absorb solar thermal energy. Demands for design and construction of solar absorber plates to achieve reduced energy consumption and its applications in the areas of electrical energy, heating and cooling systems lead to the development of growing of black nickel coatings [1]. Fundamental properties of black nickel coatings are currently excessively studied because of their potential application in numerous fields such as electronic devices, opto-electronic, optics, biotechnology, human medicine, solar energy conversion and etc [2]. Black nickel is one of the most commonly used solar selective coatings in solar collector systems for the efficient conversion of solar energy into thermal energy [3]. Such coatings are identified by high solar absorptance (α>95%) and low thermal emittance (ε<40%). Considering all studied cases selected for selective solar absorber coating, black nickel plates due to lower consumption of requirement electrical energy also electroplating in large scale for production and development in the industry are considered as one of the most appropriate coatings [4]. There are different methods for the deposition of black nickel coatings, including Chemical vapor deposition (CVD), sputtering, spray pyrolysis[5], electroless[6], pulse plating[7] and electrodeposition [8,9]. Among these methods, because of simple setup, low cost process of coating in industrial scale, easy control of production processes and high speed production, the electroplating method attracted special attention.

Electroplating of metallic films is one of the appropriate techniques to obtaining absorber coatings with selective optical properties for solar collectors. Electrical current and reclamation agents that are used in this process are cheap and this good economic sense to develop this approach. By using this method, optical coatings with suitable properties for solar absorber plate's applications with large scale are provided.

Electroplating is a process in which by using electrical current, a thin layer of metal is deposited on the surface of another metal. Figure 1 shows the schematic of electroplating system in hull cell. The presence of the bright nickel middle layer causes changes in the optical properties, including absorptance and emittance, of the films.

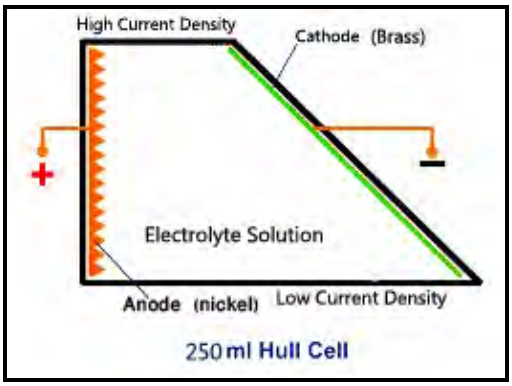

Fig. 1. The schematic of electroplating system in hull cell

2. Methodology

Black nickel coatings have been deposited on three different substrates namely brass, copper and stainless steel by electroplating method. Before deposition at First, the desired metal plates in dimensions of 7 × 1 0 cm perfectly polished and then thoroughly washed with distilled water. After that all substrates were degreased with a hot commercial alkaline solution followed by rinsing in distilled water. Finally they are placed in the chloride electrolyte solution for black nickel plating. All the coating process is carried out in hull cell. The Quality of black nickel coatings depend on the electrolyte solution composition and its concentration, electrodes, solution pH, bath temperature, current density and (deposition) duration (time). Therefore to obtain optimum optical properties for black nickel coatings, deposition parameters have to be optimized. In this type of coating, the soluble nickel metal used as a anode with 99% purity. Direct current passes between two electrodes in a conducting solution of nickel salts. The chemical bath for black nickel deposition consisted of a mixture of distilled water, nickel, zinc, tin and ammonium chloride with potassium thiociyanate. By flowing the current through the electrolyte, one of the electrodes (anode) is dissolved in the solution and the other electrode (cathode) is covered by a black nickel layer. In the electrolyte solution Ni positive ions (Ni^{++}) present so as the electrical current flows through the electrolyte, positive ions by absorbing two electrons on the surface of cathode are converted to nickel metal and deposited on the cathode surface. Reverse reaction occurs at the anode. So with the consumption of nickel in the cathode, the nickel ions are provided by anode. The concentrations of additives were varied to improve the optical performance. After numerous tests the best conditions for strongly adherent and durable black nickel coating, as mentioned in table 1, were obtained as follow: solution with pH 4.2, electrolyte bath temperature 65°C, plating time 10 min and current density 0.1 A/dm^2.
The effect of different substrate metals including brass, copper and stainless steel without the presence of the middle bright nickel layer and with the presence of it, on the optical and structural properties of the black nickel coatings have been investigated. Changes in the physical as well as optical properties of black nickel coatings are measured. SEM and XRD analysis are carried out by Philips PW3710 and Philips XL 30; the absorption spectra of coatings and emittance spectra are measured by carry 500 and Jasco FTIR respectively.

Table 1: Optimum conditions of coating

Current density	Temperature	pH	anode	cathode	Deposition time
0.1 A/dm^2	65℃	4.2	Nickel metal	Brass plate	10 minute

3. Results

3.1. Evaluation of optical properties, absorption analysis

Absorption spectrum curves of the black nickel coatings for various wavelengths depending on the metal substrate; including brass, copper and steel with and without bright nickel middle layer are presented in Fig.1-a and Fig.1-b. As can be seen from the graphs below, the black nickel coating has high absorption coefficient. The results from Graphs show that by changing the substrate, the absorption spectrum will change. The highest absorption is related to the coating layer on brass substrate without bright nickel and lowest absorption is belonged to the coating layer on stainless steel substrate with present of bright nickel.

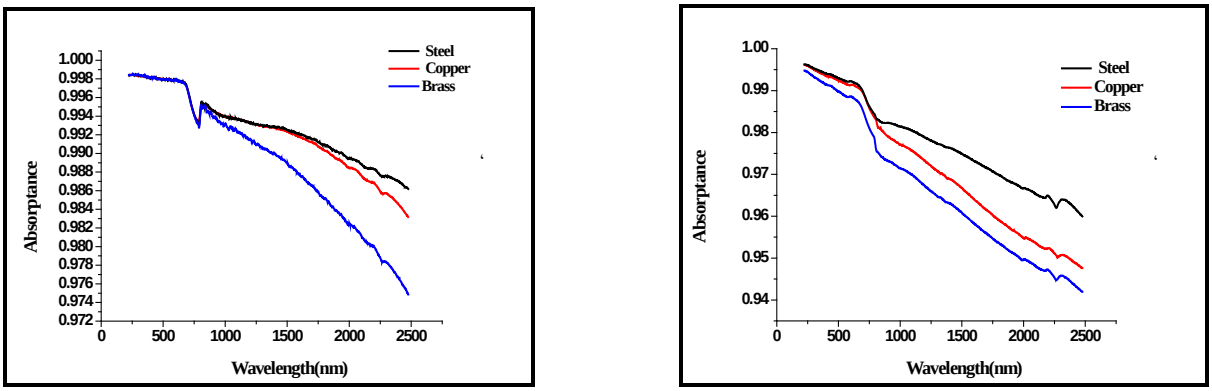

Figure (1 – a) absorption spectrum of black nickel on brass, copper and steel substrates without bright nickel, as a function of wavelength. Figure (1 – b) absorption spectrum of black nickel coating on copper, brass and steel substrates with bright nickel as a function of wavelength.

3.2. Emittance analysis

Below figure shows the result of emittance. By comparing the results the lowest emittance is belonged to the brass substrate and highest emittance is belonged to the steel substrate.

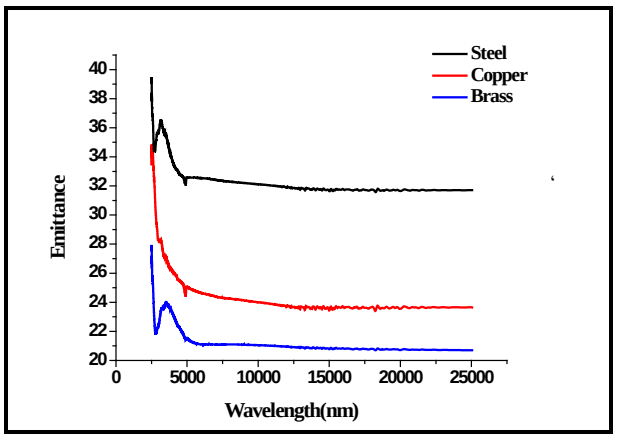

Figure (2) emittance spectrum of black nickel on brass, copper and steel substrates without bright nickel, as a function of wavelength.

3.3. SEM analysis

Scanning Electron Microscopy (SEM) Images of nano black nickel coatings prepared from nickel chloride bath with and without the presence of bright nickel middle layer. fig 3-a and 3-b shows the image of black nickel coating on brass substrate without and with bright nickel middle layer respectively.

By comparing the images of SEM it can be distinguished that layers with bright nickel have larger grains in comparison with layers without bright nickel. Since layers without bright nickel have a higher absorptance spectra so as result when grain size increase absorbtance spectra decrees.

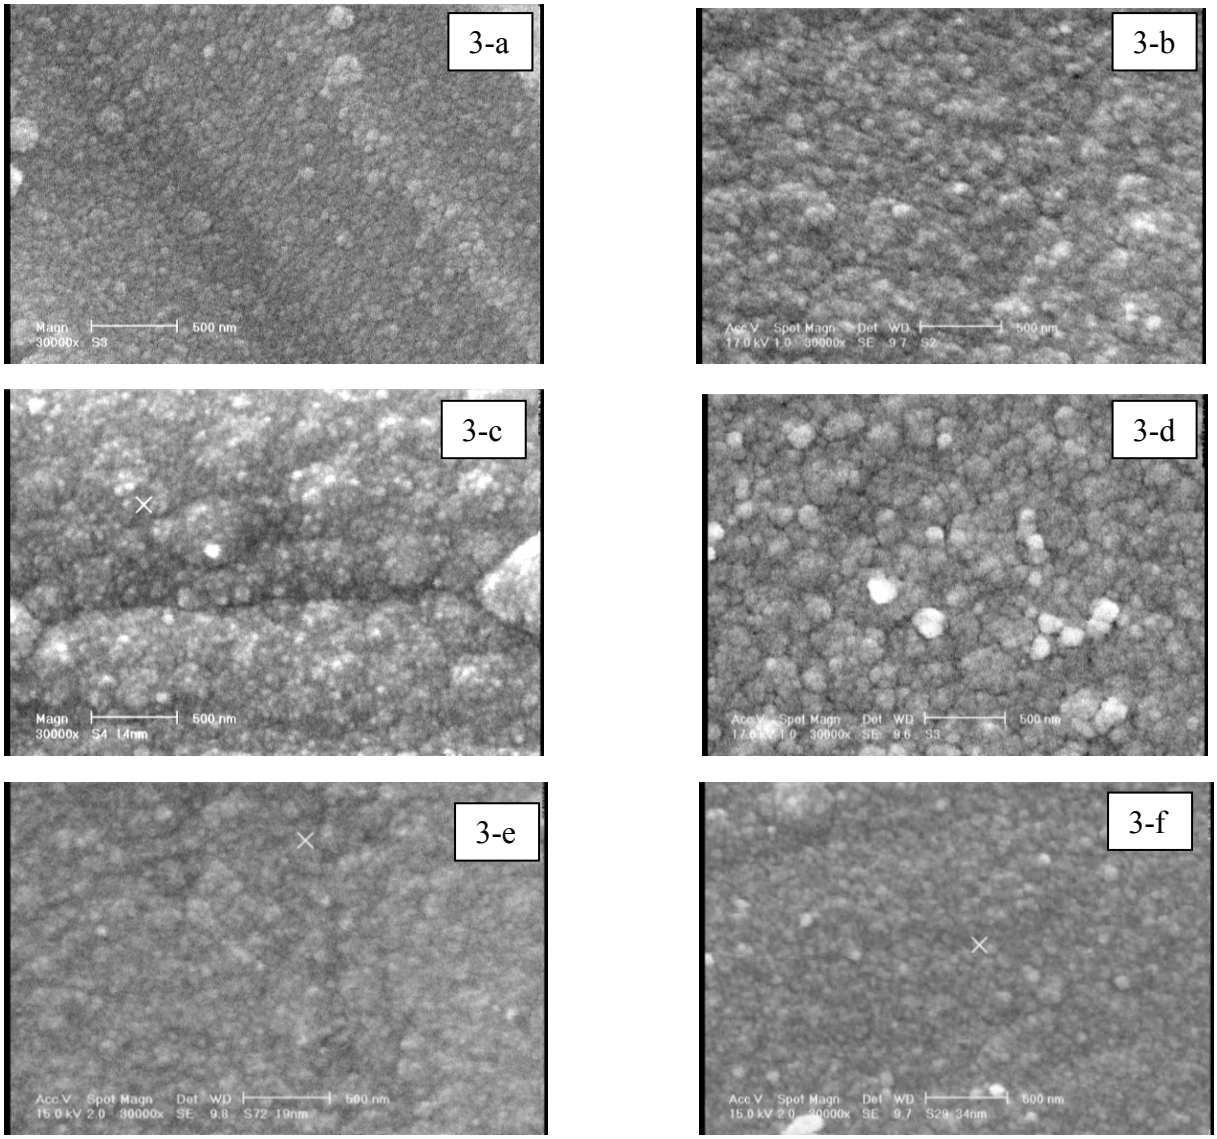

Figure 3: (SEM) Images of the black nickel coating
a) SEM image of a black nickel coating without bright nickel layer on the brass substrate b) SEM image of a black nickel coating on the brass substrate with bright nickel layer c) SEM image of a black nickel coating without nickel layer on the steel substrate d) SEM image of a black nickel coating With the bight nickel layer on stainless steel e) SEM image of a black nickel coating on copper without the bright nickel layer f) SEM image of a black nickel coating on copper with bright nickel layer

3.4. Results of X-ray diffraction and elemental analysis(EDAX)

Figure 4-a and 4-c show X-ray diffraction pattern of electrodeposited black nickel coatings on brass substrate. Two different structures clearly can be seen with and without the presence of bright nickel. Without presence of bright nickel there was no peak related to crystalline nickel and only the peaks belong to brass substrate have grown. While with regard to the 4-b, the presence of Ni element in the deposited films is provided by elemental analysis EDAX. The major difference between two structures can be recognized in fig 4-c. In XRD analysis of layer deposited in the presence of bright nickel the preferred orientations (111), (200) and (220) belong to nickel can be seen.

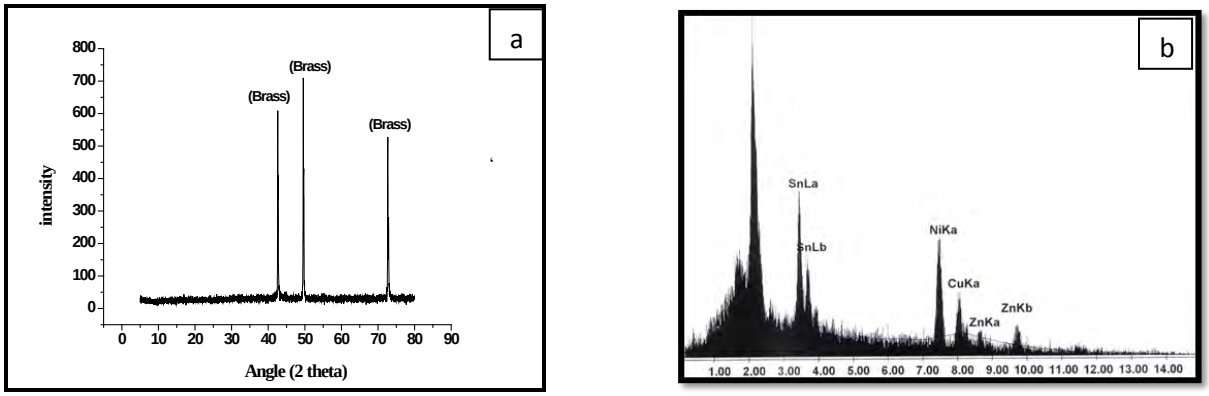

Figure 4– a, b X-ray diffraction pattern and elemental analysis black nickel coating without bright nickel

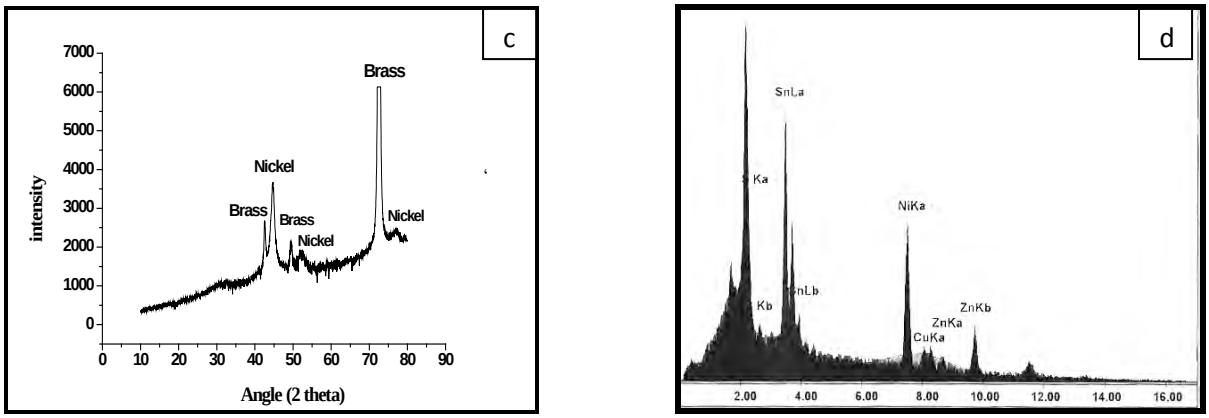

Figure 4–c, d X-ray diffraction pattern and elemental analysis black nickel coating with bright nickel

In order to identify the predominant nickel phase in the deposited films, it is necessary to investigate the coatings using X-ray diffractometer. Fig. shows the typical XRD pattern for the bright nickel substrate coated with black nickel films. This result is in good agreement with result of EDAX analysis.

4. Conclusion

The black nickel coatings with high absorption coefficient are suitable for solar applications. The coatings are very adhesive and have good thermal stability, with high absorption coefficient. SEM images show the relationship between absorption spectra with fine diameter of spherical particles, so that the layer of black nickel deposited on brass substrate without bright nickel coating have very small spherical particles and consequently optical properties of selected increases. Conversely, with the presence of bright nickel layer the particle size increases and absorption spectrum decreases. The highest absorption is for layer deposited on

brass without bright nickel and low absorption spectrum associated with the nickel coating on steel with bright nickel middle layer. EDAX analysis indicates presence of nickel on formed films. X-ray diffraction analyses show that electrodeposited films have polycrystalline structure and black nickel films were mainly consisting of metallic nickel. This result is matched with result of EDAX analysis. The presence of bright nickel middle layer cues the growth of nickel structure in orientation of (111), (200) and (220).

Abstract: The research had two aims-1 st. determine the airflow temperature distribution depending on the thickness of the collector air channel and collector length, where the absorber is a steel tinplate ; 2 nd. search non-traditional (utilized) materials (slices of black coloured beer cans, different size black colour seed boxes made of polypropylene) that could be used as absorbents of air heating solar collectors
0.1x0.5x1.0 meters long flat-plate collectors (FPC) for experimental research into the materials of solar air heating collector were built. The air velocity at the experiments was v=0.9 m/s, covered material - polystyrol plate**.** We used the sun following collectors, which guarantees perpendicular location of the plane of absorber from the flow of sun irradiance.
From the experimental data were obtained an analytical expressions that describe the solar radiation and collector air channel size influence to the flowing air temperature in FPC using steel tinplate absorber.
The panel of black colored slices of beer cans can be used for air heating solar collectors as absorber. The experimental data show the temperature difference in outlet of sun following collector reaches up to 10-11 degree with sun irradiance 1000 W/m^2 at different weather conditions. It is a little more better than the best seed boxes.

Keywords: *Solar Collector, Air, Temperature, Absorber*

1. Introduction

The greatest advantage of solar energy comparing with other forms of energy is that it is clean and can be supplied without environmental pollution. Over the past century, fossil fuels provided most of our energy, because it was much cheaper and more convenient than energy from alternative energy sources, and until recently, environmental pollution has been of little concern. The limited reserves of fossil fuels cause a situation in which the price of fuels will accelerate as the reserves are decreasing.

Solar energy is used to heat and cool buildings (both actively and passively), dry products, heat water for domestic and industry use, heat swimming pools, generate electricity, for chemistry applications and many more operations [1].

The application of solar energy is completely dependent on solar radiation, a low-grade and fluctuating energy source. An intrinsic difficulty in using solar energy is caused by the wide variation in the solar radiation intensity. The availability of solar irradiance depends not only on the location, but also on the season. Extreme differences are experienced between summer and winter, and from day to day.

In general, solar water and solar air heaters are flat-plate collectors (FPCs), consisting of an absorber, a transparent cover, and backward insulation. Despite the similarity in designs, the different modes of operations and different properties of the heat transfer medium greatly affect the thermal performance and electric energy consumption for forcing the heat transfer medium a through the collector. Solar water heaters are operated as a closed-loop system whereas, in most cases, solar air heaters are operated in the open-loop mode.

The performance of solar air heaters is mainly influenced by meteorological parameters (direct and diffuse radiation, ambient temperature, wind speed), design parameters (type of collector, collector materials) and flow parameters (air flow rate, mode of flow). The principal requirement of these designs is a large contact area between the absorbing surface and air.

The efficiency of solar collector depending on the collector covered materials (polyvinylchloride film, cell polycarbonate PC, translucent roofing slate) [2-5], absorbers (black colored wood, steel-thin plate etc.), with different air velocities in collector was investigated [6-9]. The main efficiency parameter of solar collector is the air heating degree and it we chose as a criterion of efficiency.

The plane of FPC absorber is perpendicular to the flow of sun irradiance at sun following collector therefore this type is more powerful than stationary collector. The sun rays fall under angle to collector plane (it means it falls under angle to covered material) and it gives more reflection.

For manufacturing of collectors it is important to know their thickness and its effect on the temperature distribution of heated air. As one of the best absorbers is a tin plate in the middle of collector, then it is interesting to know how heated air temperature changes above and below the plate.

There is a need to test the various, cheap, easily available materials in an absorbent material for manufacturing of solar collectors.

2. Methodology

In the laboratory a *0.1×0.5×1.0* meters long experimental solar collectors were constructed for research into the properties of absorber materials. The air velocity at the experiments was v=0.9 m/s. Our investigations are devoted the sun following collectors, which guarantees perpendicular location of the plane of absorber from flow of the sun irradiance (Fig.1).

In the experiments, the collector covered material was a polystyrol plate. This material has gained immense popularity due to such properties as safety, mechanical crashworthiness, translucence and high UV radiation stability. The covered material - polystyrol plate reduced irradiance by 12-15 %.

The experimental data are recorded by means of an electronic metering and recording equipment of temperature, irradiance and lighting REG [10]. It is equipped with 16 temperature transducers and metering sensors of solar irradiance and lighting. The reading time of the data can be programmed from 1 to 99 minutes (1 minute in our case).
The recorded data are stored in the REG memory (there is a place for 16,384 records) and in case of need it is transferred to a computer for archiving with further processing. For evaluation and analysis of the results software REG – 01 has been developed, which is meant for transfer to the computer and processing of the recorded data. The information is stored in the form of a table and in case of need it is depicted as a graph.

The air heating experiments by this collector were made at different weather conditions. The solar irradiance measuring instrument is a pyranometer. The data of sun irradiance are dependent on clouds, shadows and we aligned the experimental data with the method of least squares using Eq. (1) [11].

$$\overline{y_i} = \frac{1}{35}[17y_i + 12(y_{i-1} + y_{i+1}) - 3(y_{i-2} + y_{i+2})] \quad (1)$$

where $\overline{y_i}$ - aligned data, y_i - experimental data, i- index.

Fig. 1. Sun following collector at work

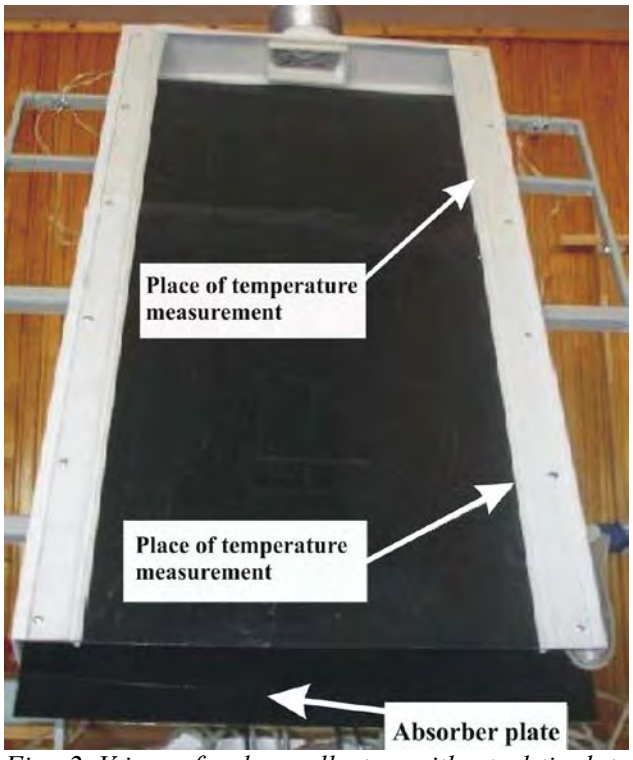

Fig. 2. View of solar collector with steel-tinplate absorber in middle.

3. Results

At first we researched a situation when the absorber (black coloured steel-thin plate) is put at the bottom and middle of the collector (Fig.2). Using the experimental results and statistical processing data we received correlation between the distance from absorber, sun irradiance to absorber plate and air temperature change in the collector. We got expressions for air temperature changing over steel-thin plate absorber in FPC at 35cm and 60cm from inlet.

The temperature change ΔT over absorber at 0.35 m distance from input can be expressed with Eq. (2);

$$\Delta T = 3.8 \cdot 10^{-3} \cdot R + 21.3 \cdot y - 318.5 \cdot y^2 - 4.6 \cdot 10^{-3} \cdot R \cdot y \ , \quad (2)$$

where y-distance from absorber,(m), R- sun radiation (W / m^2).

Close connection of this expression and the experimental data shows coefficient of determination $\eta^2 = 0.804$ in temperature increase domain $\Delta T \in (0;3)\ ^{O}C$.

The temperature change ΔT over absorber at 0.60 m from inlet we can be expressed with Eq.(3);

$$\Delta T = 1.57 + 0.011 \cdot R - 4.15 \cdot 10^{-6} \cdot R^2 - 34.8 \cdot y + 369.8 \cdot y^2 - 0.021 \cdot R \cdot y \qquad (3)$$

with coefficient of determination $\eta^2 = 0.855$.

The visual interpretation of expressions (2), (3) is shown in Fig.3-4.as contour plot .

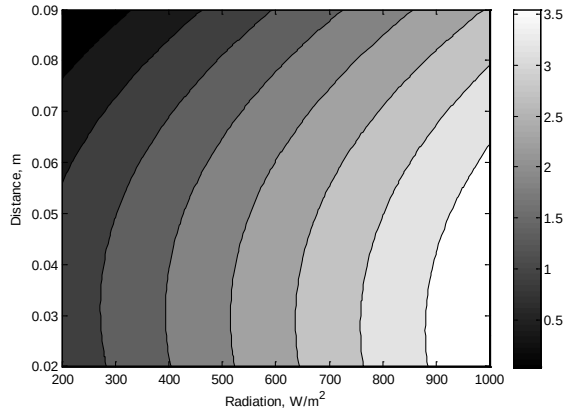

Fig. 3. Plot of air temperature increase ΔT depending on distance over absorber y (m) and radiation R (W/m^2) at 0.35 m from inlet

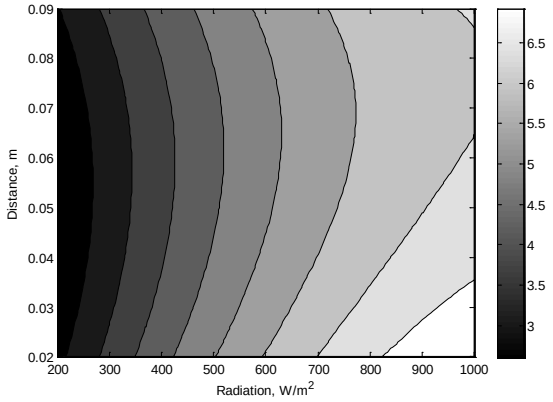

Fig. 4. Contour plot of air temperature increase ΔT depending on distance y(m) over absorber and radiation of sun R (W/m^2) at 0.6 m from inlet.

The temperature change ΔT in the collector length over absorber (steel-tinplate) put in the middle of the air channel can be expressed with Eq. (4);

$$\Delta T = 0.0073 \cdot R - 5.4 \times 10^{-6} R^2 + 17 \cdot x - 25.6 \cdot x^2 + 0.028 \cdot R \cdot x \ , \qquad (4)$$

where x-length of collector,(m). Coefficient of determination $\eta^2 = 0.98$ in temperature increase domain $\Delta T \in (0;18)\ ^{O}C$.

The temperature change ΔT in the collector under absorber can be expressed with Eq.(5) ($\Delta T \in (0;10)\ ^{O}C$):

$$\Delta T = 4.2 \cdot x - 4.9 \cdot x^2 - 2.8 \times 10^{-3} \cdot R + 3.4 \times 10^{-6} R^2 + 0.012 \cdot R \cdot x \ , \qquad (5)$$

with coefficient of determination $\eta^2 = 0.955$.

The graphical interpretation of these expressions is shown in Fig.5, Fig.6.

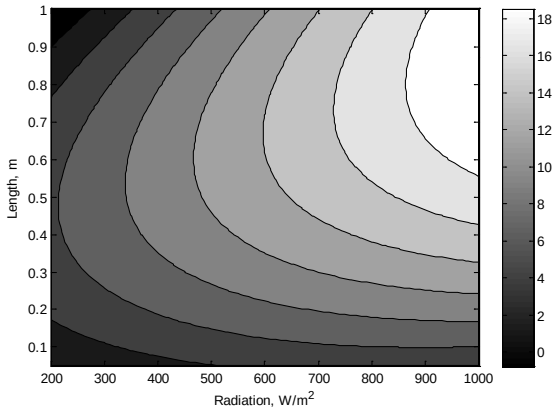

Fig. 5. Air temperature increase ΔT over steel-tinplate absorber depending on collector length x (m) and radiation R (W / m^2)

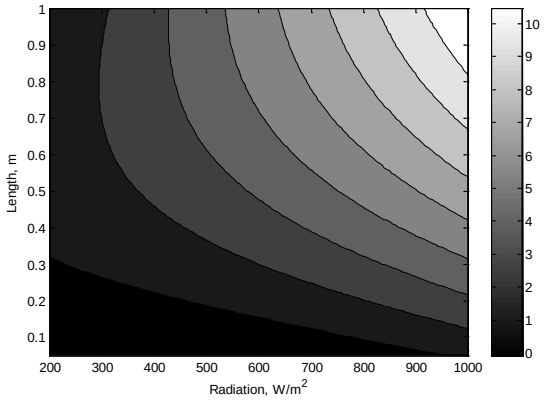

Fig. 6. Air temperature increase ΔT under steel-tinplate absorber depending on collector length x (m) and radiation R (W / m^2)

Second we tested new absorber materials which can be used in hand made air heated solar collectors. These materials must be cheap, light and simple use. We made panels with different size black seed boxes which were made of polypropylene (Fig.1, Fig.8) and a panel with coloured slices of beer cans (Fig.7, Fig.1) . These slices help to mix the air flow in the collector and rise the outlet air temperature.

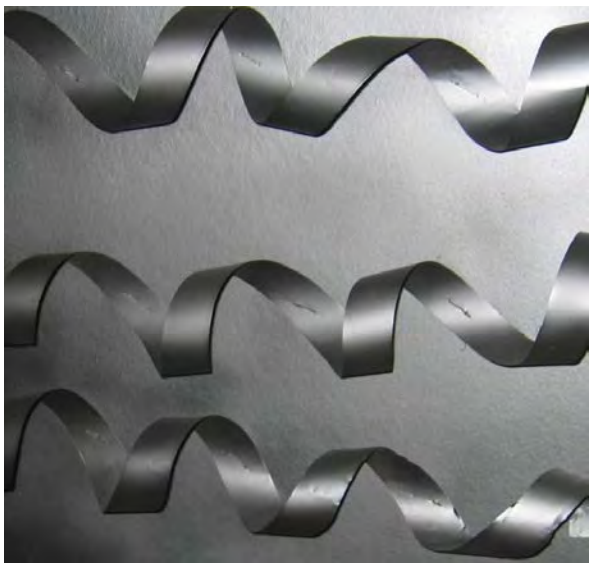

Fig.7 Black coloured slices of beer cans as absorbers of air collector

Fig.8 The panel of 13 seed boxes as absorbers of air collector

Air heating level is not highly dependent on ambient temperature. Much more it is influenced by solar radiation. Experimental results which was made in 7.September 2010. showed it (Fig.9).

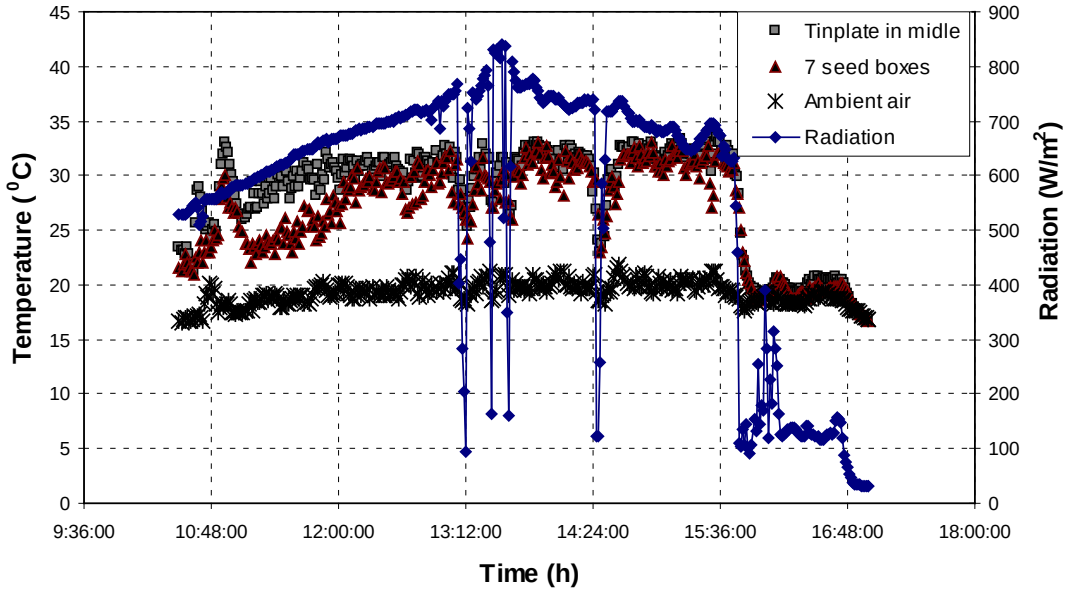

Fig.9 Ambient air, collectors(with tinplate, seed boxes absorbers) outlet temperatures and solar radiation changes (10:30 -17:00 o'clock).

Ambient air heating degree serves as the main effectiveness of collectors at the same size collectors with the same fan power. Comparing the absorbers with 7 seed boxes in line (the best variant of seed boxes [8]) and the absorber panel with slices at the same weather conditions we can see that the absorber panel with slices of cans gives little bit better results (temperature increases at the outlet of collector) than the variant of seed boxes Fig.10. The air inflow temperature equal with ambient air temperature and it changed from 17 ^0C to 25 ^0C during the experiment.

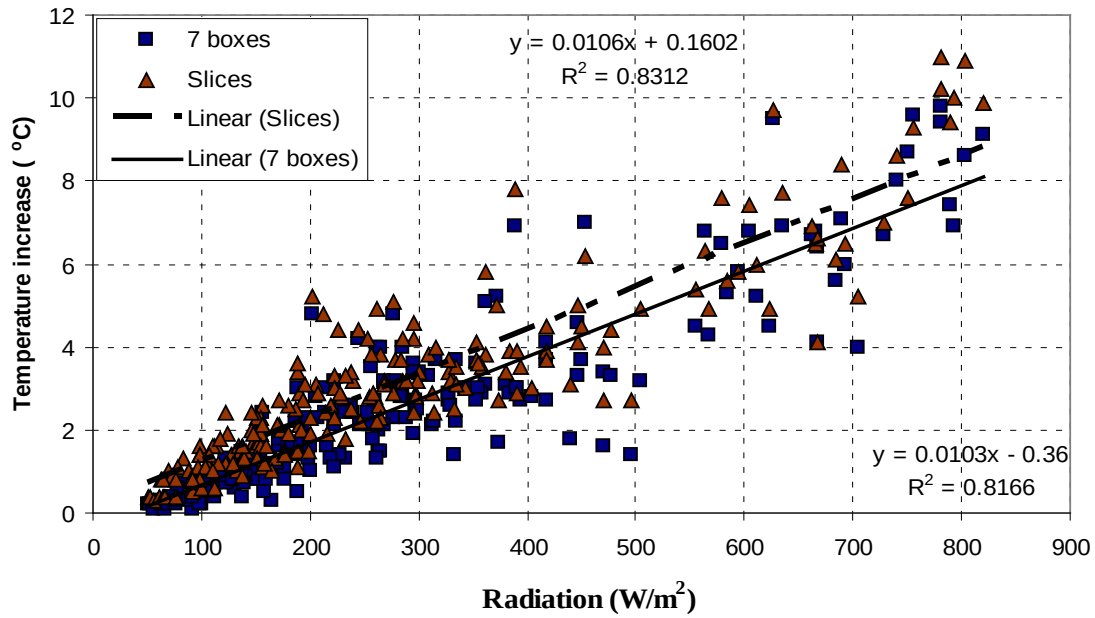

Fig.10 Air heating temperature difference with black coloured slices and 7 element seed boxes in line depending upon solar irradiance in sun following collector (11:00 -18:00 o'clock).

The experimental data show very good linear correlation between solar radiation and air-heating degree (correlation coefficient greater than 0.9).

The efficiency of solar air collectors is influenced both by the design and air circulation and by the properties of the material used for cover, absorber and insulation. The efficiency of this absorber material can be explained by the type of absorber which mix the air flow in thickness and width of the collector area. It is important because without air mix, air exchange at corners and near sides of the collector does not take place.

4. Conclusions

1. The theoretical expressions for air temperature which are changing over steel-thin plate absorber in FPC at 35cm and 60cm from inlet are obtained. These expressions show temperature distribution depending on the distance to the absorbent tin plate and radiation.

2. Using experimental data processing temperature distribution above and below the absorbent sheet according to the length of the collector and solar radiation was obtained.

3. Absorber black colored slices of beer cans can be used for air heating solar collectors. The experimental data show that the temperature difference in outlet of sun following collector reaches up to 9-11 degree with sun irradiance 1000 W/m^2 at different weather conditions.

4. Air solar collectors due to their physical and mechanical properties are suitable in Latvia for heating the air. At favorable weather conditions the heating degree of ambient air reaches more than 10 degrees at exit with the absorber length 1 m and air velocity v=0.9 m/s.

Abstract: The surface and optical properties of black chrome films prepared by two different electrochemical baths were characterized. The black chrome films have been deposited on bright nickel substrates by electroplating technique. The surface morphology and phase structure of the films were investigated by using scanning electron microscopy (SEM) and X-ray diffraction (XRD), respectively. The chemical composition of prepared films was determined by energy-dispersive x-ray analysis (EDS). The spectral reflectance was also measured in the UV-Vis-NIR and IR regions. From the SEM analysis, it was found that prepared films by the first chemical bath is denser with nano size grains and by the second chemical bath they become porous, with micro sized grains. The XRD results show that in both cases chrome is the main chemical component in the films. The films prepared by second chemical bath have better optical properties than the films prepared by first chemical bath.

Keywords: *Black chrome, Electroplating, Solar collector.*

1. Introduction

The growing energy demand through out the world has attached great important to the study of renewable source [1]. The cost and effective utilization of solar energy and conversion of that into thermal energy requires an efficient solar coating as having high solar absorptance (>0.9) in the visible region and very low thermal emittance (<0.1) in the infrared to minimize the radiation heat loss [2, 3]. This property is named selectivity [4]. The higher the selectivity value, the better the thermodynamical efficiency of the solar energy collectors [1]. Other necessary properties of a practical solar selective coating are ease and availability of application, low cost and long-term durability under solar radiation [5]. Black chrome is one of the most commonly used solar selective coatings in solar collector systems for the efficient conversion of solar energy into thermal energy. A variety of deposition techniques such as chemical oxidation, CVD, spray, sputtering and electroplating are available for preparation of solar selective surfaces. Of the above techniques, electroplating is attractive due to its simplicity, low cost and large area involved [2]. Electroplating of metallic films is one the appropriate techniques for obtaining absorber coatings with selective optical properties for solar collectors. Electroplated black chrome is one of the most widely used solar absorber, mainly due to its high absorptance, good stability in a wide rang of oxidizing/reducing environments and high thermal resistance [3]. Coatings used as solar selective surface in solar collectors have low thicknesses, therefore these coatings cannot protect the substrate against atmospheric corrosion and thermal oxidation. For solving this problem bright nickel coating before black chrome deposition is recommended [6]. Nickel under coat before black chrome deposition decreases thermal emissivity and increases thermal resistance of black chrome coatings [3].

2. Experimental method

Electroplating is an electrodeposition process for producing a dense, uniform, and adherent coating, usually of a metal or an alloy, upon a conductive surface by the act of electric current. The core part of the electroplating process is the electrolytic cell (electroplating unit). In the electrolytic cell a current is passed through a bath containing electrolyte, the anode, and

the cathode. The workpiece to be plated is the cathode (negative terminal). The anode, however, can be one of the two types: sacrificial anode (dissolvable anode) and permanent anode (inert anode). The sacrificial anodes are made of the metal that is to be deposited. The permanent anodes can only complete the electrical circuit, but cannot provide a source of fresh metal to replace what has been removed from the solution by deposition at the cathode. Electrolyte is the electrical conductor in which current is carried by ions rather than by free electrons (as in a metal). Electrolyte completes an electric circuit between two electrodes. Upon application of electric current, the positive ions in the electrolyte will move toward the cathode and negatively charged ions toward the anode. This migration of ions through the electrolyte constitutes the electric current in that part of the circuit. The migration of electrons into the anode through the wiring and an electric generator and then back to the cathode constitutes the current in the external circuit. The metallic ions of the salt in the electrolyte carry a positive charge and are thus attracted to the cathode. When they reach the negatively charged workpiece, it provides electrons to reduce those positively charged ions to metallic form, and then the metal atoms will be deposited onto the surface of negatively charged workpiece [7].

Black chrome electroplates are obtained by replacing the sulphate ion in conventional chrome plating baths by fluoride, silicofluoride, acetate, borate, nitrate or sulphamate ions. Care should be taken to ensure complete removal of the sulphate ions; these are deleterious to the bath. The substances introduced in to the bath as catalysts can be divided into three groups, acetate baths, floride-catalysed baths and nitrates and other catalysts. In the fluoride or mixed catalyst plating baths a higher plating efficiency, a harder, more corrosion and wear-resistance deposit is obtained. The fluoride is commonly added as the SiF_6^{2-} ion in amount of 2-3g/l. this chemistry provides better substrate activation for plating on bright nickel [8].

The deposition of black chrome was carried out on bright nickel plated brass substrates in an electrochemical bath by electroplating technique. The brass substrates of 0.1 mm thickness were cut in strips of 5.5 cm × 6.5 cm for electroplating of bright nickel. The brass substrates were pretreated by different cleaning procedure. Mechanical polishing was done with a grinding paper No.2000, followed by rinsing in distilled water. Then substrates were cleaned in a hot commercial alkaline cleaner, followed by rinsing in distilled water and activated in an aqueous 10 vol% H_2SO_4 solution, followed by rinsing in distilled water. Then bright nickel deposited on prepared brass substrates by electroplating technique. The chemical bath for bright nickel deposition consists of nickel sulphate ($NiSO_4$), nickel chloride ($NiCL_2$) and boric acid (H_3BO_3). The bright nickel deposition carried out in 0.5A/dm^2 current density for 5 min in 50 °C-60 °C temperatures. Nickel metal with 99.9% purity used as anode for bright nickel deposition and brass substrate was used as cathode. Prior to the deposition of black chrome, the prepared bright nickel substrates were cleaned in a hot commercial alkaline cleaner, followed by rinsing in distilled water and activated in an aqueous 10 vol% H_2SO_4 solution. Following activation the plates were thoroughly rinsed in distilled water to remove all trace sulphate. Then black chrome was deposited on bright nickel substrates. The deposition conditions to get black chrome were optimized by varying the chemical bath composition, current density and plating time. In this paper, two chemical baths were used for electroplating to comparison of surface and optical properties of these surfaces and selecting the better films.

The first bath for black chrome deposition consists of chromic acid, acetic acid and barium acetate (acetate bath). Electrodeposition carried out in 3A/dm^2 current density for 180 seconds in 50 °C temperature. The second bath for black chrome deposition consists of chromic acid,

fluorosilicic acid and barium carbonate (floride-catalysed bath). Deposition carried out in 6A/dm2 current density for 120 seconds in 25 °C temperature. Several experiments were done to prove the reproducibility of the samples.

Details of the optimized plating processes used in this study are given in table 1.

Table 1. Experimental electrodeposition parameters.

Bath	Composition	Temperature (°C)	Current density (A/dm^2)	Plating time (s)
First	Chromic acid (CrO_3) Acetic acid (CH_3COOH) Barium acetate ($Ba(CH_3COO)_2$)	50	3	180
Second	Chromic acid (CrO_3) Fluorosilicic acid (H_2SiF_6) Barium carbonate ($BaCO_3$)	25	6	120

Barium compounds such as the carbonate, acetate or hydroxide are usually added to black chrome plating solutions. Their role is to precipitate any sulphate ions from solution, and apart from possible complexation of the carbonate ion with Cr (III), they are not expected to significantly affect black chrome electrochemistry [9].
For the black chrome deposition Pb-Sb alloy, which contains only 2-5% Sb, was used as the anode(the permanent anode) and bright nickel substrate used as cathode. After deposition the samples were cleaned in distilled water and air dried at room temperature. Surface morphology of the coatings was characterized with scanning electron microscopy (SEM), manufactured by Philips, XL30 model. The X-ray diffraction (XRD) analysis was done using a PW1840 diffractometer. The normal spectral reflectance of the electrodeposited black chrome coating in UV-Vis-NIR and IR regions was recorded using a Cary 500 Scan UV-Vis-NIR spectrophotometer and FTIR Jasco, respectively.

3. Results and discussion

3.1. SEM analysis

Fig. 1 gives the scanning electron microscopy (SEM) of magnification 15000× for black chrome films prepared from two different baths. Figure 1 shows that the surface morphology of films deposited from different bath composition are different. From the SEM analysis it was found that the black chrome films achieved from the first bath is denser with nano size grains but films deposited from the second bath they become porous, with micro sized grains.

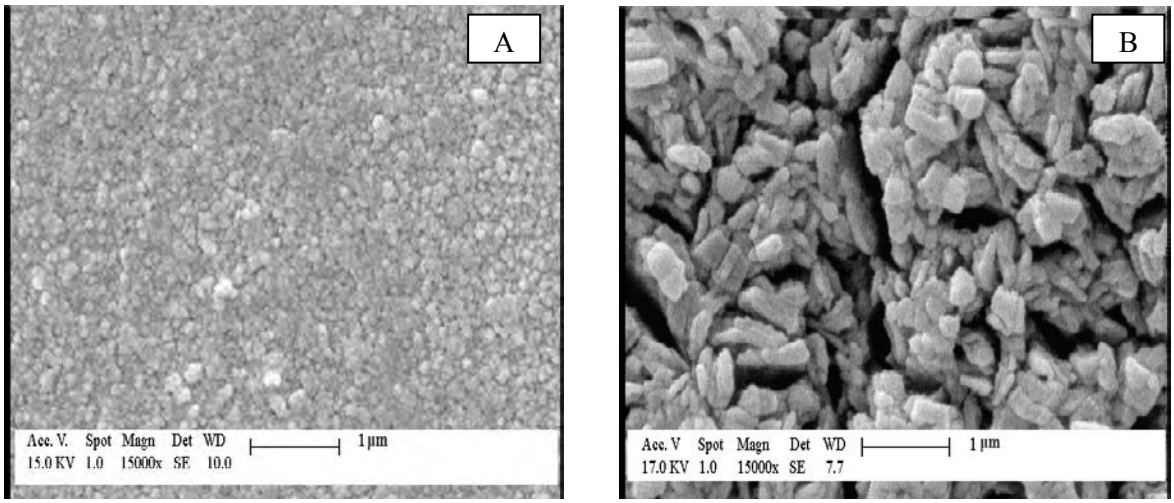

Fig. 1. The SEM images of black chrome films deposited on bright nickel substrates from two different baths. A: first bath, B: second bath.

3.2. EDS analysis

Fig. 2 a nd Table 2 show the chemical composition of black chrome deposited from two different baths. The data indicate that films prepared from both baths have contained chrome in their composition. Wight percentage of chrome in films prepared from the second bath is more than of the films prepared from the first bath.

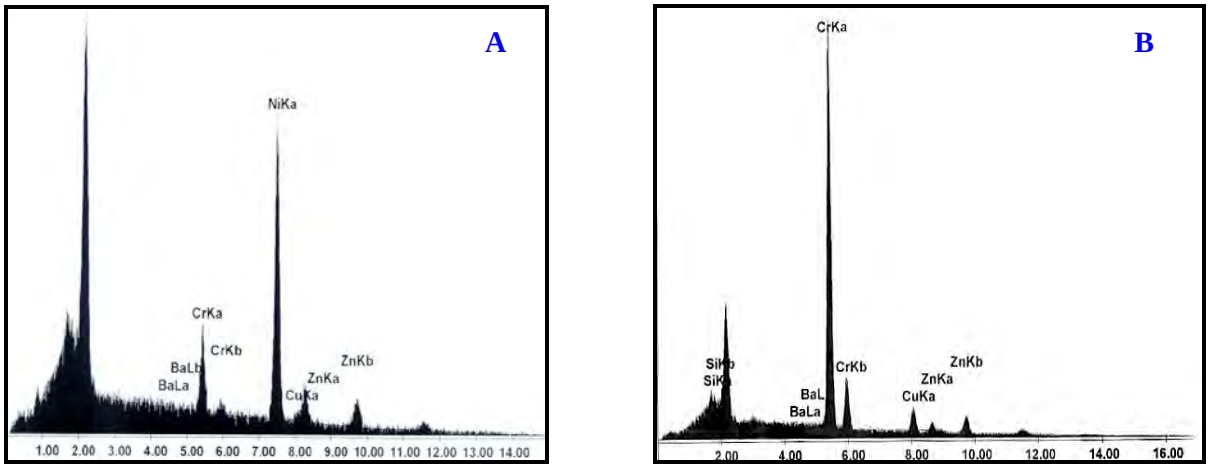

Fig. 2. The EDS spectrum for black chrome films deposited d on bright nickel substrate from two different baths. A: First bath, B: Second bath.

Table 2. The EDS analysis of black chrome deposited from two different baths.

Elements	Wt.% first bathe	Wt.% second bath
Cr	8.38	62.62
Ni	84.23	12.50
Cu	4.58	12.80
Zn	1.65	8.53
Si	-	1.92
Ba	1.16	1.63

3.3. XRD analysis

In order to identify the predominant chrome phase in the deposited films, it is necessary to investigate the coatings using X-ray diffractometer. Fig. 3 shows the XRD patterns for the bright nickel substrate coated with black chrome films. It is possible to detect that the bulk structure of the black chrome films were mainly consist of metallic chrome with the crystallographic plane (110) perpendicular to the substrate [6, 7]. As can be seen from Fig. 3, the different compositions of chrome are obtained in these two films prepared from two different baths.

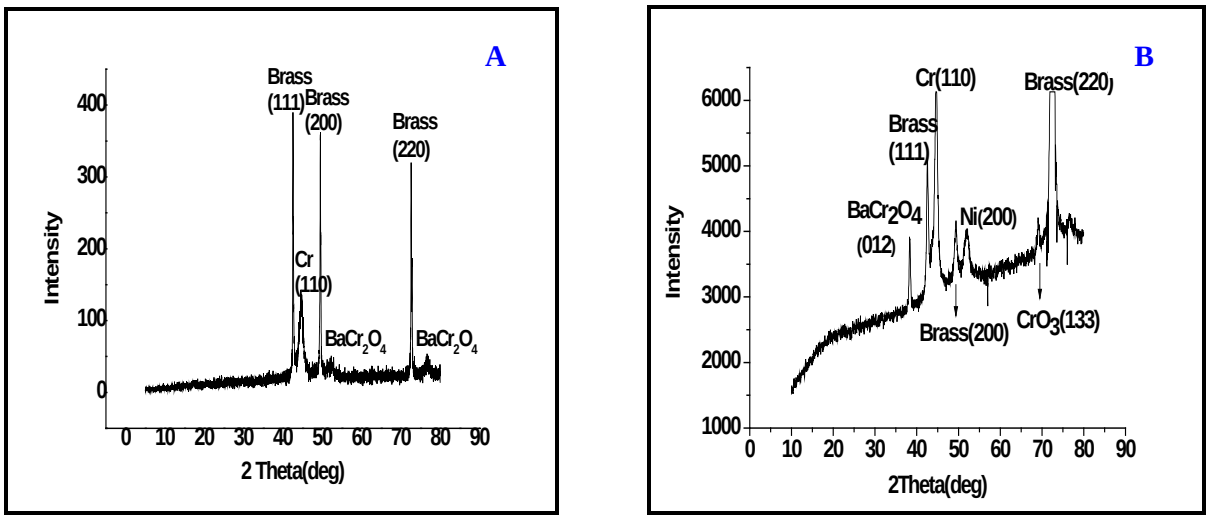

Fig. 3. The XRD patterns for black chrome films deposited on bright nickel substrate from two different baths. A: First bath, B: Second bath.

3.4. Spectral reflectance

The influence of two different electrochemical baths on the selective absorber properties of black chrome films are given in Figs. 4 and 5. Figs. 4 and 5 shows the spectral reflectance in the UV-Vis-NIR and IR regions for black chrome deposited on b right nickel substrates prepared from two different baths respectively. From figure 4 it is evident that the spectral reflectance in UV-Vis-NIR region is below 12% for black chrome films deposited on bright nickel prepared from both baths, indicating that in this spectral region the solar absorptance is quite high [2]. Spectral reflectance for black chrome films prepared from the second bath is less than of films prepared from the first bath, hence, its absorption is higher. This difference is probably due to the rougher surface and chemical composition of these samples which enhances the absorption of the radiation and can explain the high absorptance level of this material. Hence, using of second bath is recommended to get good solar selective black chrome coating in the UV-Vis-NIR region. Fig. 5 indicates that the spectral reflectance of black chrome films in the IR (2.5μm-20μm) region, and hence the emissivity of them. From Fig. 5 it is evident that films prepared from the second bath have lower thermal emittance. It can be seen in the figure 5 that by using of the first bath spectral reflectance is reduced and hence increases the thermal emittance of films will increase.

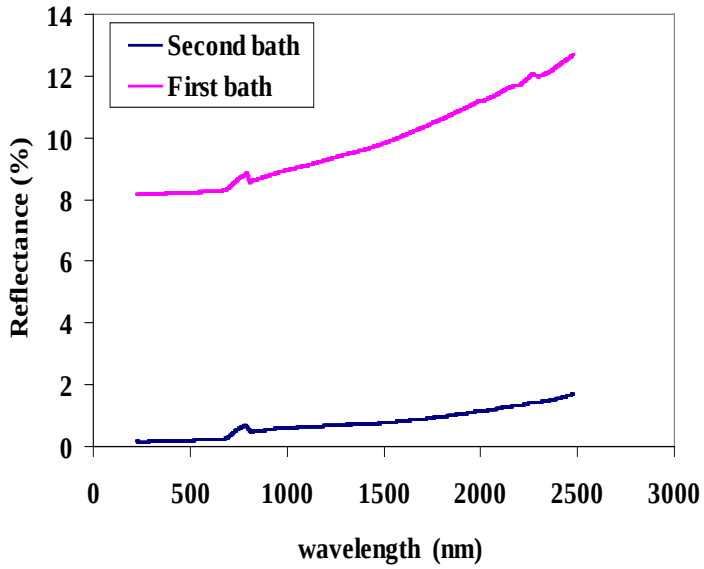

Fig. 4. The Spectral reflectance in the UV-Vis-NIR region for black chrome films deposited on bright nickel substrates from two different baths.

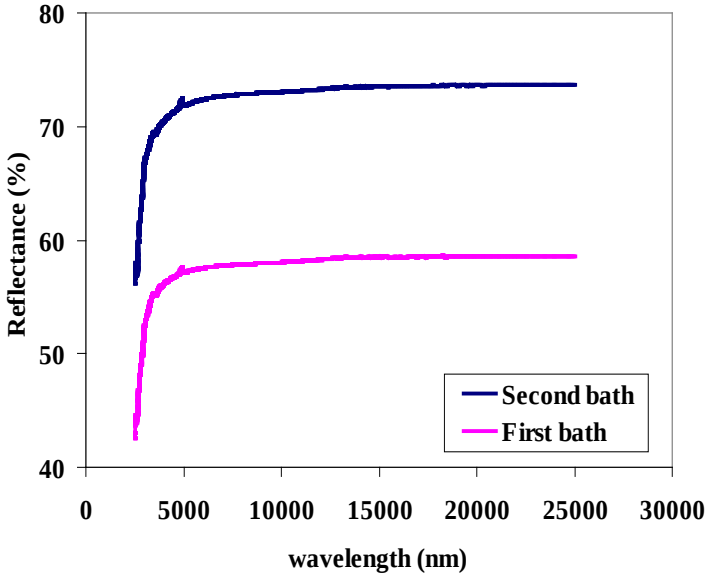

Fig. 5. The Spectral reflectance in the IR region for black chrome films deposited on bright nickel substrates from two different baths.

4. Conclusion

The black chrome films were prepared by electroplating technique from two different baths on bright nickel substrates. SEM analysis shows that films prepared from first bath is denser with nano size grains while films prepared from the second bath become porous, with micro sized grains. The EDS analysis results indicate the presence of chrome on films prepared from both baths. The chrome amount in the films prepared from second bath is higher than one. XRD analysis shows that structure of black chrome films from both baths were mainly consist of metallic chrome with (110) orientation. Black chrome films have good optical properties for solar energy absorption. The spectral reflectance in the UV-Vis-NIR and IR regions shows that films prepared from the second bath have higher absorption and lower emittance, Hence these films are better for using in solar collectors.

Abstract: A sol-gel technique has been established at a laboratory scale for low cost production of high efficient selective solar absorbers comprising a composite material of nano-structured carbon in a nickel oxide matrix. In order for these materials to be applied in real world scenarios it is necessary to extensively scale up the fabrication process to allow large area coatings. This can be done by adapting this sol-gel technique to large area deposition.
In this project, we are undertaking research and development activities for three-years to make a 'Lab to Large scale' transition in order to eventually integrate into existing solar collectors for low cost domestic water heating in a rural area for social good.
A spray coating technique has been used to deposit these C/NiO coatings on aluminum substrates. Preliminary optical results have shown absorptance of up to 90 %. The preparation and characterization as well as the process towards developing a large-area solar selective coating for low cost domestic heating will be discussed.

1. Introduction

Hot water is required to maintain adequate sanitation and health. Often, water has to be boiled in order to make it safe for drinking. In rural Africa, the traditional fuel used for heating water is firewood, which produces smoke and is generally unsafe. Access to energy from fossil fuels such as oil, gas, and coal, by expanding grid electricity is either impractical or too expensive in these countries. There is therefore a clear need for low-cost and environmental friendly means of water heating.

Solar energy is a promising alternative energy source that can address these challenges. It is a resource readily available in every country around the world, and is not a threat to the environment through pollution or to the climate through greenhouse gas emission. As a matter of fact, most African countries have around 325 days of strong sunlight a year, on average, more than 6 kWh energy per square meter a day [1]. Solar thermal energy is a technology for harnessing solar energy for thermal energy (heat). Solar thermal collectors for water heating use a spectrally selective surface that absorb sunlight and convert it to heat. High performing selective surfaces already exist in the market, but most of these products are produced using complicated manufacturing process and are expensive. The spectral selective surfaces are the most costly component of a solar thermal collector [2]. This means that if one reduces the price of selective solar absorbers one can hopefully reduce the cost of a solar thermal collector.

A sol-gel technique has been established at a laboratory scale for low cost production of high efficient selective solar absorbers comprising a composite material of nano-structured carbon in a nickel oxide matrix [3,4]. These coatings were deposited using a spin coater. Some of the

advantages of this novel technique to fabricate carbon-metal oxide composite coatings are that it is simple and easy to control, utilizes readily available chemicals, does not require sophisticated equipments, the coatings can be deposited at ambient pressure conditions, and the process is low in material consumption. Therefore, the method is very promising for developing countries and could hopefully reduce the production costs for spectrally selective absorbers [5]. In order for these materials to be applied in real world scenarios it is necessary to extensively scale up the fabrication process to allow large area coatings. However, the spin coating process cannot be used for large area coatings. To succeed as a useful manufacturing technique, the specific deposition approach must be highly scalable while still producing films with the quality of laboratory deposition methods, e.g., spin coating. Spray deposition is historically scalable to large areas, and may also be applicable to deposit these C/NiO composite coatings. Thus, large area coating can be done by adapting this sol-gel technique to large area deposition.

In this study, we will demonstrate the preparation of sol-gel C/NiO nanocomposite coatings with reasonable optical properties on aluminum substrates by spray-coating technique and show the dependence of variation of the optical properties on different deposition process parameter.

2. Experimental

The absorbing films were coated on rough highly reflecting aluminum substrates. The substrates were cut into a 55 × 55 mm^2 size and cleaned before deposition. The pre-cleaning process involved cleaning the substrates with aqueous detergent and distilled water in order to remove the grease. Due to poor adhesion to the aluminum surfaces (uncleaned or cleaned with soap and water), the substrates were etched. The pre-cleaned substrates were thoroughly rinsed and dipped in a phosphoric acid bath at 60 °C for about 30 minutes or in an HCl bath kept at room temperature to remove the protective oxide layer. They were then thoroughly rinsed using distilled water to remove the acid. Finally they were blown dry with a N_2 and coated immediately.

The preparation of the solution was adopted from a previous experiment [4]. The NiO precursor solution was prepared by dissolving an appropriate quantities of nickel acetate [($NiAc_2$), $Ni(CH_3COO)_2.4H_2O$] in 50 ml of absolute ethanol [(EtOH), CH_3CH_2OH] followed by magnetic stirring at room temperature. An amount of diethanolamine [(DEA), $NH(CH_2CH_2OH)_2$] was added as a chelating agent. For the carbon precursor, sucrose was dissolved in doubly distilled water in the mass ratio 1:1 prior to mixing with the matrix precursor solutions. After a period of stirring appropriate quantity of polyethylene glycol[(PEG), $HO(CH_2CH_2O)nH$], a structure directing template, was added to the NiO matrix precursor sol. The oxide and carbon precursor solutions were mixed and stirred again. The resultant solution was then further stirred until the formation of a sol. The final solution was poured into the spray gun and a conventional air compressor is used to eject the solution on top of the pre-cleaned aluminum substrates. The schematic representation of the spray deposition used during this study is shown in Fig. 1. A relatively low pressure (30-90 kpa) was used during deposition in order to ensure a fine atomization while preventing blowing off the droplets already deposited on the substrate. The distance of the spray gun from the substrate was kept at 50 cm. In order to vary the thickness of the coatings, number of passes of the spray gun across the substrate was varied.

Once the substrates were spray coated, the samples were put into a tube furnace for pyrolysis and crystallization. The furnace temperature was raised to 450 °C at a rate of

20 °C min^{-1}, maintained at that temperature for 60 minutes, and then left to cool to room temperature naturally. Nitrogen gas was continuously flown through the furnace throughout the heat treatment in order to maintain an inert atmosphere.

The near-normal spectral reflectance of the samples was measured in the 0.3-2.5 μm wavelength range with a Perkin Elmer Lambda 900 spectrophotometer. A spectralon sample was used for reference spectrum measurements. A Bruker Tensor 27 spectrophotometer with a gold mirror reference was used to measure near normal reflectance in the 2.5–20.0 μm wavelength range. The reflectance measurements were used to calculate solar absorptance, α, and the thermal emittance, ε, of the samples at 100 ° C using Eqs (1) and (2), respectively [6]:

$$\alpha_{sol} = \frac{\int_{0.3}^{2.5} I_{sol}(\lambda)(1-R(\lambda))d\lambda}{\int_{0.3}^{2.5} I_{sol}(\lambda)d\lambda} \quad (1)$$

$$\varepsilon_{ther} = \frac{\int_{2.5}^{20} I_P(\lambda)(1-R(\lambda))d\lambda}{\int_{2.5}^{20} I_P(\lambda)d\lambda} . \quad (2)$$

The thermo-gravimetric analysis (TGA) was done on Perkin-Elmer TGA 4000 t hermo-gravimetric analyzer. Approximately 100 mg final mixture of C/NiO precursor solution was placed in open 190 μl alumina pan and heated from 25 °C to 980 °C at a heating rate of 5 °C min^{-1} in N_2 atmosphere (flow rate 50 ml min^{-1}). The differential scanning calorimeter (DSC) results were collected on Mettler Toledo DSC 1 instrument. The surface morphology of the coatings was investigated using a ZEISS ULTRA plus FEG-SEM scanning electron microscopy. The Energy Dispersive Spectroscopy (EDS) analysis was done using a JEOL-JSM 7500F Scanning Electron Microscope. Raman spectra were collected using a Raman spectroscopy (Jobin-Yvon T64000 spectroscope), equipped with an Olympus BX-40 microscope attachment. An Ar^+ laser (514.5 nm) with energy setting 1.2 mW from a Coherent Innova Model 308 was used as an excitation source.

3. Results

In order to determine the optimal temperature of heat treatment, the C/NiO precursor solution was thermally analyzed by TGA and DSC techniques. Figure 2 displays a typical TGA and DSC curves for the C/NiO precursor solution. It can be seen from the figure that the DSC curve shows 1 endothermic peak at 83 °C and 4 exothermic peak at 210 °C, 262 °C, 342 °C and 436 °C. TGA curve exhibit four weight loss stages: 53 % the initial weight loss occurred

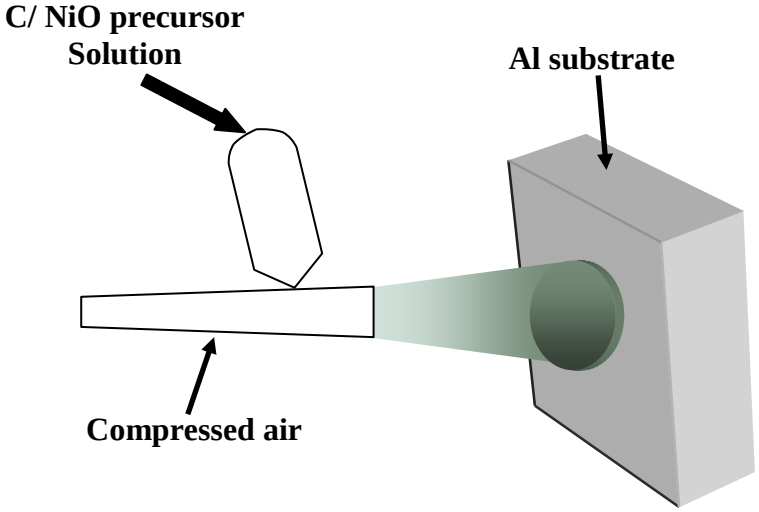

Fig. 1. A schematic diagram of the spray deposition technique used to deposit C/NiO nanocomposite coatings on Al surface.

31 and 57 °C, 10 % between 75 and 144 °C, 15 % between 144 and 295 and the final weight loss (13 %) between 295 and 341. The first weight loss was likely due to the evaporation of ethanol whereas the second and third was probably due to desorption of moisture and desorption of organic molecules, respectively. The fourth weight loss was most likely due to carbonization. Above 450 °C no noticeable weight loss has occurred. This stabilization of weight loss is accompanied by a distinct DSC exothermic peak at 437 °C which indicates the crystallization of the composite material. It is therefore decided to anneal the samples at temperatures between 450 °C to 550 °C . This choice has also been accompanied by the improvement of the optical absorption for samples heat treated in this temperature range (not shown).

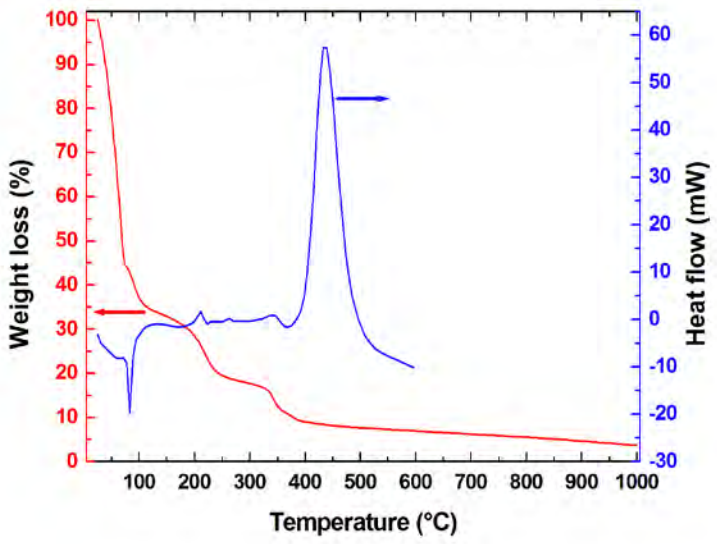

Fig. 2. Typical TGA and DSC spectra for C/NiO precursor solution.

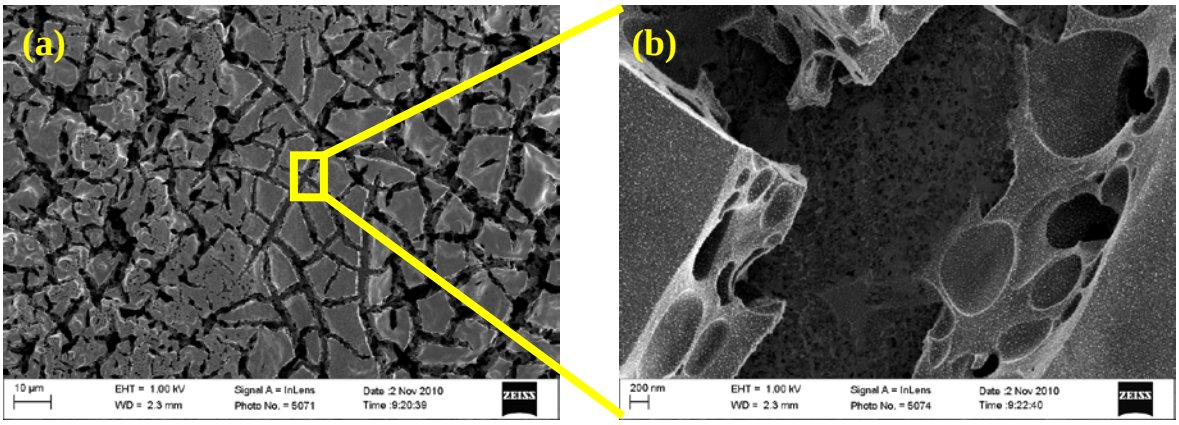

Fig. 3. (a) FE-SEM images of C/NiO nanocomposite coated on aluminum substrate, (b) enlarged image.

Figure 3 (a) depicts a typical SEM image of a C/NiO composite coating. The higher magnification image is shown in Fig. 3(b). As can be seen from Fig. 3 (a), the surface of the coating is uniform and cracked. The enlarged image (Fig 3(b)) shows that the coatings are porous. It is believed that the porosity of this film can produce high absorptance by multiple reflections [7]. The size distribution of the spherical particles in the coating is between 10 and 20 nm.

The composition of C/NiO composites was investigated using EDS (Fig. 4(a)). It reveals the presence of C, O, and Ni, which confirms the existence of NiO nanoparticles in the coating. The Al signal originates from the substrate used for coating. The presence of carbon in these films is further evidenced by Raman studies conducted on these coatings. Figure 4(b) shows a typical Raman spectrum of the C/NiO nanocomposite. The D band at ~ 1350 cm^{-1} originates from amorphous carbon and structural defects; the G band at ~ 1580 cm^{-1} is attributed to graphite structures, stems from tangential shearing mode of the carbon atoms [8-10]. The G' band at ~ 2700 cm^{-1} is an overtone of the D band which indicates the long range graphite ordering. Higher order Raman modes are also visible in the region 2920- 3220 cm^{-1}.

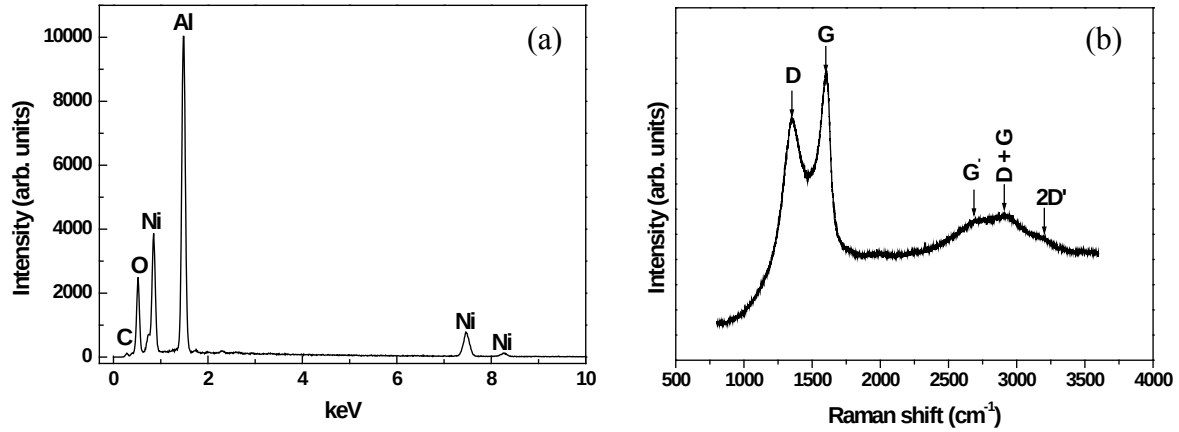

Fig. 4. (a) A typical EDS spectrum for C/NiO nanocomposite coated on aluminum substrate, (b) Raman spectra of the C/NiO nanocomposite coating.

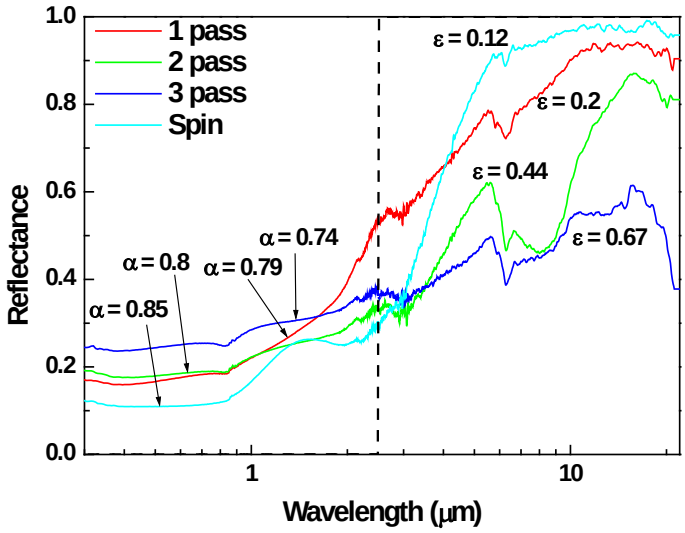

Fig. 5. The near normal reflectance spectra of C/NiO nanocomposite deposited with different passes on aluminum substrate etched with H_3PO_4. The spectrum for spin coated samples is also included for comparison. The broken line represents the reflectance spectrum for an ideal selective solar absorber.

Figure 5 shows the reflectance spectra of spray deposited samples with different passes, together with a spin coated sample as a reference. The dips in the spectra at about 6.3 μm are due to water absorption (O–H bending vibrations at 1,600 cm^{-1}) [11,12]. The O–H bending vibrations for the spray deposited samples are much stronger than the spin coated samples. This implies that spray coated samples have higher emittance (lower reflectance) values.

The reflectance spectra of the C/NiO nanocomposite deposited on a luminum substrate cleaned with HCl are presented in Fig. 6. It can be seen from the figure that the O–H mode vibrations are also present in this C–NiO samples. Although the solar absorptance values for some of the samples cleaned using HCl are better than the spin coated sample, they are highly emitting.

4. Discussion

The main reason for film cracking is due to film shrinkage because of solvent out gassing during the heat treatment [13]. Although it is minor, the thermal expansion rate difference between the coatings and the aluminum substrate can also contribute to the cracking during the cooling process [13]. According to Borström *et al.* [14], film homogeneity and propensity of film cracking is very important for solar absorbing thin films. The durability of the coatings will be severely affected due to infiltration of water and subsequent degradation of aluminum substrates. This clearly suggests that further study is necessary in order to reduce these cracks.

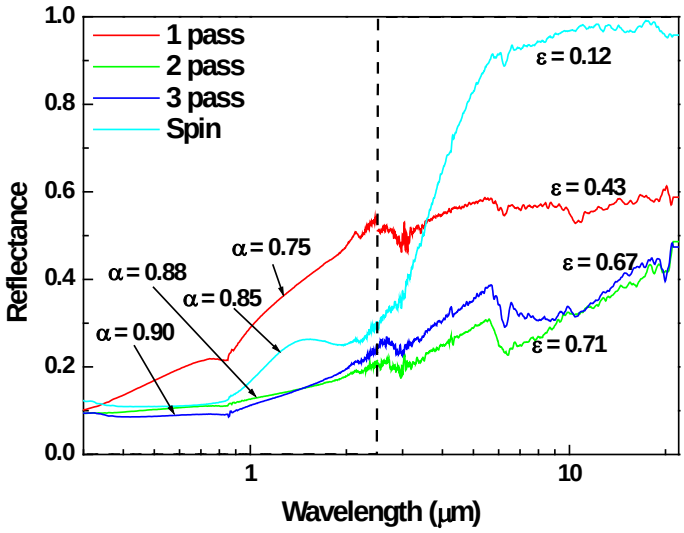

Fig. 6. The near normal reflectance spectra of C/NiO nanocomposite deposited with different passes on aluminum substrate etched with HCl. The spectrum for spin coated samples is also included for comparison. The broken line represents the reflectance spectrum for an ideal selective solar absorber.

In an effort to increase the absorptance of this single layer we have pretreated the substrate surface by etching with H_3PO_4 and HCl. It is well known that the solar absorptance of selective absorber coatings can be enhanced by producing a textured surface [13]. The surface texturing of the aluminum surface with HCl enhanced the absorptance of the coating considerably (Fig. 6). However, the emittance of these coatings becomes worse. The magnitude of the surface roughness accompanying the pretreatment has to be much smaller than the peak thermal radiation wave length and comparable to the solar wavelength [14].

The production cost for a 1 μm thick coating material for a lab scale is estimated to be R 0.35/m^2 ($ 0.05 / m^2). This price can change significantly if the precursor materials are purchased in bulk. All other additional production costs and heat treatment were not estimated. The price for aluminium substrate is R61.76/m^2 ($ 8.6/m^2). This implies that the material cost for the coating is very small compared to the substrate price. The material cost for a 100 nm thick coating for Ni-Alumina coatings were estimated to be 0.14 €/ m^2 (R 1.4 / m^2) [2]. It should be noted that the additional costs and heat treatment as well as transfer efficiency of the paint during spraying might slightly increase the cost.

Further research will focus on the optimization of the spray process parameters and the study of the durability of these coatings.

5. Conclusion

Spray deposition method was adapted for large-area deposition of sol-gel prepared C/NiO nanocomposite coatings on aluminum substrate for selective solar absorber application. The coatings were made possible by using conventional air compressor. The number of passes was varied in order to optimize the thickness of the coatings. The performance of the sprayed samples was compared with the spin coated. The preliminary results have shown that the sprayed samples have comparable solar absorption properties with the spin coated suggesting that the sol-gel synthesized and sprayed C/NiO composite films is very encouraging.

The properties of these coatings will, however, require further developments before it could be integrated into an existing solar collector for low cost domestic water heating in a rural area for social good.

Abstract: The aims of the research, was to investigate black colored steel-tinplate use for absorber and covered material of collector and compare the efficiency of three types of air heating collectors. This heated air we can exploited for drying of agricultural produce, room ventilation and room heating and etc.
0.1∗0.5∗1.0 meters long flat-plate collector (FPC) for experimental research was built. Air velocity at the experiments was v=0.9 m/s. We used the sun following collectors. The experimental data were measured and recorded in the electronic equipment (REG). The experiments were carried out in September 2010 at the same weather conditions.
Collectors of insulated and un-insulated surfaces with steel-tinplate absorber as covering material warmed ambient air up to 10-12 and 5-6 degrees corresponding (at irradiance 800 W/m^2). This difference indicates the great importance of insulating the collector body. It can explain with intensify heat exchange between absorber and ambient air which reduce efficiency of collector. There was good correlation with irradiance and air heating degree.
Our investigations showed that more effective FPC was collector with absorber tinplate at middle of collector body. At favorable weather conditions the heating degree of ambient air at the outlet reaches 6-8 degrees more that at the outlet of insulated collector covered by steel-tinplate.

Keywords: *Solar Energy, Air Heating, Collector, Solar Wall, Absorber.*

1. Introduction

Under Kyoto targets, the European Commission member states and stakeholders identified and developed a range of cost-effective measures to reduce emissions. The new package sets a range of ambitious targets to be met by 2020, including improvement of energy efficiency by 20%, increasing the market share of renewable to 20%. In a renewable energy-intensive scenario, global consumption of renewable resources reaches a level equivalent to 318 EJ ($E = 10^{18}$) per annum of fossil fuels by 2050, but it is less than 0.01% of solar energy reaching the earth's surface each year [1].

Solar energy is used to heat and cool buildings (both actively and passively), drying production, heat water for domestic and industry use, heat swimming pools, generate electricity, for chemistry applications and many more operations [1].

One of the solar energy uses is a solar wall. Solar wall system is simple, effective, inexpensive, ecological, building integrated into any solution [2-3]. This system, raising the temperature of indoor air for 5 - 25 degrees above the outside air temperature, allowing to save 20 - 70% of fuel energy while supplying the area with fresh air.

This system successfully used around the world since 1977, when the Canadian government subsidized the eco-system tests. Solar wall missions are located in North America, Europe and Asia - a total of more than 25 countries worldwide.

There is no need for heat ventilation at the expense of the economy, because the system provides fresh air circulation, while the walls of the building do not overheat in the summer, because the system acts as a coolant. In many countries, is increasing interest in solar wall panels use. Solar wall panels use is discussed a lot in works of Italian climates [4].

Using solar collectors efficiency studies [5], the idea was to use steel-tinplate absorber as a solar panel on the wall. Steel-tinplate absorber can be used on the roof, thereby providing ventilation and heating in early spring and autumn, with the heat and fresh air, and drying the products with heated air in the summer.

Our aim was to find the collector's (the adsorbent is used as a coating material) efficiency of insulation using and warm-up stage of air.

2. Methodology

The aim of the research was to investigate black colored steel-tinplate use for absorber and covered material of collector and compare the efficiency of three types of air heating collectors: collectors with insulated and un-insulated surfaces with covered material - steel-tinplate and classical collector with covered material - polystyrol plate and absorber black colored steel-tinplate in middle. View of flat-plate collector (FPC) when the absorber (black colored steel-tinplate) is put in the middle of the collector is shown in Fig.1. In the second case, absorber placed collector coverage place, it means at the top of collector.

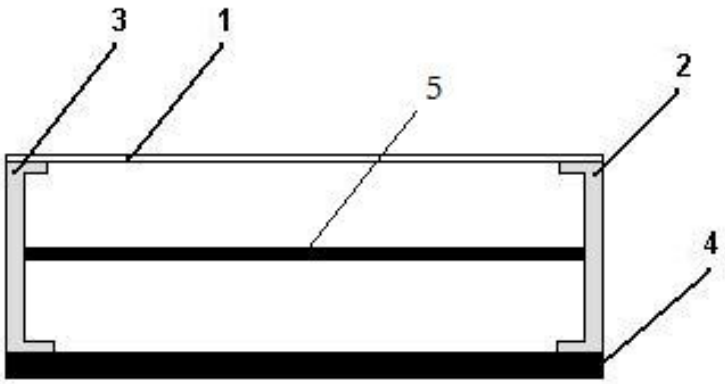

Fig. 1. Schema of solar collector frontal view: 1 – covered material; 2, 3 – side surface /plastic/; 4 – floor of collector; 5 – absorber (steel-tinplate)

In the experiments, the collector covered material was a polystyrol plate. This material has gained immense popularity due to such properties as safety, mechanical crashworthiness, translucence and high UV radiation stability.

In the laboratory a *0.1∗ 0.5∗1.0* meters long experimental solar collector was constructed for research into the properties of absorber materials. Air velocity at the experiments was v=0.9 m/s. Our investigations devoted the sun following collectors, which guarantees perpendicular location of plane of absorber from flow of sun radiation.

Experimental data is recorded by means of an electronic metering and recording equipment of temperature, radiation and lighting (REG) [6]. It is equipped with 16 temperature transducers and metering sensors of solar radiation and lighting. Solar radiation measuring instrument was the pyranometer. The isolated collector was made by the collector surfaces faced with cellular plastic 2 cm plates.

We compare three equal sizes FPC: collectors of insulated and un-insulated surfaces with absorber steel-tinplate as a covering material and classic collector with the covering material polystyrene plate and absorber tinplate in the middle of collector. Experiments were made in

September 2010 in different weather conditions at different atmospheric air temperatures. To assess different absorbers influence was made comparatively research at similar weather conditions. Inflow air temperature in collector is equal to the ambient air temperature. Ambient air temperature was changing from 13ºC to 18ºC in our experiments.

The data of sun radiation are depended from clouds, shadows and we aligned experimental data with method of least squares using Eq. (1). [7]

$$\overline{y_i} = \frac{1}{35}[17y_i + 12(y_{i-1} + y_{i+1}) - 3(y_{i-2} + y_{i+2})] \qquad (1)$$

Where $\overline{y_i}$ - aligned data, y_i - experimental data, i - ordinal number.

3. Results

Using the experimental results and statistical processing data we received a relation between the length of the collector, sun radiation to absorber plate and air temperature exchange in the collector.

We research situation when absorber (steel-tinplate) puts at top of collector (Fig. 2). To compare insulated and un-insulated collectors with steel-tinplate as a covering material we can see that at the same weather conditions for insulated collector is warming up air to 3 degree up (at radiation 800 W/m^2) than collector with un-insulated surfaces (Fig. 3).

Fig. 2. Sun collector comparatively research in experiment.

We can see that the solar radiation changes significantly affect the passing air temperature. This effect does not happen instantly, but with a delay of 3-5 minutes. It should be noted that the un-insulated collector efficiency is highly influenced by wind speed, which cools the surface of the collector body.

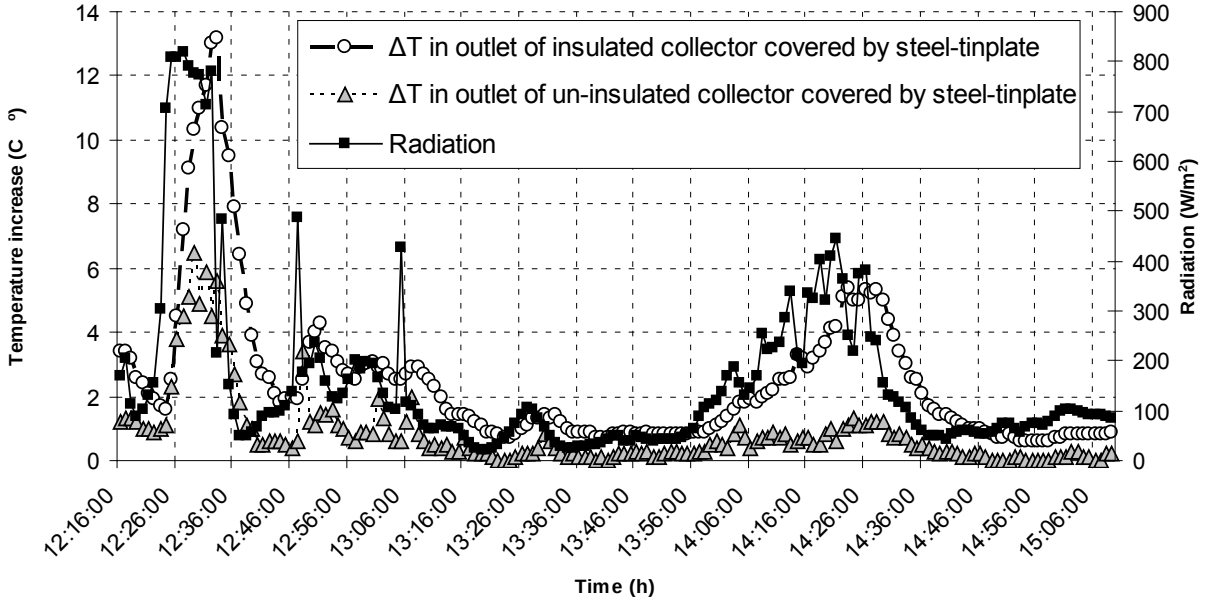

Fig. 3. Temperature difference in outlet of collector with steel-tinplate covering material for insulated and un-insulated surfaces comparing with sun radiation.

As you can see in Fig. 4, near little sun radiation are not visible constitutive air heating, but increasing sun radiation is growing air heating level and you can see that collector with absorber steel-tinplate at middle of collector body is more powerful than collector with steel-tinplate absorber as covering material. Air heating level is not highly dependent on ambient temperature. Much more it is influenced by solar radiation and insulation. If the collector is covered with the steel tinplate then this collector efficiency is highly influenced by environmental conditions, especially wind and ambient air temperature. These conditions reduces absorber own temperature. In the classic collectors whose effects are much smaller (Fig. 4)

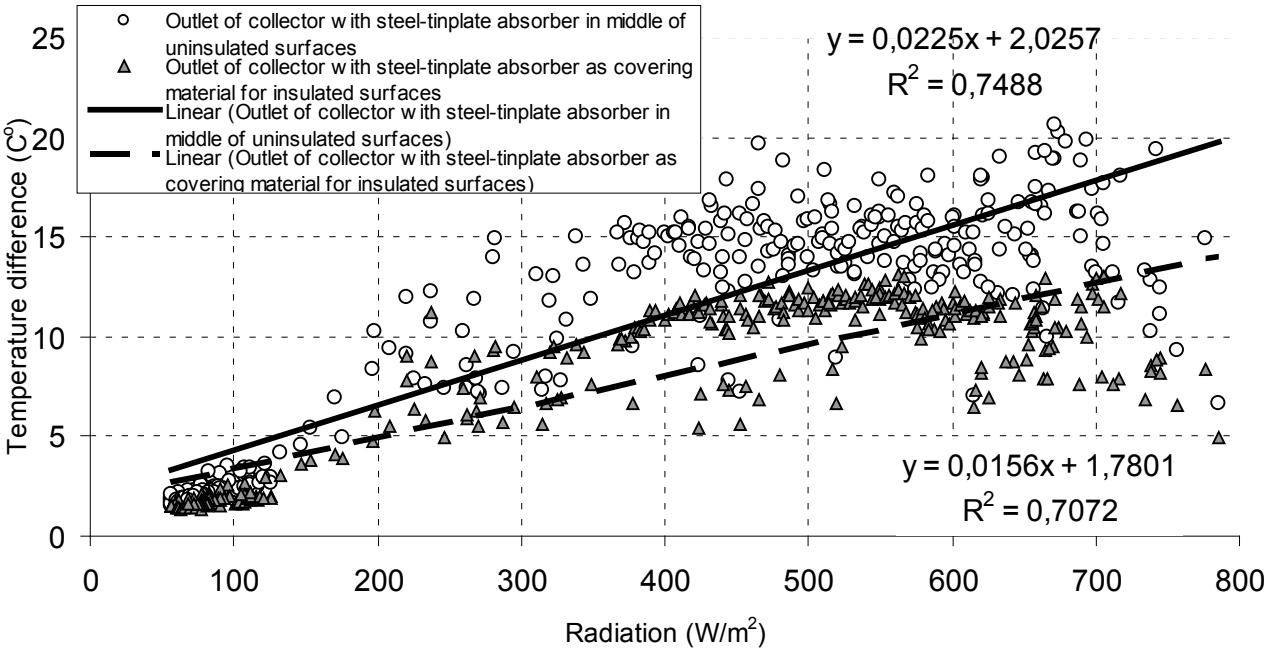

Fig. 4. Temperature difference in outlet of collector (with absorber tinplate at middle of collector body and with steel-tinplate absorber as covering material) comparing with sun radiation.

Near little sun radiation are not visible constitutive air heating, but increasing sun radiation is growing air heating level and you can see that collector with absorber steel-tinplate at middle of collector body is more powerful than collector with steel-tinplate absorber as covering material.

Using the experimental results and statistical processing data we received a relation between the air temperature exchange under the steel-thin plate absorber in the collector, length of the collector and sun radiation to absorber plate.

The temperature change ΔT under tinplate can be expressed with the Eq. (2).

$$\Delta T = 1.3 \cdot 10^{-2} x \cdot R - 4.8 \cdot 10^{-3} R - 1.9 \cdot 10^{-6} R^2 - 0.3x + 0.68x^2, \qquad (2)$$

Where x – length of collector (m); R – sun radiation (W·m^{-2}).
Coefficient of determination is $\eta^2 = 0.771$. The graphical interpretation of Eq. (2) is shown in Fig.3.

In Fig. 5. you can see contour plot of air temperature (under absorbent) increase dependence on length of collector and sun radiation for un-insulated collector with absorber with steel-tinplate as a covering material.

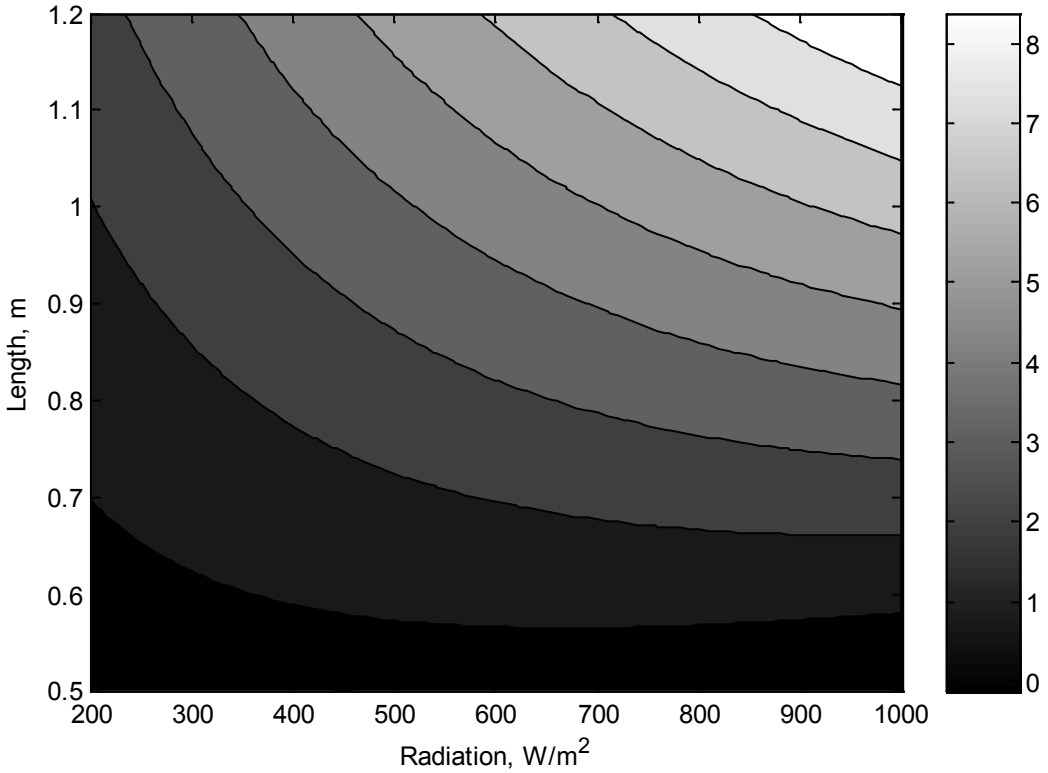

Fig. 5. Contour plot of air temperature (under tin plate) increase dependence on length of the collector and sun radiation.

4. Conclusions

1. Collectors of insulated and un-insulated surfaces with steel-tinplate absorber as covering material warmed ambient air up to 10-12 and 5-6 degrees corresponding (at irradiance 800 W/m^2). This difference indicates the great importance of insulating the collector body.

2. Use of isolation for collector construction dose not give inportant role if there is no wind to cool collector.

3. Using the experimental results and data statistical processing we received a relation between the air temperature exchange under the steel-thin plate absorber in the collector, length of the collector and sun radiation to absorber plate.

4. At favorable weather conditions the heating degree of ambient air at the outlet of collector with absorber tinplate at middle of collector body reaches 6-8 degrees more that at the outlet of insulated collector covered by steel-tinplate.

5. Our investigations showed that steel-tinplate absorber use as covered material of flat-plate collector for ventilated air heating is possible in Latvia.

Abstract: Black cobalt thin films on bright nickel plated on brass and copper substrates were prepared by the electrodeposition method. The Influence of substrate metal and heat treatment process on the surface morphology and absorptance of samples was investigated. Surface morphology and spectral reflectance of films were measured by scanning electron microscopy and spectrophotometer in the visible and near-IR region of spectrum respectively. Scanning electron microscopy images showed that the black cobalt films have porous structure. The absorptance of prepared films is over than 90%, which makes them suitable for using as solar absorbers.

1. Introduction

The preparative aspects of cobalt oxide thin films have been a subject of investigations by various workers because of their numerous applications in various fields of technology. They are attractive in application to solar thermal energy collectors as selective absorbing layers [1]. Spectrally selective surfaces exhibiting high values of solar absorptance α and low values of thermal emittance (ε) improve the thermal performance of solar collectors by reducing the radiative heat loss component [2]. Such surfaces are employed as receiver coatings in flat plate evacuated tube and concentrating collectors and may under stagnation conditions in the latter application, experience temperatures of 500˚C. Many surface coating types have been developed which have potential for application as selective absorbers [3]. An attractive aim of selective surface research studies is the development of a single coating type which could be used for all solar collector designs. For successful industrial development such a coating would not only possess favourable optical properties but also would be readily reproducible, durable, thermally stable and inexpensive to produce. Selective solar absorber coating in solar thermal systems, working under moderate concentrations, experience operating temperatures in the rang 300-500˚C. Cobalt oxide coatings [4] are proposed as potential candidates for this use. However, little is known about their stability and the modes of degradation when operated at high temperatures. It is well known that the metal substrate microstructure strongly influences the grain size and morphology of the in-situ grown film [5]. It is also well known that the microstructure of electrodeposits varies markedly with deposition parameters and that various impurities from the plating bath may be incorporated into the deposit [5].

A general class of absorber coatings is those formed by chemical “conversion” processes. The previous works on the electrochemical preparation of cobalt oxides can be divided in to two groups: direct and indirect. In the former, a solution is prepared by dissolution of the chemical components that allow the directly preparation of black cobalt on the substrate at the cathode in the electrolysis process [6]. On the latter the formation of cobalt oxide is

accomplished in two steps, i.e. first the metallic cobalt is deposited on the substrate and secondly, the cobalt is oxidized to black cobalt through chemical or thermal oxidation [6]. Because of its optical, semiconducting, magnetic and electrochemical properties, black cobalt is a promising material among transition metal oxides, which renders it attractive for solar photochemical applications and electrochemical devices as a counter electrode [7]. Today, although there are six physical mechanisms of solar absorptance [8]. It is recognized that one of the most efficient solar absorber films base their optical properties on its microstructural volume and surperficial parameters. However, in spite of all the existing mechanisms, the textured surfaces are the most dependent of the surface morphology than whatever other material is. These materials show a high solar absorptance by multiple reflection of the incident radiation among dendrites that are approximately two microns apart, while the long-wavelength thermal emittance is rather unaffected by texture. Several techniques, such as chemical conversion and thermal oxidation of metallic films and electrodeposition, are currently used to achieve such spectrally selective, black-metal, solar absorber surfaces [9]. However, the desired characteristics of the metallic coating could be better controlled by directed electrodeposition. In this paper electrodeposition of cobalt photothermal material, suitable for using in solar energy collection, has been studied.

2. Experimental Details

Black cobalt thin films on bright nickel plated on brass and copper substrates were prepared by the electrodeposition method. The core part of the electroplating process is the electrolytic cell. In the electrolytic cell a current is passed through a bath containing electrolyte, the anode and the cathode. The workpiece to be plated is the cathode (substrate). The Anode is a metal which is coating on the cathode surface. Electrolyte is the electrical conductor in which current is carried by ions rather than by free electrons (as in a metal). When a direct electric current passes through an electrolyte, chemical reactions (Oxidation/Reduction) take place at the solution. Reduction takes place at the cathode, and oxidation takes place at the anode. Electrolyte completes an electric circuit between two electrodes. Upon application of electric current, the positive ions in the electrolyte will move toward the cathode and the negatively charged ions toward the anode. The metallic ions of the salt in the electrolyte carry a positive charge and are thus attracted to the cathode. When they reach the negatively charged workpiece, it provides electrons to reduce those positively charged ions to metallic form, and then the metal atoms will be deposited onto the surface of the negatively charged workpiece.
Brass and copper plates were thoroughly degreased and cleaned, then subjected to a 1-min acid etch in 5% sulphuric acid prior to bright nickel deposition. According to watts bath [10] bright nickel deposition was carried out under the conditions mentioned in table 1. A piece of nickel metal with 99.9% purity was used as anode.

Table 1: Deposition condition and bath composition for deposition of bright nickel.

Composition bath		Current density	Temperature
Nickel sulphate	250 gl^{-1}	0.5 A/dm^2	70°C [11]
Nickel chloride	50 gl^{-1}		
Boric acid	50 gl^{-1}		

After bright nickel plating, the panels were rinsed with distilled water. Finally black cobalt deposition was carried out under the conditions described in table2 according to McDonald electrolyte bath [6]. The anode was cobalt metal with 99.9% purity and bright nickel plated brass and copper was used as cathode.

Table 2: Deposition condition and bath composition for deposition of black cobalt.

Composition bath		Current density	Temperature	pH
Cobalt sulphate	400 gl^{-1}	3 A/dm^2	30˚C	4
Cobalt chloride	50 gl^{-1}			
Cobalt nitrate	4 gl^{-1}			
Boric acid	40 gl^{-1}			

The cobalt sulphate is the main source of cobalt ions, the cobalt chloride helps to improve the conductivity of electrolyte solution and the boric acid is a leveling agent. Cobalt nitrate was added to the bath to obtain a black layer on the sample.
The films deposited on brass substrate and bright nickel plated brass substrate annealed in the air environment at temperature 400 ˚C for 20 Min to study their physical properties after heat-treatment. The absorptance was calculated from the equation 1-R, in the visible region [12]. Where R is the room temperature reflectance measuremement. Reflectance in the visible region was determined with a Carry 500 spectrophotometer. The morphology of the surfaces is detected by scanning electron microscope (SEM) model Philips XL30.

3. Results and Discussion

3.1. SEM Analysis

Figure 1 depicts the surface morphology of black cobalt films deposited on different bright nickel plated substrates. Fig.1.a is for a brass substrate and Fig.1.b belongs to a copper substrate. It is obvious that the crystal structure of black cobalt film deposited shows a porous structure. There is no evident difference between the morphology of films deposited on different substrates. While by changing the substrate metal the porous sizes have changed from micro, for copper substrate, to nano-sized porous structure for brass substrate. Figure 2 shows the surface morphology of black cobalt films deposited on brass substrate, (a) before heat-treatment and (b) after heat-treatment. From figures 1 and 2 it is clear that the films deposited on brass substrates after annealing had more cracks on the surface and the porosity of the structure was increased. By comparing fig.1a and fig.2a it is evidence that the presence of bright nickel middle layer causes a more uniform structure without any crack in the surface of electrodeposited black cobalt films on brass substrate. In addition by using the bright nickel middle layer the porosity of structure increased. This porous structure results enhanced the absorptance in coatings and makes these layers suitable for solar absorber application.

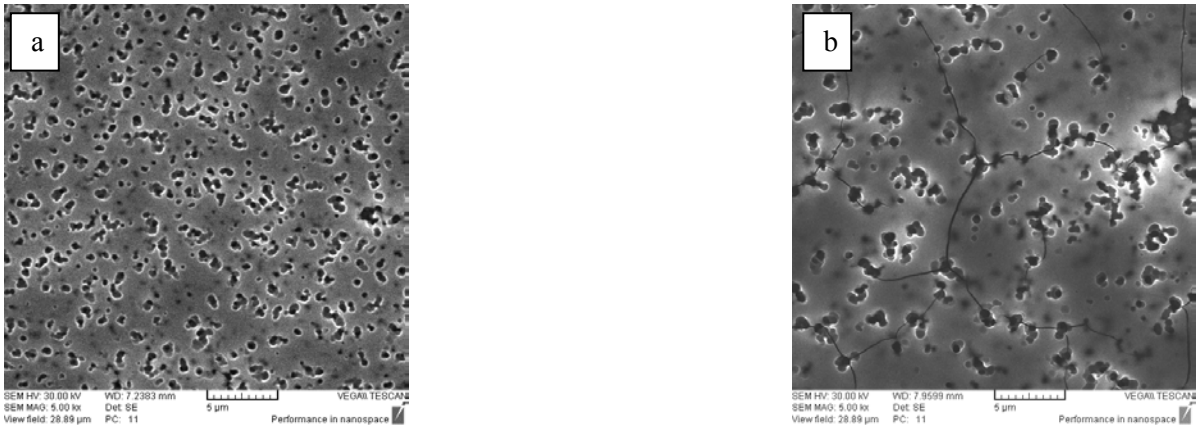

Fig. 1. The surface morphology of black cobalt film deposited on bright nickel-plated substrates (a) for brass substrate (b) for copper substrate.

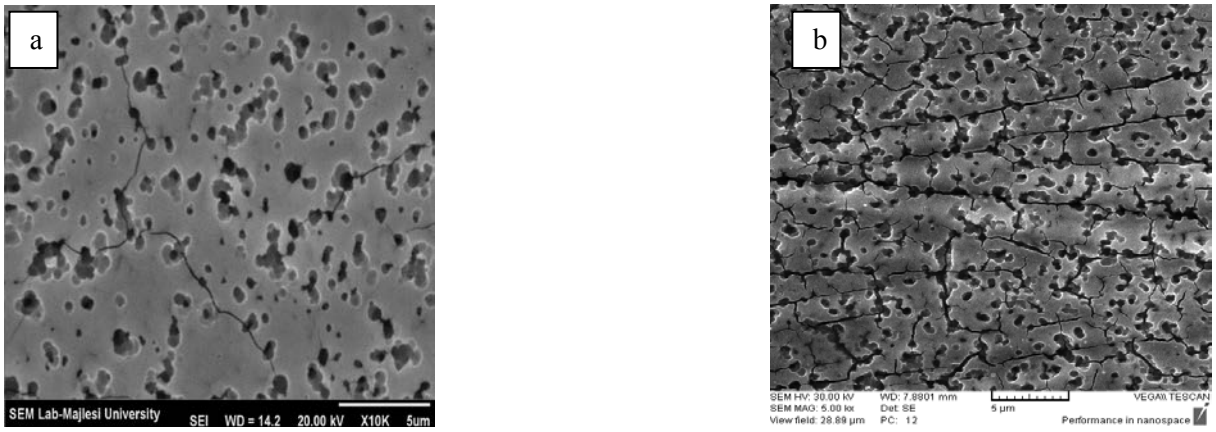

Fig. 2. The surface morphology of black cobalt films deposited on brass substrate (a) before annealing (b) after annealing.

3.2. EDAX Analysis

Figure 3 and table 3 show the elements in electrodeposited cobalt film on brass substrate by EDAX analysis. These Data expressed that the main elements in black cobalt coating, is cobalt metal.

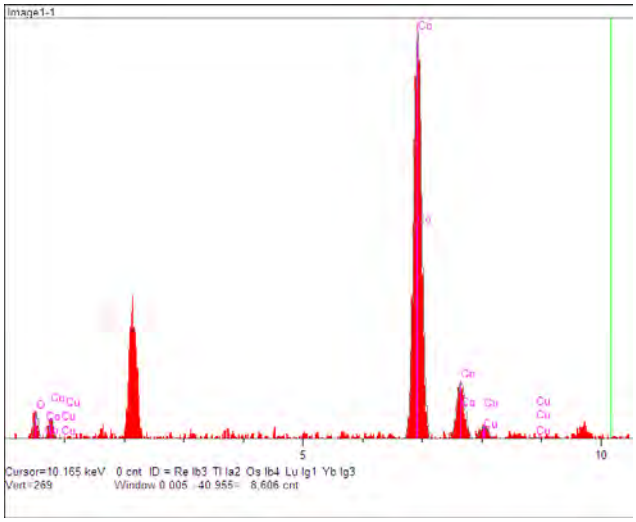

Fig. 3. EDAX of black cobalt as-deposited on brass substrate.

Table 3. The elemental concentration of black cobalt film deposited on brass substrate.

Intensity(c/s)	Conc. (Wt %)	Element
14.11	4.648	O
420.67	90.610	Co
13.34	4.742	Cu

3.3. Solar Absorptance Analysis

The changes in absorptance of layers by the wavelength for bright nickel-plated brass and copper substrates are shown in Fig.4. And the films absorptance of black cobalt films deposited on brass substrate before heat treatment and after heat treatment in visible region of wavelength are shown in Fig.5. The optimal solar absorptance was 98%-99.55% at wavelength range 400-1200 nm for the as-deposited films and films after heat treatment.

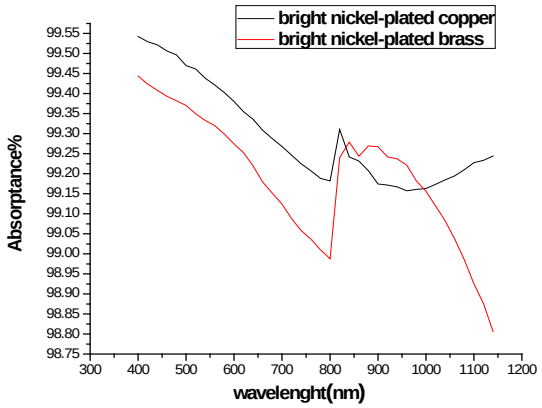

Fig. 4. The relationship between the absorptance and wavelength of black cobalt films deposited on different substrates.

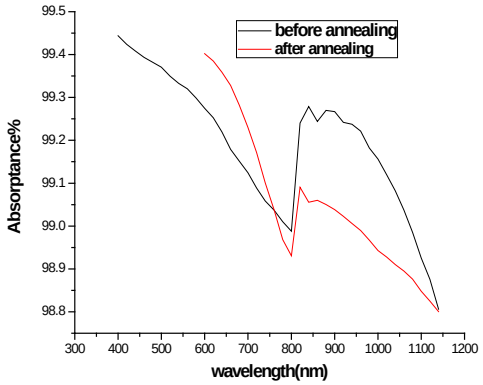

Fig. 5. The relationship between the absorptance and wavelength of black cobalt deposited on brass substrate (a) before heat treatment (b) after heat- treatment.

4. Conclusions

Black cobalt coatings on bright nickel plated on brass and copper substrate were prepared by the electrodeposition method. The influence of heat treatment on optical absorption and surface morphology of black cobalt films deposited on brass substrates has been studied. Heat treatment of black cobalt films deposited on br ass substrates caused cracks in the surface structure. Heat treatment of black cobalt deposited on br ass caused a slight decrease in an absorption in the near-IR region. Due to high absorption in visible region the best substrate for a black cobalt solar absorber coating is bright nickel-plated on copper substrate.

Abstract: Normal skylights bring light into the spaces located below them. By the use of infrared radiation (IR) transmissive polymer films and IR-emitting and absorbing gases, an advanced version of the skylight may supply cooling and thermal insulation to the room located below it. This novel radiative skylight can, in its cooling mode, lead heat from the room below, to the cool skies located above the skylight. When cooling is no longer needed or attainable this connection will be cut, thus providing the room with an optimal amount of thermal resistance. This article is a progress report on the modeling of the skylight. The main work is done to combine the different heat transfer methods into one single model by the use of the commercial program Comsol 4.1. The results show that a cooling effect of 100 W/m^2 is achievable when the skylight is compared to a similar skylight containing only air.

Keywords: *Radiative cooling, heat transfer in participating media, skylight.*

1. Introduction

Skylights are popular in building technology due to their ability to bring light into a space. However, as they light up a space, they also heat it up. T his heat can be unwanted and therefore, has to be removed. This article will present the results from a numerical modeling of a skylight, which can function either as a radiative cooler or as a thermal insulator. Radiative cooling is a passive cooling method that connects a warm object located e.g. on top of a building to a lower sky temperature through heat radiation; one could describe it as an inverse solar collector [1].

The improved skylight contains a quantity of gas that is active in radiative heat transfer (i.e. a participating gas), and a cooling or insulating effect is achieved by controlling the circulating motion of this gas. The use of gases in the spaces between windows has been studied mainly with the goal of increasing thermal resistance by replacing air with a gas having lower conductive properties. Another option is to use gases that absorb and emit thermal radiation and thus decrease the radiative heat transfer through the window [2]. The use of such gases, which are active in radiative heat transfer, has also been studied for radiative cooling purposes; these studies show that cooling is also attainable during the day [3–5]. However, a window or a skylight that combines the three functions is a novel idea.

2. Methodology

The skylight model, whose design and function is described in [6], was designed at the authors' laboratory at Åbo Akademi University to determine its performance as a passive cooler and a thermal insulator. As shown in Figure 1, it consists of three windows. The outer and the inner window are made of an IR-transmitting polymer, τ=0.19, and the middle window is made of silica glass, which is highly reflective to IR radiation at all wavelengths, ρ=0.9. The spaces between these windows contain a greenhouse gas that acts as the system´s heat carrier. The walls are assumed to be thermally insulated and to have an absorptivity of α=0.9. Heat that originates directly from the sun is not incorporated into this model as both

the windows and the gas are assumed not to absorb short wave heat radiation in the interval of 0.1–3μm.

When the skylight is set in its cooling mode, heat is transferred to the gas through the lower window (Glass 1) by radiation, conduction, and convection from the room below. The heated gas rises to the upper compartment due to the decrease in the gases´ density. In the upper space, the gas is cooled by radiative heat transfer through the upper polymer window (Glass 2) and the "atmospheric window" to the colder air masses in the upper atmosphere. There also exists a forced convective heat transfer between the upper part of the skylight and its surroundings. The effect of this heat transfer depends on the temperature of the surroundings; for the modeled cases, it is cooling.

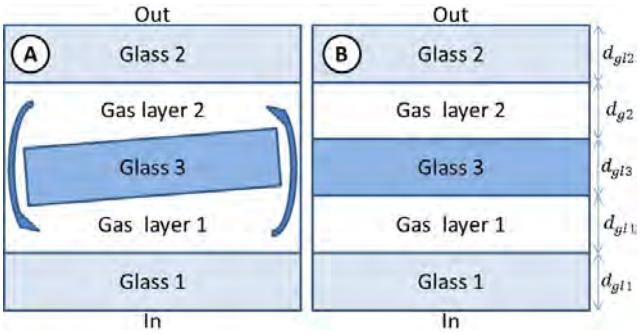

Fig. 1.Skylight in cooling mode "A" and in insulating mode "B"

When the greenhouse gas cools, its density increases, and it flows down to the lower part of the skylight. This convective heat flow is induced by the slightly tilted middle window. The angel of the tilt and the width of glass 3 has been chosen according to Fig. 2 so as to decrease the formation of hindering Bérnard cells (convective swirls).

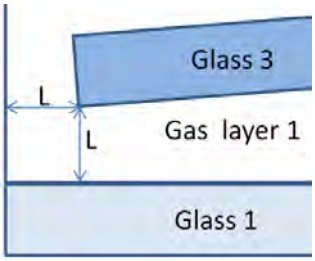

Fig. 2. Detail of the skylight in cooling mode

Then when no c ooling is needed, the connection between the two gas spaces is cut, thus changing the task of the roof components from a passive radiative cooler to a thermal insulator. The weather parameters that are used in this modeling are average values for the months of February and July for year 2008 in Helsinki, Finland. The data for February is used to model when a skylight with a maximal amount of thermal resistance is needed and the data for July is used to model when cooling is needed. The data was procured from the Finnish meteorological institute, and it is presented in Table 1.

Table 1. Average weather data for two months in 2008 for Helsinki Finland.

Unit	February	July
$T_{ambient}$ [°C]	0.73	17.62
T_{sky}[°C]	-7.51	3.67
v_{wind} [m/s]	4.13	3.20

Modeling natural convection induced by heat radiation is, however, somewhat tricky; an attempt to do this was made by the author in [6]. It has also been shown that the wavelength dependency is crucial for calculating radiative heat transfer in participating media [7].

The exponential wide-band method is used in this paper to calculate the gases absorptivity and emissivity, which are assumed to be equal [8]. The studied gas is chosen to be CO_2 which absorptivity is calculated to be, α=0.19, as an isothermal and a gray value (no wave length dependency). In future work the gas absorptivity will be treated as temperature and wavelength dependent variable.

3. Results

The results from the modeling are given in Table 2 where the total heat transfers from the room to the skylight are presented. This data is calculated by the Comsol model in W/m as the model is 2 dimensional. These results are in turn squared to get them into a more comfortable unit of W/m^2. These results are from the last time step of a 1000 second long dynamic simulation. The reason for solving this problem as a time dependent instead of a stationary problem is to avoid unstable equilibrium points. The time of 1000 seconds was assumed to be a time period long enough for the heat flows to stabilize. However, some of the simulations seem not to have stabilized.

Table 2 shows that a cooling capacity 98 W/m^2 can be obtained during the summer by this design, when comparing the cooling case with CO_2 to the insulating case with air. The table also shows that if the skylight is set in its insulating mode for the winter an unnecessary heat loss of 80 W/m^2 would be achieved. This same effect is also achieved if the skylight is filled with air. A reason to this could be that the simulations were not simulated for a long enough time.

Table 2. Average heat transfer for two months in 2008 for Helsinki, Finland.

[W/m^2]	Summer Cooling	Winter Insulating	Summer Insulating	Winter Cooling
CO_2	117	966	88	883
Air	15	983	19	655

Nonetheless, if the gas in the cooling skylight would be replaced with air instead of the greenhouse gas, CO_2 in this case, is it obvious that the cooling would drop by as much as 85%. The reason for this is that air does not absorb or emit heat radiation and cannot therefore be directly cooled down by the sky. If the winter insulating cases are then compared to each other is the skylight with the CO_2 at α=0.19 a somewhat better thermal insulator than the skylight containing air. The reason for this is that CO_2 is a better conductive insulator than air; however, CO_2 is a better transfer medium for convective heat than air and therefore works better in the cooling mode.

So for the skylight to work as attended is it important to choose the thickness of the skylight correctly. The skylight should be thin enough to prevent convective air movement to form when the skylight is in the insulating mode but thick enough that a convective heat flow can occur between the two compartments when the skylight is in its cooling mode. The thickness of 10 cm has shown to give good results and is therefore used in this study; the width of the skylight is 0.5 m. While then observing Fig.3-a to Fig. 4-b it becomes obvious that the figures presented are not in scale; these distortions allow the figures to be more easily understood without taking too much space.

3.1. Skylight filled with CO_2

3.1.1. Cooling mode

The goal in the cooling mode is to get the gas inside the skylight to move from the lower compartment to the upper one. This movement should in turn transfer heat from the room to the sky. When observing the simulation results in Fig. 3-a and Fig. 3-b one can observe that this flow is taking place. Additionally, the gas that is moving around in the skylight, as pictured in Fig. 3-a, is clearly cooled down by radiative heat exchange between the sky and the skylight. This is certain as the temperature of this gas flow is lower than that of both the temperature of the room and the temperature of the ambient.

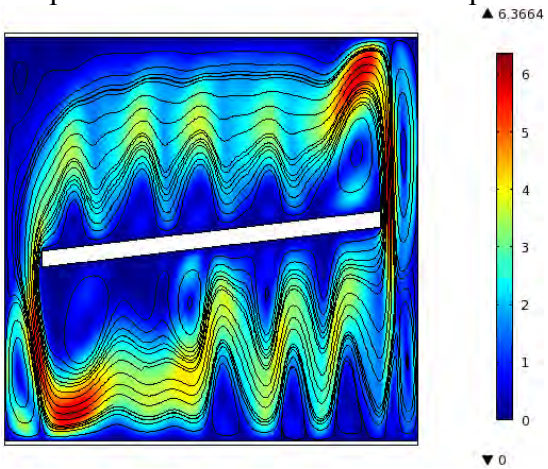

Fig. 3-a. Velocity profile in [cm/s] for cooling mode during summer[*]

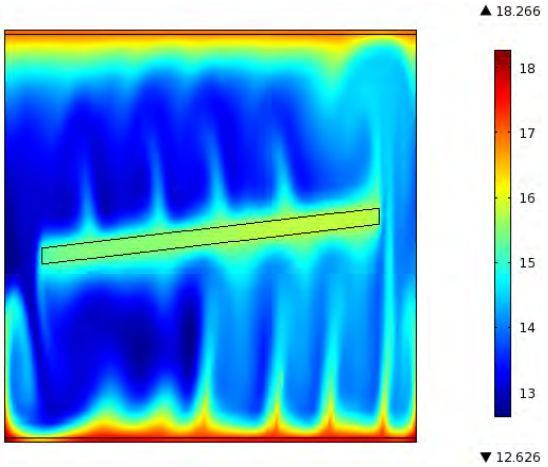

Fig. 3-b. Temperature profile in [°C] for cooling mode during summer[*]

3.1.2. Insulating mode

As mentioned above, for the insulating case to work optimally, the gas movement in the skylight should be kept to a minimum. This, however, is only partially achieved as clear Bérnard cells can be seen in the lower part of the skylight, with also some minor circles in the upper compartment. This suggests that more work could be done to find an optimal depth for the skylight. An interesting phenomenon can be seen in Fig. 4-b where the lowest temperature is achieved in the lower part of the upper compartment. This has to do w ith the high reflectivity of the middle glass window.

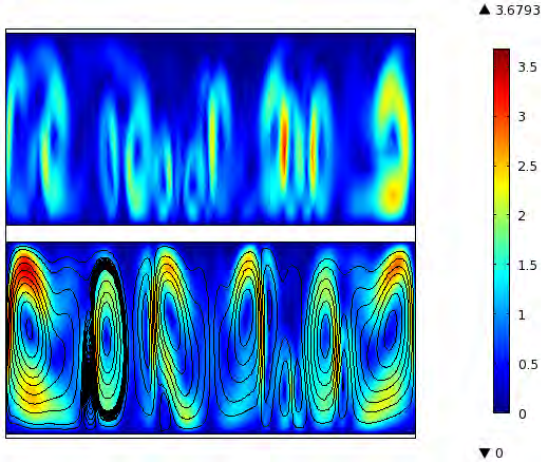

Fig. 4-a. Velocity profile in [cm/s] for insulating mode during winter[*]

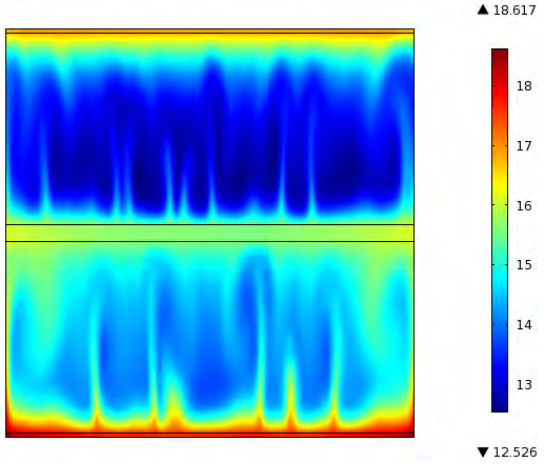

Fig. 4-b. Temperature profile in [°C] for insulating mode during winter[*]

[*] Note that the figures are not in scale.

3.2. Skylight filled with air

For comparison, the same analyses as presented in chapter 3.1, have also been made for a skylight filled with air.

3.2.1. Cooling mode

Even though the skylight is filled with air, a flow pattern is formed between the two compartments; this shown in Fig. 5-a. However, the flow velocities are somewhat slower in Fig. 5-a. than in Fig. 3-a. Furthermore, the temperature profile presented in Fig. 5-b shows that temperatures do not reach lower temperatures than that of the ambient and thus the air is not cooled by the sky.

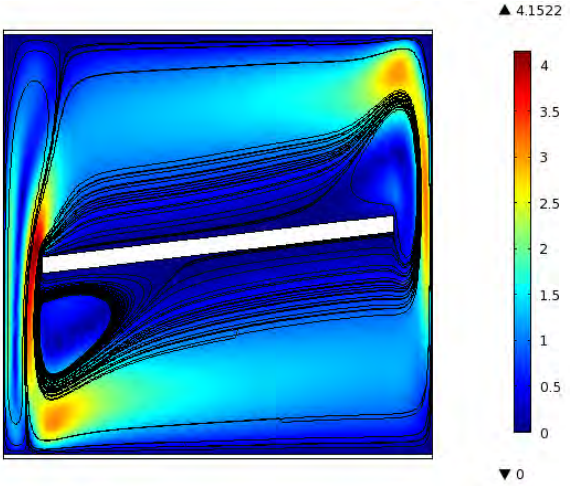

Fig. 5-a. Velocity profile in [cm/s] for cooling mode during summer†

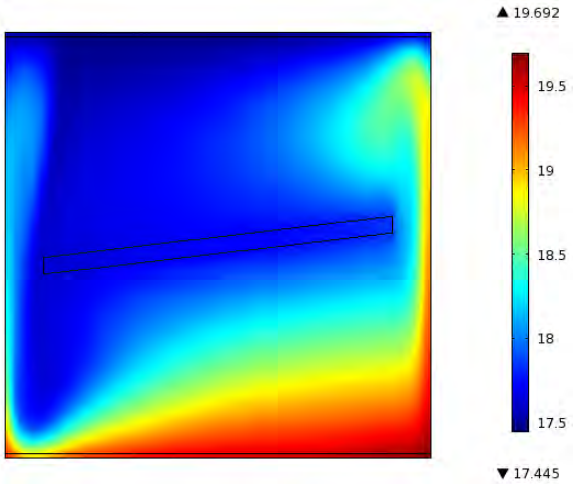

Fig. 5-b. Temperature profile in [°C] for cooling mode during summer†

3.2.2. Insulating mode

Interestingly the air filled skylight has the worst insulating properties. The main reason for this is the high air velocities that are presented in Fig. 6-a; another could one could be that the simulation time of 1000 seconds was too short. The temperature profile presented in Fig. 6-a reinforces that temperatures below the ambient are not achievable in a skylight filled with air.

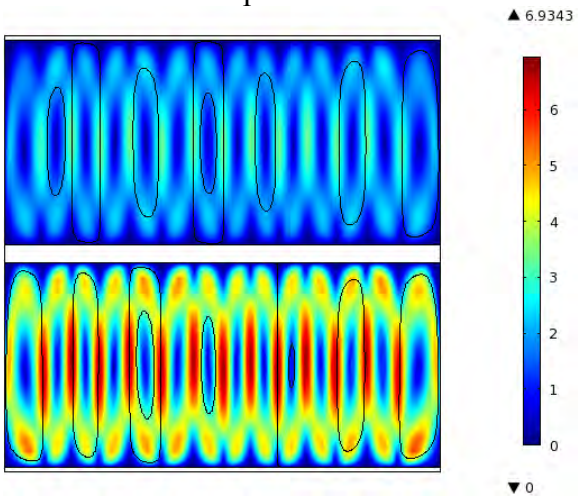

Fig. 6-a. Velocity profile in [cm/s] for insulating mode during winter†

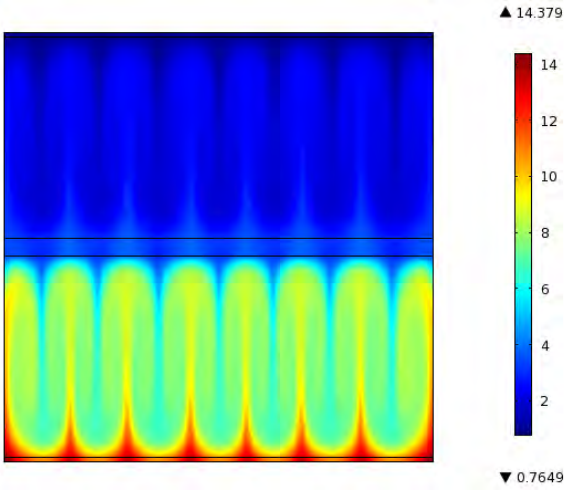

Fig. 6-b. Temperature profile in [°C] for insulating mode during winter†

† Note that the figures are not in scale.

4. Summary and Conclusions

This article presents an idea for using a regulated skylight to control heat flow in and out of a space located below. The concept was evaluated using a commercial multiphysics program Comsol.

This study shows that cooling effects of up to 100 W/m^2 are achievable under normal summertime conditions in southern Finland. However, improvements to the design could still be made and thus increase this cooling effect. These improvements would be a result from a careful analysis and optimization of the difference in heat transfer between the two skylight modes. Further improvements to the modeling would be to run Comsol parallel with Matlab so that wavelength dependency could be incorporated into the model, as it is an important factor for radiative heat exchange in participating media. The method chosen for calculating the wavelength dependency would be the exponential wide-band model.

If this system was successfully implemented, savings could be achieved by reducing the use of conventional cooling methods. Unfortunately, window materials that possess the necessary transmission properties typically have poor mechanical properties.

An experimental setup is being designed to assess the modeling results and to study different combinations of materials.

Abstract: A solar powered intermittent absorption refrigeration system has been developed at the Centro de Investigación en Energía of the Universidad Nacional Autónoma de México. The system was evaluated with the ammonia/lithium nitrate/water (NH3/LiNO3/H2O) mixture. The system was designed to produce up to 8 kg/day of ice. The system consists of a Compound Parabolic Concentrator (CPC) with a cylindrical receiver acting as the generator/absorber, a condenser, an evaporator and an expansion valve. The system operates exclusively with solar energy and no moving parts are required. Evaporator temperatures as low as - 11°C were obtained for a period of time up to 8 hours. Coefficients of performance as high as 0.098 were obtained. These coefficients were 24% higher than those obtained with the same system operating with the binary ammonia/lithium nitrate (NH3/LiNO3) mixture previously reported in the literature. The results showed that the developed system seems to be a good alternative for refrigeration in zones where electricity is not available.

Keywords: *solar cooling, absorption systems, ice production, ammonia/lithium nitrate/water.*

1. Introduction

Solar refrigeration is a useful application in areas of the world with high insolation levels where there is a demand for cooling and there is not electricity to supply conventional power systems.

Although the basic concepts of solar refrigeration appeared since about five decades, to date there are only a limited number of developed systems reported in the open literature, some of the most important works are the following. Erhard et al. [1] reported the performance of a solar refrigeration system operating with $NH_3/SrCl_2$. The main part of the device is an absorber/desorber unit which is mounted inside a concentrating solar collector in which the heat of absorption is transported out of the solar collector by means of two horizontally working heat pipes. The overall efficiency defined as the cooling capacity to the solar radiation received by the solar collectors of the cooling system varied from 0.05 to 0.08. Wang et al. [2] published the results of a combined adsorption heating and cooling system which operated with activated carbon/methanol. The system was tested with electric heating and it was found that with 61 MJ heating it was able produce up to 9 kg ice were made. The calculated Coefficient of Performance (COP) which is defined as the cooling capacity to the heat supplied to the generator of the system

was 0.0591. Li et al. [3] published the experimental study on dynamic performance of a flat-plate solar solid-adsorption refrigeration for ice maker operating with activated carbon/methanol. The experimental results showed that this machine can produce 4–5 kg of ice after receiving 14–16 MJ of radiation energy with a surface area of 0.75 m^2, while producing 7–10 kg of ice after receiving 28–30 MJ of radiation energy with 1.5 m^2. Hildbrand et al. [4] reported the results of the performance of an adsorptive solar refrigerator built in Yverdon-les-Bains, Switzerland operating with the adsorption pair silicagel + water. Cylindrical tubes function as both the adsorber system and the solar collector. The condenser is air-cooled and the evaporator contains 40 l of water that can freeze. The results showed that the gross solar coefficient of performance defined by the authors varied between 0.1 and 0.25 with a mean value of 0.16. Khattab [5] presented the description an operation of a novel solar-powered adsorption refrigeration system operating with activated carbon/methanol. The system consisted of a modified glass tube having a generator (sorption bed) at one end and a combined evaporator and condenser at the other end and a simple arrangement of plane reflectors to heat the generator. The daily ice production was 6.9 and 9.4 kg/m^2 and the net solar COP was 0.136 and 0.159 for cold and hot climate respectively. Li et al. [6] developed a no valve, flat plate solar ice maker on the basis of previous research achievements. The system operated again with activated carbon/methanol. The authors reported that the no valve solar ice maker prototype was approached to practical application of mass production from view of cost and techniques. Rivera et al [7] published a paper about the development of a solar intermittent system operating with the ammonia/lithium nitrate mixture. The authors reported that solar coefficients of performance as high as 0.08 can be obtained whit the developed system

From the literature review it is clear that although has been relevant research on developing solar refrigeration systems the most of them have been focused in adsorption systems which have in general low coefficients of performance. Because of this in the present paper the system developed previously by Rivera [7] was evaluated but using now the ternary mixture ammonia/lithium nitrate/water with the purpose to increase the mixture conductivity and to decrease the mixture viscosity trying to increase the system efficiency. Physical and thermodynamic properties of the ternary mixture were taken from Libotean et al [8,9].

2. System description

The system was designed to operate with the ammonia/lithium nitrate/water mixture for a maximum capacity of 8 kg of ice/day. It consists of a compound parabolic collector CPC with a cylindrical receiver acting as the generator/absorber, a condenser, a storage tank, an expansion valve, a capillary tube, an evaporator and a (see Fig. 1). The system operates exclusively with solar energy and no moving parts are required.

During the day, the ammonia/lithium nitrate/water mixture in the generator-absorber is heated by the solar radiation incident on the CPC until it reaches the saturation temperature. Then the ammonia is partially evaporated from the solution. Due to the increase of the temperature and consequently of the pressure of the solution in the cylindrical receiver of the CPC, the ammonia vapor goes to the condenser, where it is condensed by water and then it is stored in the tank. In the night, the temperature and pressure in the generator-absorber decreases because of the decreases of the ambient temperature and the ammonia liquid passes through the expansion valve (which is opened manually) decreasing its pressure and temperature, producing the refrigerant

effect in the evaporator. After the ammonia has absorbed heat from the water stored in the trays inside the evaporator, the pressure in this component increases. In this way, the pressures are inverted in the components in natural way, and the ammonia vapor returns to the generator-absorber where it is absorbed by the strong solution. About 7 o´clock in the morning, after the ice has been produced and the ammonia has been absorbed by the solution stayed in the cylindrical receiver of the CPC, the expansion valve is closed and the ice removed from the trays leaving the system ready for a new cycle.

The CPC is made out of an aluminum sheet with a reflectance of 0.85. The cylindrical receptor is covered with a selective black paint with a range of emittance from 0.25 to 0.49 and absorptance from 0.88 to 0.94; it resists temperatures higher than 300°C. The CPC's concentration ratio is 3.3, with a half-angle of 11.54° and an aperture area of 2.54 m^2. The condenser is a heat exchanger composed of a helicoidal aluminum coil, immersed in a water store. The water inside of the condenser is continuously recirculated by a pump that is connected to a cooling system. It is important to mention that the pump is used just in order to keep the condenser temperature fixed eliminating the system variability with regard to the ambient temperature, however, this pump it is not necessary in normal operating conditions. Furthermore the cooling system and the pump are used exclusively to control the temperature of cooling water for experimental purposes. The cylindrical storage tank has a capacity of 8.5 L; a tube to measure the level is connected to the tank. Leaving the tank, there are two expansion devices: the capillary tube and the needle valve. Only one of these expansion devices is used during the evaporation process. The capillary tube is recommended because it permits the automation of the evaporation process. The evaporator is a heat exchanger that consists of a coil inside an insulated metal container with a front door, in which the ice is produced. The coil is horizontally distributed along five levels, each one bearing an aluminum tray. Water to be frozen is contained in these trays. Fig. 2 shows a photograph of the developed system.

In order to evaluate the system, 14 thermistors, 7 wall thermocouples, 5 pressure transducers, 2 manometers, 1 level tube (placed in the storage tank) and 1 pyranometer were used (see Fig. 1).

3. Evaluation parameters

Five main parameters were used in order to evaluate the experimental system: (i) the amount of the ammonia produced in the generator, (ii) the insolation, (iii) the solar energy received by the CPC, (iv) the cooling capacity and (v) the solar coefficient of performance.

The amount of the ammonia produced in the generator can be obtained as:

$$m_{NH_3} = \rho v_{NH_3} \quad (1)$$

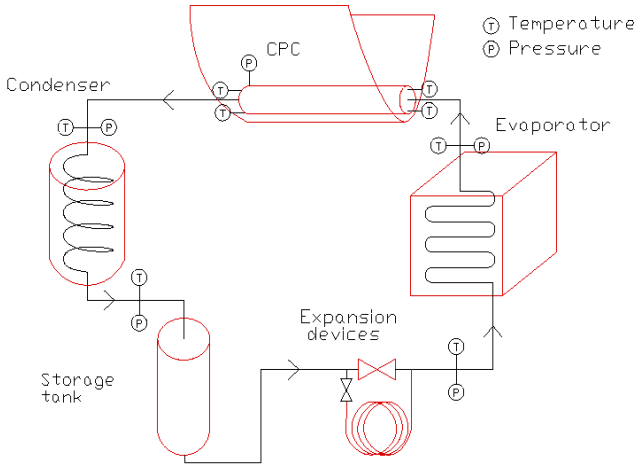

Fig. 1. Schematic diagram of the solar intermittent absorption refrigeration system.

Fig. 2. Photograph of the solar intermittent absorption refrigeration system developed.

The energy received from the solar radiation is calculated as the sum of the contributions of the product of the irradiation, the time and the aperture area.

$$Q_R = \sum_{i=1}^{n} G_i t A \tag{3}$$

The cooling capacity is the sum of the sensible heat to reduce the water temperature from ambient to 0°C plus the heat of fusion of ice

$$Q_{EV} = m_{H_2O}\,(h_{fus} + C_p \Delta T) \quad (4)$$

Finally, the solar coefficient of performance is defined as the cooling capacity in the evaporator to the energy received from the solar radiation.

$$COP_S = \frac{Q_{EV}}{Q_R} \quad (5)$$

4. Results

In order to experimentally evaluate the solar refrigeration system operating the two mixtures, more than 40 tests runs were carried out mainly during summer time, however, only 18 were taken in the analysis since in the others the solar radiation was considerably low (lower than 14MJ) because of long cloudy skies periods (normally higher than 2 hours).

During the experimental test runs, the main evaluating parameters such: temperatures, solar radiation and pressures were logged every 15 seconds.

Fig. 3 shows the maximum pressure reached in the cylindrical receiver against the maximum solution temperature reached during the generation stage. It can be observed that the pressure increases slightly win the increment of the solution temperature. The solution temperatures varied from 87°C to 112°C, meanwhile the pressures varied from 13 bar to 16.1 bar.

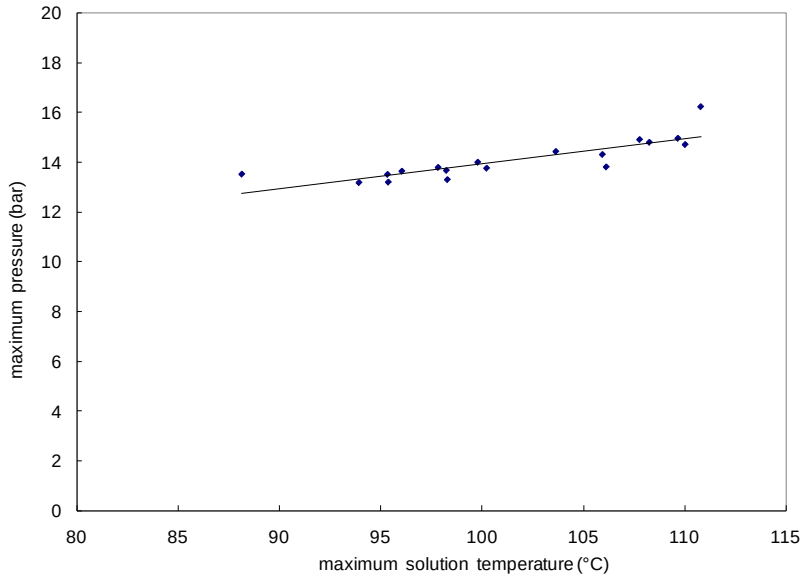

Fig. 3. Maximum pressure against maximum solution temperature for the solar system.

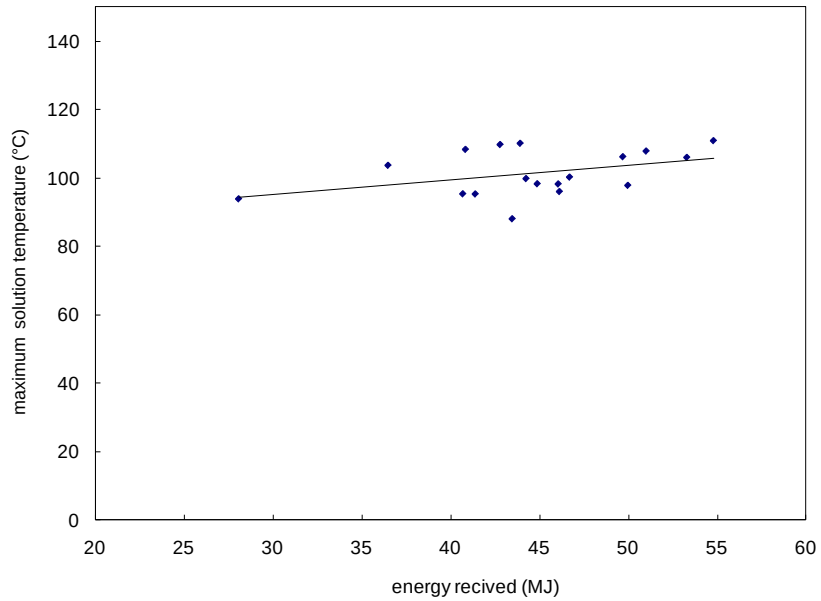

Fig. 4. Maximum solution temperature against the energy received by the CPC.

Fig. 4 shows the maximum temperature reached by the solution during the generation stage as function of the energy received by the CPC during the sunshine hours. In this figure it can be seen that there is a considerable data dispersion between these two parameters, however, it can be observed as it was expected that the solution temperature increases with the energy received by the CPC. It can be observed that the energy received by the CPC varied considerably from about 27 MJ to 56 MJ which is almost two times the minimum value. The high difference that exist among the energy received values is related with the cloudy of each day, since the solar radiation was almost the same since the most of the values (16 of the total) were obtained during the same season (summer).

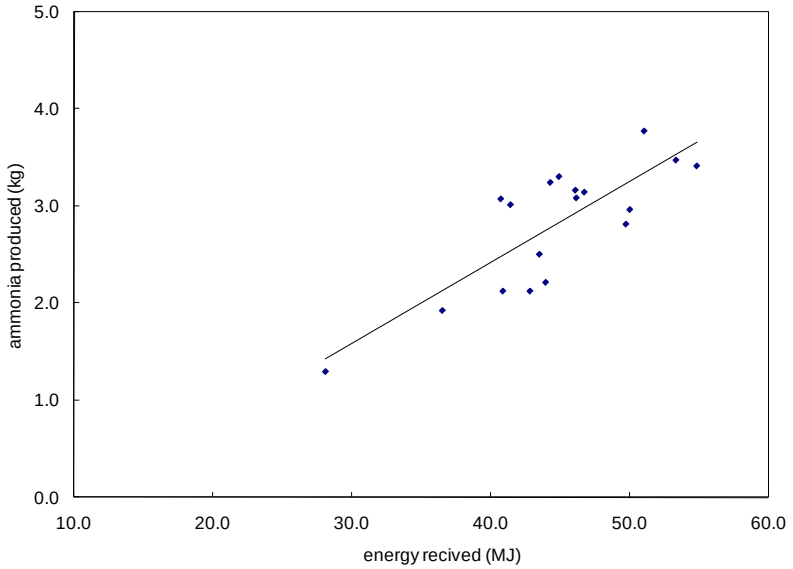

Fig. 5. Ammonia produced during the generation stage against the energy received.

In Fig. 5 it can be seen that the amount of ammonia produced (measured after the sunshine hours in the level tube placed in the condensate tank) increases considerably with the increase of the energy received by the CPC. The amount of ammonia produced varied from 1.3 kg at an energy received of 28.2 MJ to 3.8 kg at an energy received of 50 MJ. From this figure and from the explained in Fig. 4 that the amount of refrigerant produced (ammonia) is very dependent of the solar radiation received by the CPC.

In Fig. 6 it can be seen the solar coefficient of performance against the cooling capacity. It can be observed that the solar coefficient of performance increases considerably with and increases of the cooling capacity. The solar coefficient of performance varied from 0.06 at a cooling capacity of 1.7 MJ to a 0.098 at a cooling capacity of 4 MJ.

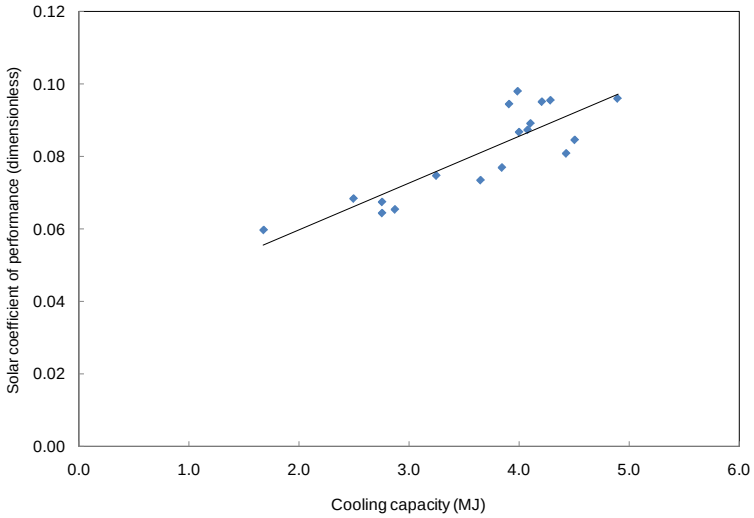

Fig. 6. Solar coefficient of performance against cooling capacity.

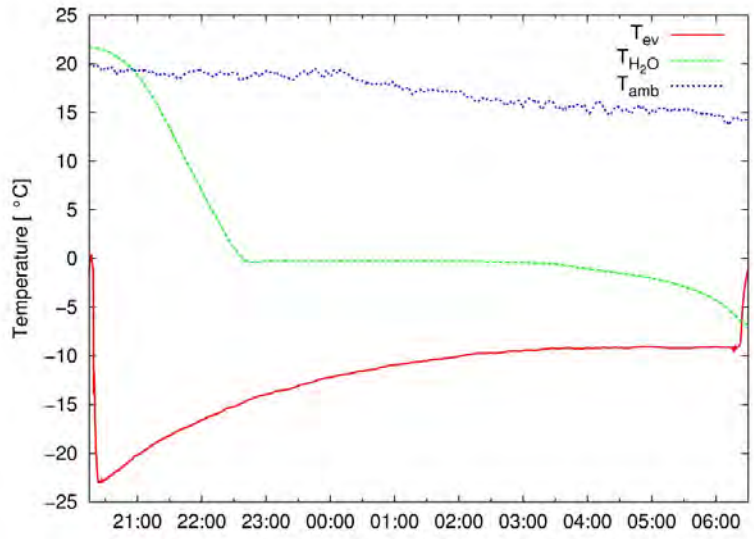

Fig. 7. Evaporator, water and ambient temperatures against time.

In Figure 7 it can be seen that the evaporator temperature was lower than -11°C for a period

higher than 8 hours. Also it can be seen how the water temperature decreases from the ambient temperature to 0°C and remains constant while the ice is been produced.

5. Conclusions

A solar intermittent refrigeration system for ice production has been evaluated with the ammonia/lithium nitrate/water mixtures at the Centro de Investigación en Energía of the UNAM. Evaporator temperatures as low as - 11°C were obtained for a period of time up to 8 hours. The solar coefficient of performance reached values up to 0.098, which is 24% higher than the maximum obtained previously by Rivera [7] operating the system with the ammonia/lithium nitrate mixture.

Acknowledgments

The authors would like to thank to PAPIIT-UNAM project number IN110706-2 to sponsor the present research and to Dr. Victor Hugo Gómez Espinoza for his invaluable help.

Abstract: The paper demonstrates how effectively hoteliers and corporate can architect and utilize both solar thermal and green gas energy for the production of zero carbon foot print food products. It involves the usage of shefflers, solar parabolic reflectors, solar ovens, solar cookers, solar dryers, solar water heaters, biomass gasifiers, biogas plant, etc which have been suitably designed and placed architecturally in the green kitchen premises to harvest maximum solar thermal green energy for effective production of low and zero carbon foot print food products with minimal loss of nutritional value. Further, the digested slurry of biogas plant is used as humus rich fertilizer for spice garden spread around the green kitchen to beautify the ambient. Replacement of conventional energy partially by green and thermal energy reduces the energy cost substantially. It not only cuts down the cost of fuel but also maintains a clean environment in canteen area and its surroundings in addition to providing nutritious food. The methods developed in this project may also be implemented in vast rural mass and community centre for cost effective and hygienic food production.

Keywords*: Fossil fuel, Carbon foot print, Green canteen, Solar energy, Biomass energy*

1. Introduction:

Today, India is growing with an average GDP growth of 8.9% per annum, which signifies the tremendous growth of its economy. Massive investment are being laid out by the Government and private sectors for the development of small and large manufacturing software industries and in service sectors like education, healthcare, hotels and real estates. These are being constructed throughout the country and environment becomes a concern everywhere. Our Government is enforcing norms to ensure that all these projects remain as much greener as possible. In any corporate offices, hotels, schools and colleges, quantity kitchen is mandatory to support their employees, students and customers so that they can avail nutritional food [1]. A survey has been conducted with some hotels and schools located in the rural part of Odisha State of our Country about the greenery of their kitchen and about their waste disposal. Today most of these industries, corporate offices, hotels and motels are very much aware of the energy saving equipment but have least ideas to make their environment green by applying the cheapest and easiest methods of non-conventional energy [2]. We tried to collect the feedback to understand their knowledge about energy saving devices, carbon emission, carbon footprint products and application of non-conventional energy for quantity kitchen.

It is a matter of concern of rural hotels and schools where food is prepared for more than 500 people per day with all conventional fuel and equipment. Our survey found most of these organizations trying to project their awareness by using energy efficient electrical and ceramic appliances, low-cost wood and coal steamers and also by disposing the food waste in isolated places without making the assessment how much damage is made to the environment [3].

The aim of this project is to develop a model green kitchen to demonstrate an effective and cheaper prototype which shall

1. Reduce carbon dioxide emission to a substantial level by the application of solar thermal reflectors, ovens and driers [4].
2. Establish a convenient waste management system and through it produce methane in order to utilize it in the kitchen [5] and to generate bio-fertilizer for its easy utilization in the spice garden.
3. Produce zero carbon footprint food products with higher nutritional value.
4. Reduce the total operational cost by at least 40% of the conventional one.

2. Materials and Methodology

2.1. Materials for green kitchen and its layout

A green kitchen attached to a 500 person capacity quantity kitchen was established at C.V. Raman College of Engineering, Bhubaneswar, India as per the layout shown in Fig. 1.

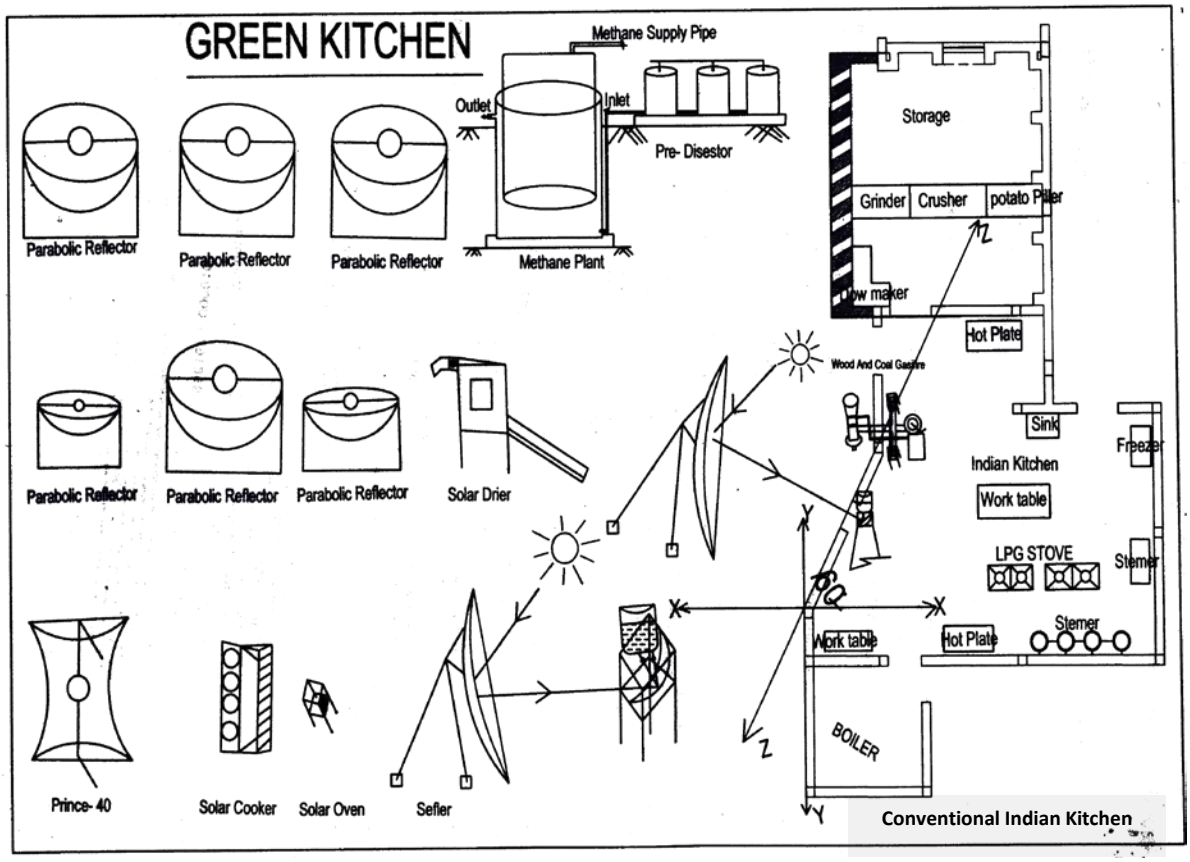

Fig. 1 Layout of green kitchen

Devices like solar reflectors of parabolic type, Schefflers, solar dyers, solar oven [6], solar water heaters, biomass gasifier and a food waste digester methane plant were installed. All these equipments have been installed by taking the following points into consideration:

1. The conventional kitchen wall facing the Scheffler was in east-west direction
2. Sheffler foundation was done taking latitudinal angle into consideration[7]
3. Thermal reflectors were located where maximum sun-light is available [8]
4. Schefflers fixed focus concentrator
5. Methane plant was installed near the conventional kitchen wall with less sun-light

From the survey conducted, it was realized that the small, medium and large hotels and motels of the locality had expressed serious concern regarding the effective utilization of solar thermal equipments in quantity food preparation and found that the food waste disposal outside the kitchen boundary as the most easiest and cheapest way. By way of this disposal, they were ignorant about the emission of methane gas to the atmosphere which has more than 20 time green house effect than that of carbon dioxide gas. They were also very much doubtful to accept the concept of the reduction fuel consumption by the food waste.

The layout of solar and green energy devices as shown Fig. 1 was designed for the demonstration to hoteliers and corporate to observe as well as analysed how the green kitchen effective and convenient for the reduction of cost of food production. This project had taken all the observations and experiments considering 78,000 Lux intensity of sun light as a reference during the month of August to December, the winter season. In a sunny day of the period green kitchen was able to cook grains, vegetables, meats and produce hot water continuously for more than six hours in a day from 9 hour morning to 15 hour evening. During summer the Lux intensity of sun light might rise for the locality as per temperature weather relationship curve, shown in Fig. 2 [7].

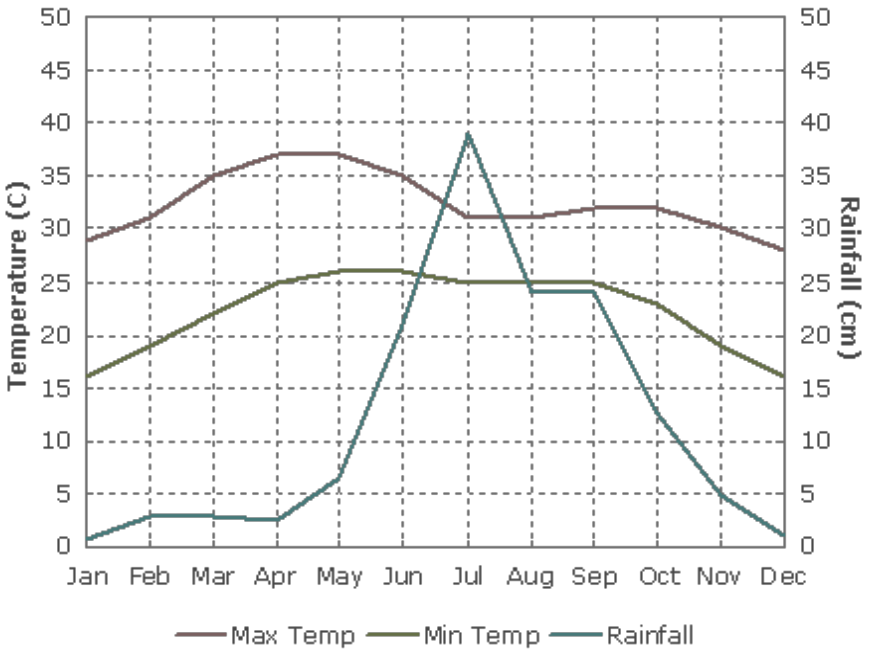

Fig. 2 Relationship of atmospheric temperature, average rain fall vs season

2.2. Methods adopted for the installation of green energy devices

The details of green energy devices are presented in Fig. 3 along with specification and cost.

Sl. No.	Name of equipment	Photograph	Cost of the equipment (in Indian Rupees)
01	Scheffler – 1		80,000
02	Scheffler – 2		1,20,000
03	Parabolic reflector-1		37,000
04	Parabolic reflector-2		32,000
05	Solar drier		10,000
06	Solar oven		3,000
07	Solar water heater		1,00,000
08	Methane plant		5,00,000
09	Biomass gassifier		10,000
			8,92,000

Fig. 3 The detailed specification and cost of green energy devices

2.3. Theoretical background for the installation of Scheffler

The installation of Scheffler-1 disc above the ground was taken as 5.2 m and the distance of the receiver from the disc centre as 3.8 m while the height of the receiver above the ground was evaluated using the equation 1.

$$Y = B-\{X*\sin(A)\} \quad \text{-------} \quad (1)$$

where, Y = height of the receiver, B = height of the disc above the ground, X = distance of receiver from disc centre and, A = latitudinal angle at any place
In order to keep the focal line constant, orientation of scheffler was adjusted with a programmable motor fitted device as per the movement of the solar rays on earth.

2.4. Basic principles of the installation of other solar devices

2.4.1. Parabolic Reflector

Both parabolic reflectors shown in Fig. 3 (Sl. No. 1 & 2 - Schefflers) and (Sl. No. 3 & 4 – Prince-40) [9] were installed to receive full sun rays and get concentrated on fixed focal centre through reflection where the cooker was placed with blacken surface to absorb maximum thermal energy. Here also the orientation of reflectors were adjusted with a programmable motor fitted device as per the movement sun rays

2.4.2. Solar dryer

The solar dryer was designed on the principle of green house glass where high frequency solar radiation got absorbed through inclined glass surface by the food materials but longer wavelength radiations reflected out. Moisture content was continuously ventilated. The inclination angle was experimentally evaluated to receive maximum temperature.

2.5. Methane Plant

The cellulosic materials comprising both vegetable waste and food waste of the canteen are predigested aerobically. The digested slurry with high biological oxygen was an aerobically digested to methane rich biogas which was purified by the separation of carbon dioxide gas. The high calorific methane rich gas was found to produce $0.6x10^{-3}$ m^3 of methane gas per kg of cellulosic waste on dry basis. The digested effluent was found to be rich in P_2O_5 with small quantity of K_2O and Nitrogen ingredients to act as ideal fertilizer for spice garden making the hotel environment greener, beautiful and profitable.

2.6. Biomass gasifier

Waste dry biomass collected by locals was fired in the special designed oven and thermal energy was fire through exhaust fan drive in a special designed energy efficient oven to utilize its maximum thermal energy by the cooking vessel.

3. Results and Discussion

3.1. Cost analysis of equipments

The cost of all equipments utilized in the project with respect to the cost in Indian market are worked out and compared with the conventional devices adopted by hoteliers, etc. on the basis of preparing food for 500 consumers as given in Table 1.

Table 1: Equipments used in a conventional kitchen to prepare food for 500 persons

Sl. No.	**Name of the equipment**
01	Cooking Range 4 Burner (LPG)
02	Cooking range High Pressure
03	Convection oven
04	Griddle
05	Stock Pot Burner
06	Deep fat fryer (2 Comp.) 5 Ltr.
07	Potato Peeler Heavy Duty
08	Dough mixer
09	Steamer compartment with boiler
10	Tandoor (Gas/coal)
11	Thawing tub
12	Vegetable slicer
13	Chapatti Puffer cum holplate
14	Aluminium steamer idli
15	Deep freezer
16	Vegetable steamer big
17	Hot dog roller

The conventional Indian quantity kitchen cost is around Rs. 25 Lakhs. This is three times the cost of the green kitchen. Making a simple comparison of the total cost of a green kitchen and a quantity kitchen we have found that the former is 30% less.

3.2. Cost saving analysis

In this exercise, we have tried to calculate the savings of fossil fuel per day by utilizing all these green equipments for preparing the following items:
a. Preparation of rice, b. Preparation of vegetables, c. Preparation of meat, d. Preparation of grains. In this total exercise (Table 2), it is calculated in a sunny day by utilizing this green kitchen. Fig. 2 shows the atmospheric temperature and rain fall profile in a year at the surveyed place.

Table 2: Saving of fossil fuel, its cost and environmental benefits by the implementation of solar thermal devices and methane gas plant for 500 people per meal

Sl. no.	Recipe	Quantity		Ambience of light (Lux)	Total time taken (Min.)	Quantity of savings of		
		Ingredient	Water (Lit.)			Fossil fuel(kg)	CO_2 (kg)	Cost (Rs.)
01	Cooked rice	Raw rice (60 kg)	144	78,000	72	9.6	29	288
02	Vegetables	Vegetables (75 kg)	60	78,000	69	12	36	360
03	Grains	Dal (25 kg)	90	78,000	108	6.75	18	180
04	Meat	Chicken (70 kg)	252	78,000	108	16.8	50	504

To prepare two meals in a day for 500 people the employed boiler consumes about 40 kg fire woods. On the other hand, upon employing gasifier it reduces 50 % of fire wood (20 kg) consumption in addition to 20 kg equivalent of CO_2 emission.
Approximately 120 kg of food waste is produced daily from the canteen emitting CH_4 and CO_2 as green house gases to the environment. Methane (CH_4) has 21 times stronger green house effect than CO_2. By generating bio gas out of this food wastes and considering all losses into account about 4 lakhs Indian rupees is saved in compensation to LPG consumption.

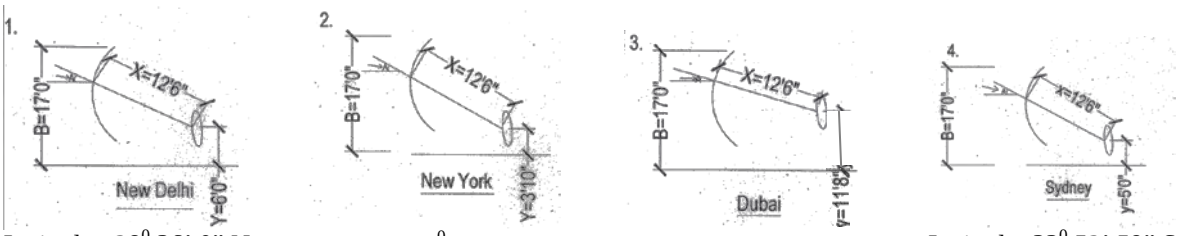
3.3. Application in spice garden

In most of the hotels, motels and corporate we have seen they spent a substantial amount of money in manure to keep their garden attractive and flowering. In our project we have introduced a concept of organic spice garden which we have demonstrated by doing a beautiful green landscape and planting 63 varieties of spices in the garden as an alternative to traditional rock and flower garden. In this food waste plant which we have installed that contains digested effluent which is being utilized in this spice garden to grow healthy and produce organic spices which can be reutilize in kitchen by using all the food wastes in the system.

We are yet to calculate the total value of spices generated in 1.5 acres of land in one year which can be worked out in the next year.

3.4. Theoretical background for architect

Green kitchen can be installed very conveniently at low installation cost if it is planned during the construction of the project. Architect should have fundamental knowledge about the geographical location of the place for installation of thermal reflectors because they can adjust the floor level of the kitchen to an operational height which cannot be done with an established kitchen. We have given an example of 4 places and shown a calculation as per equation (1) conveying the idea of geographical location of the place is important to install the thermal reflectros as shown in Fig. 4.



Latitude - 28^0 36’ 0” N
Y = 6.017’ or 6’0”

Latitude -40^0 42’ 51” N
Y = 3.847’ or 3’10”

Latitude -25^0 15’ 8” N
Y = 11.668’ or 11’8”

Latitude -33^0 52’ 59” S
Y = 5.089’ or 5’0”

Fig. 4: Diagram showing the angle of incidence of solar ray on Scheffler and its height from the ground at different location

This study shows if the architect is aware of these factors then will keep in mind so that the reflector can be installed at a convenient height for operation. Apart from reflector the architecture should workout for disposal of waste from methane plant in such a way that it will not have any negative impact on the environment and kitchen surroundings, so that the waste can be easily pumped to the green kitchen site.

4. Conclusion

The C.V. Raman College of Engineering, Bhubaneswar, India has successfully installed a composite 500 students green kitchen project for demonstration to hoteliers, corporate that how effectively to produce low and zero carbon foot print food products and also to incorporate this concept during design stage. On total in a year (operation of 6 months) using this green kitchen, around 4.8 lakh Indian rupees is saved than the conventional method of cooking along with a reduction of about 48,000 kg of green house gas emission to the environment. 50 % utilization of green kitchen in an annum, it has been evaluated that the total investment is fully recovered in a year in addition to providing tremendous safety to the environment. The methods developed in this project may also be demonstrated to vast rural mass and community centre for cost effective and hygienic food production.

Wind Energy Applications

Wind energy resources of the South Baltic Sea

Charlotte Hasager[1,*], Jake Badger[1], Ferhat Bingöl[1], Niels-Erik Clausen[1], Andrea Hahmann[1], Ioanna Karagali[1], Merete Badger[1] Alfredo Peña[1]

Abstract: The wind resources of the South Baltic Sea in the area between latitude 54 and 58 degrees North and longitude 10 to 22 degrees East are quantified from state-of-the-art methods using a combination of long-term and short-term mesoscale modeling output and satellite-based methods. The long-term overall statistics based on the NCEP/NCAR re-analysis dataset will be used in combination with more than one year of real time simulations using the Weather Research and Forecasting (WRF) mesoscale model operated at Risø DTU. The satellite Synthetic Aperture Radar (SAR) ocean wind maps and scatterometer ocean wind maps from QuikSCAT will be used to evaluate the wind resource calculation. The advantage of including SAR wind maps for evaluation is the finer spatial detail. In some regions, the mesoscale model may not fully resolve the wind-producing atmospheric structures. The satellites, however, only provides information at 10 m above sea level, whereas the mesoscale model provide results at several heights.

Keywords: *Offshore wind, mesoscale model, satellite data*

1. Introduction

The wind energy resources in the South Baltic Sea are not known in much detail despite the fact that several wind farms are being planned at sea. The existing wind farms are located typically less than 10 km offshore whereas most new wind farms are planned further offshore, up to 80 km. There are plans to construct more than 12GW installed wind farm capacity in the South Baltic Sea. The countries Denmark, Sweden and Germany already have installed offshore wind farms whereas Poland, Russia (Kaliningrad), and the Baltic countries have plans to do so. The web-site http://www.4coffshore.com/windfarms/ provides a listing and map of existing and planned offshore wind farms. It is important to know the wind climate in the planning phase of wind farms, as the expected annual energy production will be proportional to the expected financial benefit of the investment.

The European Wind Atlas[1] covers land areas http://www.windatlas.dk/Europe/Index.htm whereas the corresponding offshore atlas http://www.windatlas.dk/Europe/oceanmap.html covers sea. It is seen that the Baltic Sea is not fully covered. Furthermore, information gained since year 1999, in particular, from satellite Earth observation and from atmospheric mesoscale modeling jointly provides a new opportunity to map the wind resource with higher spatial detail.

The main objective is to provide a new wind atlas for the South Baltic Sea using available satellite images and mesoscale modeling. The results will be evaluated to meteorological data.

The satellite Earth observations used in the South Baltic wind atlas include scatterometer wind vectors from the SeaWinds instrument on-board the QuikSCAT satellite collected from 1999 to 2009 by NASA, and Synthetic Aperture Radar (SAR) data from the Advanced SAR (ASAR) on-board the satellite Envisat collected from 2002 to present by the European Space Agency (ESA).

In the South Baltic Sea a new approach to the numerical wind atlas method[2] based on mesoscale modeling is used. The mesoscale model used for the South Baltic is the Weather

Research and Forecasting (WRF) mesoscale model developed jointly by several US agencies. Additional refinement of the results will be with the microscale model Wind Atlas Analysis and Applications Program (WAsP)[3] developed at Risø DTU. The Weibull distribution scale (A) and shape (k) parameters and energy density are some of the outputs, see[1].

The results from satellite and mesoscale modeling are compared, as well as comparison to meteorological masts. The project is on-going. It is approximately mid-term in regard to finalizing the wind atlas, thus the proceedings paper presents work in progress. The investigated area is shown in Fig. 1. The project is related to the South Baltic Offshore Wind Energy Regions (OFF.E.R.) project with partners from Sweden, Germany, Poland, Lithuania and Denmark. The area and team is indicated in Fig. 1.

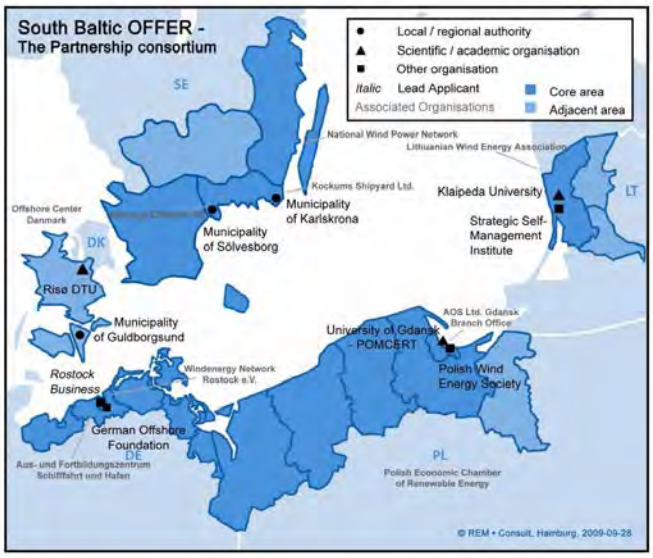

Fig. 1. South Baltic Sea highlighting regions and partners in the South Baltic OFF.E.R. project.

2. Methodology

2.1. Wind profile, meso- and microscale modeling, and satellite remote sensing

The use of satellite remote sensing is motivated by the fact that only satellites provide spatial observations of ocean winds. Meteorological masts observe winds in the local area in which they are located. Meteorological masts are costly to operate. In some cases access to data is restricted. Thus available offshore meteorological mast data in the South Baltic Sea is limited. The advantage of meteorological masts is that observations typically are collected at several heights, and therefore the vertical wind profile can be quantified. It is well known that the wind profile in its simplest form at low heights is logarithmic and that the wind profile in non-neutral atmospheric stratification and at higher heights deviates from the logarithmic profile [4-8]. For wind resource estimation, the most important level is hub-height where the wind turbines harvest the energy.

Satellite ocean winds are mapped at 10 m above sea level. It is clear that wind turbine hub-height is higher, say 80 to 100 m. Thus the satellite-based results have to be extrapolated to higher levels. One option is to use WAsP for the vertical extrapolation. Another option is to use the numerical wind atlas. The latter method is applied in the present context. The advantage of mesoscale modeling is that in such models the advection of air is effectively accounted for through modeling over long distances. In contrast, microscale models account for influences only at shorter distances. In enclosed seas such as the Baltic Sea, the surrounding lands are expected to influence winds over long distances.

2.2. Satellite techniques

The techniques of scatterometer and SAR wind retrievals are presented first. Similarities of the two satellites used – QuikSCAT and Envisat – are that they both map any area at specific local times as both satellites are in sun-synchronous polar orbits. For QuikSCAT the local mapping time is around 6 a.m and 6 p.m. while for Envisat it is around 9 a.m. and 9 p.m. in the South Baltic Sea. Both satellites carry microwave radars, i.e. active instruments sending and receiving microwave signals. Microwave radar works day and night and in all weather conditions. The microwaves penetrate cloud, rain and fog. For QuikSCAT though, rain gives rise to problems in case of heavy rain and therefore rain flags are added to the data such that the user can avoid using rain-affected data.

The physical principle of retrieving oceans winds is similar for scatterometer and SAR. The wind over ocean constantly modulates the sea surface creating capillary and short gravity waves. These very short waves are generated near-instantaneously and decay at the same rate, but appear to be in balance at all times to the mean wind speed as observed at 10 m. The Geophysical Model Function (GMF) that describe the relationship between the backscattered normalized radar cross section is found to be non-linearly proportional to the wind speed, as a function on slant range and relative wind direction in regard to the viewing geometry. For further details on ocean wind mapping see references for scatterometer [9-11] and SAR [12-14]. The nominal accuracy on wind speed is within 2 m s^{-1} for wind speeds between 3 and 25 m s^{-1}.

To highlight major differences between scatterometer and SAR the following may be noted: Scatterometer provides medium spatial resolution, around 25 km by 25 km grid size whereas SAR provides high spatial resolution, around 1 km by 1 km grid size. The resolutions here refer to the final wind results (not the raw sampling which has much higher spatial resolution).

The swath of QuikSCAT was very wide, 1800 km, and this means that most of the globe was mapped twice per day for the 10 years of active observations. This results in roughly 7300 individual ocean wind maps in the South Baltic Sea. The archive is freely available, e.g. from Remote Sensing Systems (http://www.remss.com/qscat/) as so-called level 3 products. This means as gridded geo-coded products of wind speed and wind direction.

In contrast, Envisat ASAR has a swath of 400 km in the so-called wide swath mode (WSM). The sampling in WSM provides a possibility of mapping any location in the South Baltic around 10 times per month. From simple calculation the data could amount to roughly 1000 samples everywhere on the globe. However, Envisat ASAR was and is not always mapping, as the mapping is based 'on demand', typical for science or for commercial activity, and also, the on-board data storage and downlink cannot handle continued operation. The archive at ESA (http://earth.esa.int/EOLi) provide gateway to check the actual data availability. In the present work around 3000 WSM wind maps are used, meaning roughly 400 available samples in each grid cell. For SAR-based wind mapping the raw data are retrieved by Risø DTU and processed into wind maps using the Johns Hopkins University Applied Physics Laboratory software ANSWRS[15].

Finally, an important difference between scatterometer and SAR is that while scatterometer observes the ocean surface from several angles using multiple antennae or rotating antenna (as for QuikSCAT), SAR only views the surface from one direction. This basic difference means that only scatterometer provides both wind speed and direction through the GMF. In order to map wind speed from SAR it is necessary first to estimate the wind direction, and use this *a*

priori information in the GMF. In our case we use the wind direction from the global atmospheric model by the US Navy, the so-called NOGAPS model. Further detail in[12].

2.3. Statistical-dynamical downscaling

The long-term overall statistics based on the NCEP/NCAR re-analysis dataset 1980-2009 will be used in combination with nearly two years of real time simulations using the WRF mesoscale model operated at Risø DTU. The usual procedure at Risø DTU for calculating wind resource with the numerical wind atlas method involves, as a first step, the definition of a set of wind classes. The set of wind classes represent the different wind conditions (wind speed, direction and atmospheric stability) defined from long term, large scale atmospheric reanalysis datasets.

The wind classes are based on geostrophic wind and potential temperature at 0, 1500, 3000, 5500 m above sea level. The wind classes are defined by the distribution of wind speed, direction and stability at one point. For the South Baltic wind atlas the area of interest is large. It is therefore of interest to see how well wind classes defined at one point manages to represent the large scale climate over this large area. There are two issues: 1) do wind classes represent the large scale wind climate well over the entire region of interest; 2) to what extent can a single wind class describe the wind in the region at any given time.

The WRF model is triple nested to the inner domain over Denmark with a 2 km by 2 km grid resolution for the weather forecasts, but the outer grid at an 18 km by 18 km grid covers most of the South Baltic. The weather forecasts plus some additional simulations at higher resolution will be used as basis in the statistical-dynamical downscaling.

3. Results

3.1. Satellite results

Results from the study area using QuikSCAT are shown in Fig. 2. The results are based on all available ocean wind maps from RSS without rain-flag from 10 years, 1999 to 2009. The results are maps of the Weibull A and k parameters. Weibull A is seen to vary from 8.0 to 8.5 m s^{-1} in the South Baltic Sea, and Weibull k is seen to vary from 1.9 to 2.3. Near the coastlines the white area indicates that data are not available.

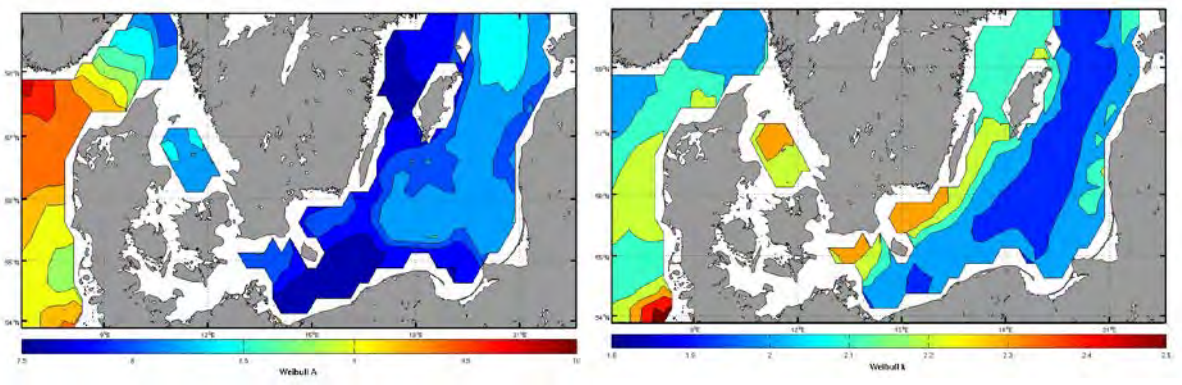

Fig. 2 Weibull A ranging from 7.5 (blue) to 10.0 (red) m $s^{-1}$and Weibull k ranging from 1.8 (blue) to 2.5 (red) in the South Baltic and Danish Seas observed from 10 years of QuikSCAT ocean wind maps. Domain size is 7° to 22° East and 53° to 59° North.

Results from the study area using Envisat ASAR are shown in Fig. 3. The upper panel shows the number of wind maps, the middle panel the mean wind speed, and the lower panel the

energy density. In most of the area there are more than 400 samples. The mean wind speed varies from around 5 m s^{-1} to nearly 11 m s^{-1}. Finally, the energy density varies from 400 to nearly 1200 W m^{-2}. In particular near the coastlines, the energy density is seen to be low. High energy density is found in the open sea.

3.2. Wind class results

Four sets of wind classes were defined, all based on the large scale conditions at 16.25E 56.25N. The sets, named SB1, SB2, SB3, SB4, contain 134, 84, 84, 36 wind classes respectively, see Fig. 4. Sets SB1, SB2, SB4 differ in that a different number of wind classes are allowed for each direction sector (14, 7, 3 respectively) but in each sector the wind speed range of each wind class varies so as to get obtain wind classes with approximately equal frequency of occurrence. Set SB3 uses 7 wind classes per sector, but the wind speed range is fixed and this the frequency of each wind classes varies within each sector.

The first question is, how well do the wind classes represent the large-scale wind climate over the South Baltic. This is answer is: The 134 wind classes of set SB1 capture the wind power in the large scale climate quite accurately with only a small error of less than 3% in the mean of the wind cubed. Whereas the 36 wind classes of set SB4 do more poorly, with an error in the region of 14% in the mean of the wind cubed. Wind classes sets SB2 and SB3 give an error in the region of 5% on the mean of the wind cubed.

The second question concerns to what extent it can be expected that a single wind class, at any given time is influencing the area of interest. The probability of a single wind class acting over a region rapidly drops off when moving away from 16.25E 56.25N. We may conclude that occasions where the same wind class influences large parts of the region of interest happen very rarely. By selecting periods where the wind classes are persistent the probability of locations experiencing the wind class is increased. However, it is not thought that persistency filtering is sufficiently powerful for the South Baltic domain. In conclusion, the variability means that an approach where several wind classes acting more locally, as opposed to acting over the whole domain, will have to be defined and used for the downscaling.

4. Discussion

Satellite wind maps from QuikSCAT provide twice daily 10 year results at 25 km by 25 km resolution. The WRF statistical-dynamical downscaling will provide 30 year results at 5 km by 5 km resolution. Envisat ASAR provides results at 1 km by 1 km resolution. The challenge of using different sources of information is the reliability of each. Comparisons between SAR and three meteorological masts in the North Sea[16] show good agreement, less than 5% error on mean wind speed, Weibull A and k. Comparisons between SAR and meteorological masts in the South Baltic Sea show similar agreement for mean wind speed, but less good agreement for Weibull A and k[17]. Mesoscale model results typically range between 10 to 15% uncertainty. Thus combining satellite wind maps and mesoscale modeling is expected to provide an accurate wind atlas for the South Baltic Sea.

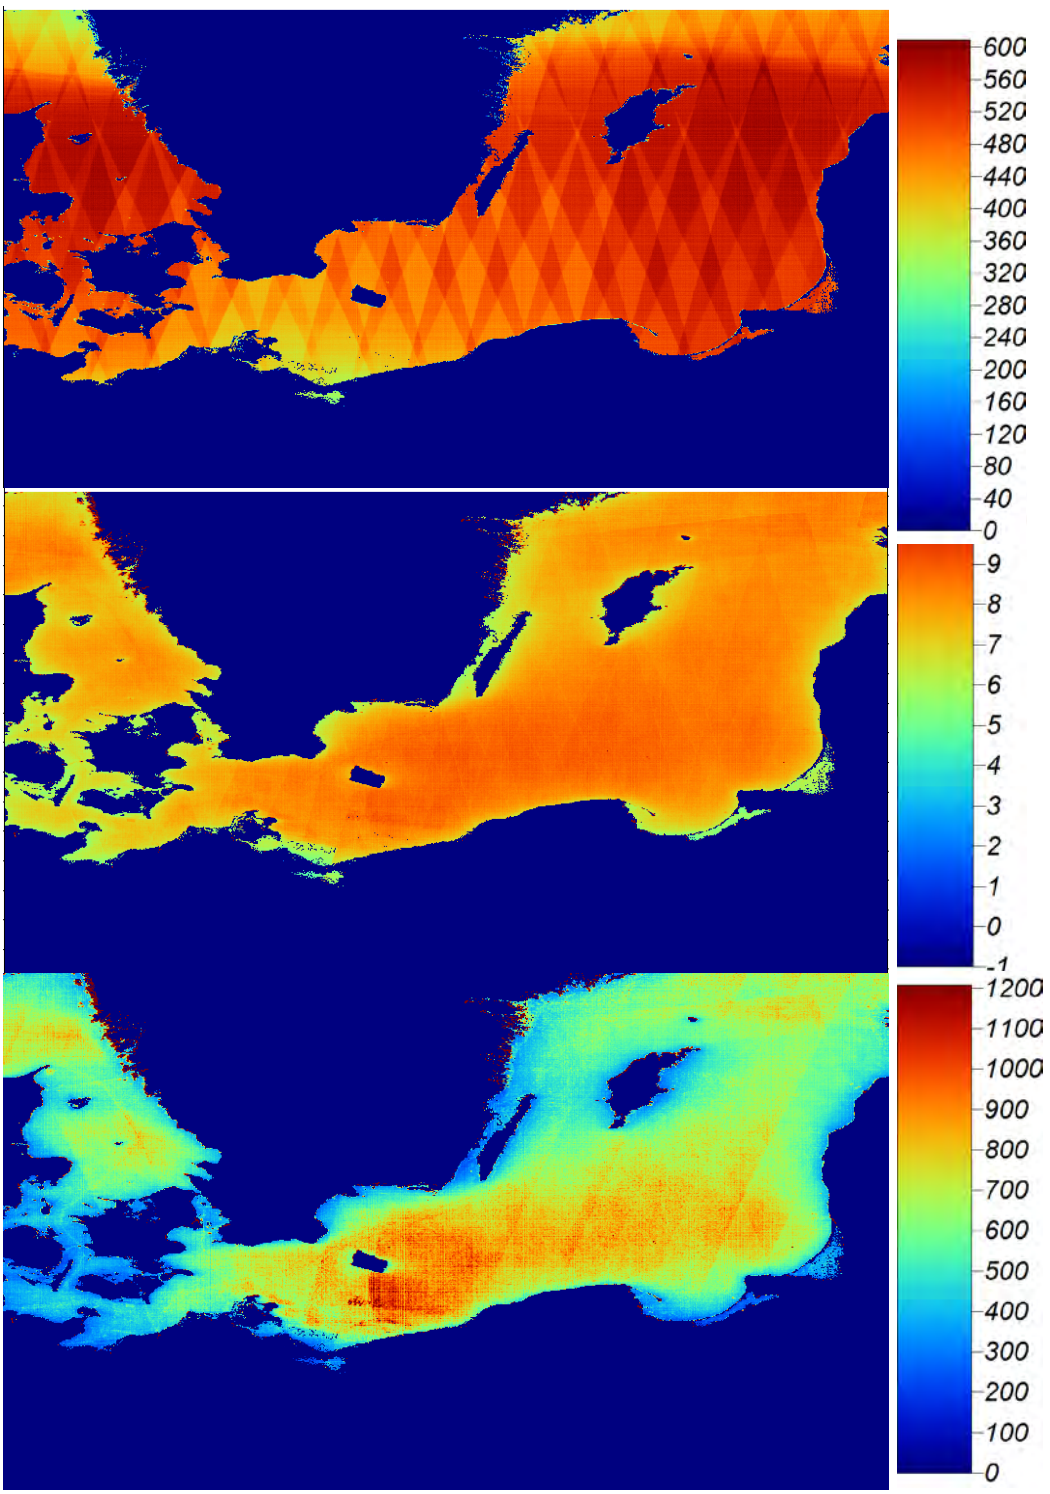

Fig. 3 Envisat ASAR wind maps: (Top) Number of wind speed maps use; (Middle)Mean wind speed in m s^{-1}; (Bottom) Wind energy density in W m^{-2} for the South Baltic Sea. Domain size is 10° to 22° East and 52° to 59° North.

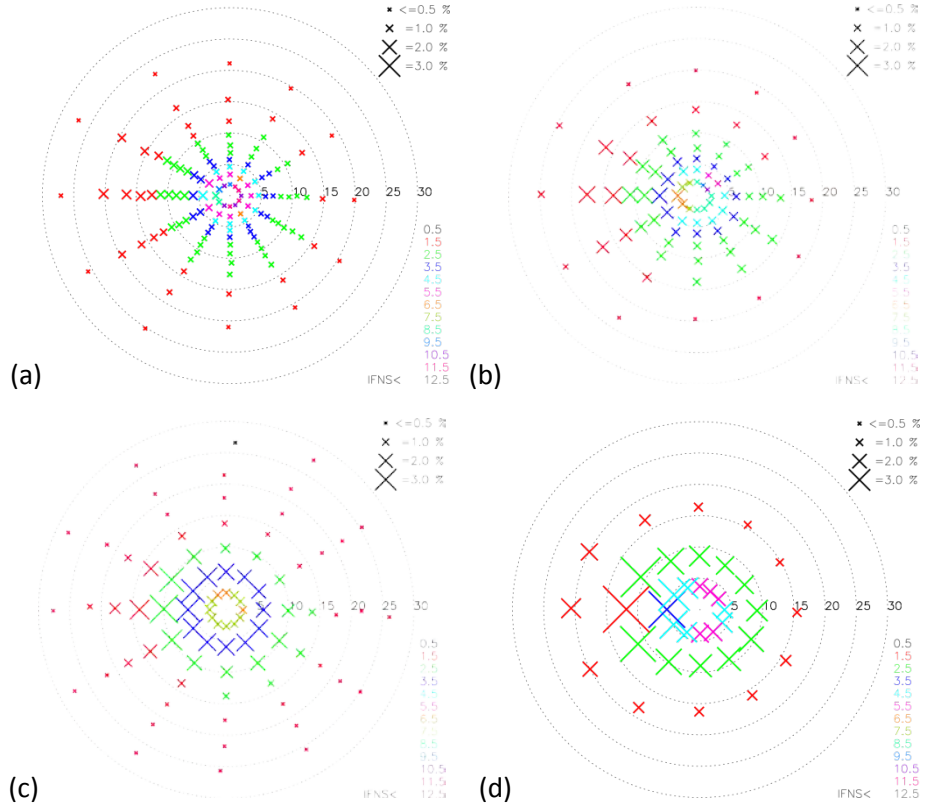

Fig. 4 Four sets of wind classes (a) SB1, (b) SB2, (c) SB3 and (d) SB4. Each cross represents a forcing wind speed (distance from the centre of the diagram) and direction. The speed scale is in m s^{-1}. The colours indicate the inverse Froude number squared (IFNS).

5. Conclusion

The wind atlas for the South Baltic Sea is in progress using satellite remote sensing and mesoscale modeling. The final results will be compared to available meteorological data to estimate the uncertainty of the results. The analysis will be completed in Spring 2011.

Abstract: There are many wind synoptic stations installed all over Iran. One of these stations in the coasts of Persian Gulf is Bardekhun station in Bushehr province. The goal of this study is to assess the wind energy potential of this region and to design a proper horizontal axis wind turbine for this site. The one-year measured hourly time-series wind speed data are extracted from measurements at a height of 10m, 30m and 40m above the ground level. The Weibull distribution gives the mean wind speed of 4.50 m/s, 5.36 m/s and 5.83 m/s and the power density per year of 125 W/m^2, 196 W/m^2 and 253 W/m^2 respectively for these heights. According to these results, a small wind turbine can be installed in the height of 30m and 40m. A MATLAB code using the blade-element-momentum theory has been developed to design and analyze the three-blade wind turbine rotor. After calculation of geometrical parameters of rotor blade, the rotor power coefficient versus rotor tip speed ratio is evaluated. The energy produced per year by this wind turbine using the Weibull distribution for wind speed will be 155MWh.

Keywords: *Wind potential, Weibull distribution, Wind turbine, produced energy*

1. Introduction

Annual growth in energy consumption and global warming are two important reasons for considering wind as an efficient and clean source of energy. Iran (Persia) is exposed to the continental streams from Asia, Europe, Africa, Indian and Atlantic Pacific. The first vertical axes and drag type windmills on record were built by the Persians in approximately 900 AD [1]. According to the research and studies, it has been estimated that the wind energy potential in Iran is more than 10000 MW for electricity production [2]. There are two wind farm producing electricity in Iran: a 70MW power plant in Manjil and a 28MW power plant in Binalood. Since Iran has many windy regions, utilization of this type of energy would not only be possible but also economically feasible. The Ministry of Energy has serious programs for the evaluation of the wind energy potential in the country. At the first stage, the country's wind energy potential evaluation is performed for a wide range of the country. At the second stage, after the exact investigation on the wind potential, the Iran's wind atlas is prepared. To prepare the wind atlas, 53 wind synoptic stations have been installed all over Iran [3]. These stations record wind data every 10 min. Also, the effects of thunderstorms and turbulences on wind stream are considered in the results.

In the recent years, many researchers have studied the wind energy potential in Iran. Mostafaeipour and Abarghooei [4] investigated the wind energy potential in Manjil area in the north of Iran. They reported it is one of the best locations in the world for installing wind turbine. Mostafaeipour [5] utilized wind speed data over a period of almost 13 years between 1992 and 2005 from 11 stations in Yazd province to assess the wind power potential at these sites. The results showed that most of the stations have annual average wind speed of less than 4.5 m/s which is considered as unacceptable for installation of the wind turbines. Keyhani et al [6] used the statistical data of eleven years wind speed measurements of the capital of Iran, Tehran to find out the wind energy potential. They concluded that the site studied is not suitable for electric wind application in a large-scale and the wind potential of the region can be adequate for non-grid connected electrical and mechanical applications, such as wind

generators for local consumption, battery charging, and water pumping. Mostafaeipour [7] performed an analysis of offshore wind speed in global scale and also studied feasibility of introducing this technology for harnessing wind in Persian Gulf, Caspian Sea, Urmia Lake and Gulf of Oman. He suggested that policy makers to invest and pay more attentions toward harnessing renewable energy sources like offshore wind in Persian Gulf and Gulf of Oman in southern parts of Iran.

This paper presents a study of the wind energy potential in the Bardekhun station. Knowledge of the wind speed distribution is a very important factor to evaluate the wind potential in the windy areas. The Weibull distribution is the best one, with an acceptable accuracy level. A stall-regulated horizontal wind turbine with nominal power of 50kW is designed for this wind station. A MATLAB code was written based on the BEM theory. This code utilizes a generalized rotor design procedure in determining the final blade shape and performance iteratively considering drag, tip losses, and ease of manufacture.

2. Site description and the wind data

This site is located in the vicinity of Deyer port in Bushehr province in the coasts of Persian Gulf. It is situated in the latitude of 27°98' N, the longitude of 51°49' W and the altitude of 4m. Its distance from capital city of Iran, Tehran, is about 1330 km. A well known wind in this region is North Wind which has effect on the architectural and environmental design of buildings. The one-year measured hourly time-series wind speed data, from January 1, 2007 to December 31, 2007 are extracted from Renewable Energy Organization of Iran, SUNA [2].

3. Wind data analysis

3.1. Weibull distribution

Statistical analysis can be used to determine the wind energy potential of a given site and to estimate the wind energy output at this site [1]. This type of analysis relies on the use of the probability density function, *p(U)*, of wind speed. One way to define the probability density function is that the probability of a wind speed occurring between U_a and U_b is given by:

$$p(U_a \le U \le U_b) = \int_{U_a}^{U_b} p(U)dU \tag{1}$$

Where U is wind speed and $\int_0^\infty p(U)dU = 1$.

In general, Rayleigh and Weibull probability density functions are used in wind data analysis. The Rayleigh distribution uses one parameter, the mean wind speed ($\overline{U}$). Determination of the Weibull probability density function requires knowledge of two parameters: k, shape factor and c, scale factor. Both these parameters are a function of wind speed, U, and standard deviation of wind speed, σ_U. The Weibull probability density function is given by:

$$p(U) = \left(\frac{k}{c}\right)\left(\frac{U}{c}\right)^{k-1} \exp\left[-\left(\frac{U}{c}\right)^{k}\right] \tag{2}$$

The cumulative distribution function of the speed U gives us the fraction of time (probability) that the wind speed is equal or lower than U. the cumulative distribution *F (U)* is given by:

$$F(U) = 1 - \exp\left[-\left(\frac{U}{c}\right)^{k}\right] \tag{3}$$

The parameters *c* and *k* are calculated based on the following empirical formulas [1, 8]:

$$k = \left(\frac{\sigma_U}{\overline{U}}\right)^{-1.086}, \frac{c}{\overline{U}} = \frac{k^{2.6674}}{0.184 + 0.816k^{2.73855}} \tag{4}$$

Annual energy produced by a wind turbine with performance curve $P_w(U)$ is [1, 9]:

$$\overline{P_w} = 365 \times 24 \int_0^{\infty} p(U)P_w(U) = 365 \times 24 \times \sum_{i=1}^{N_B} \frac{1}{2}(U_{i+1} - U_i)\left(p(U_{i+1})P_w(U_{i+1}) + p(U_i)P_w(U_i)\right) \tag{5}$$

3.2. Power density

The wind power per unit area, or wind power density, is proportional to the density of the air (for standard conditions sea-level, 15°C, the density of air is 1.225 kg/m^3), the area swept by the rotor (or the rotor diameter squared for a conventional horizontal axis wind machine) and the cube of the wind velocity. The average wind power density is:

$$\frac{\overline{P}}{A} = \frac{1}{2}\rho \int_0^{\infty} U^3 p(U)dU \tag{6}$$

4. Wind turbine aerodynamic design

The primary aerodynamic factors affecting the blade design are: design rated power and rated wind speed, design tip speed ratio, solidity, airfoil, number of blades, rotor power control (stall or variable pitch), rotor orientation (upwind or downwind of the tower) [1]. The analysis here uses momentum theory and blade element theory. Momentum theory refers to a control volume analysis of the forces at the blade based on the conservation of linear and angular momentum. Blade element theory refers to an analysis of forces at a section of the blade, as a function of blade geometry. The results of these approaches can be combined into what is known as strip theory or blade-element- momentum (BEM) theory. This theory can be used to relate blade shape to the rotor's ability to extract power from the wind. The analysis in this paper covers a simple optimum blade design including wake rotation and an infinite number of blades. This blade design can be used as the start for a general blade design analysis. The forces on the blades of a wind turbine can also be expressed as a function of lift and drag coefficients and the angle of attack. In this analysis, the blade is assumed to be divided into *N* sections (or elements) [1, 9].

5. Results and discussions

5.1. Wind energy potential

The data collected for an interval of 10 min have been used to analyze the wind energy potential of this site. All measurements in the wind station are recorded using the cup anemometer at a height of 10m, 30m and 40m above the ground level.

5.1.1. Wind speed distribution

The most critical factor influencing the power developed by a wind energy conversion system is the wind speed. Due to the cubic relationship between speed and power, even a small variation in the wind speed may result in significant change in power.

Results of wind data analysis at three different heights have been summarized in Table 1.The mean wind speed, mean cubic wind speed, standard deviation of wind data and the Weibull distribution parameters for each height are calculated. Maximum wind speed per year and its occurrence time can be used in control and structural analysis of wind turbines. These results obtained for one-year measured data.

Table 1. Results of wind data analysis at different heights

	Height		
	40m	30m	10m
Mean wind speed (m/s)	5.83	5.36	4.50
Mean cubic wind speed (m/s)	7.50	6.96	6.00
Standard deviation	3.313	3.042	4.506
Max. wind speed per year (m/s)	33 (11/4/2007 23:50)	31.1 (11/4/2007 23:50)	28.2 (15/3/2007 11:00)
Weibull distribution constants	k=1.848 c=6.568	k=1.850 c=6.037	k=1.737 c=5.058

The corresponding average wind speeds and best fits to the Weibull distribution at 30m and 40m height in comparison with the distribution of measured data are shown in Fig.1. The Weibull scale and shape factors can be found in Table 1 at each height. As shown in Fig. 1(a), the Weibull distribution function reaches the top point at about 4.00 m/s with a value of about 13.54%, however the Weibull distribution function in Fig. 1(b) reaches the top point at about 4.00 m/s with the value of frequency equal to 12.39%.

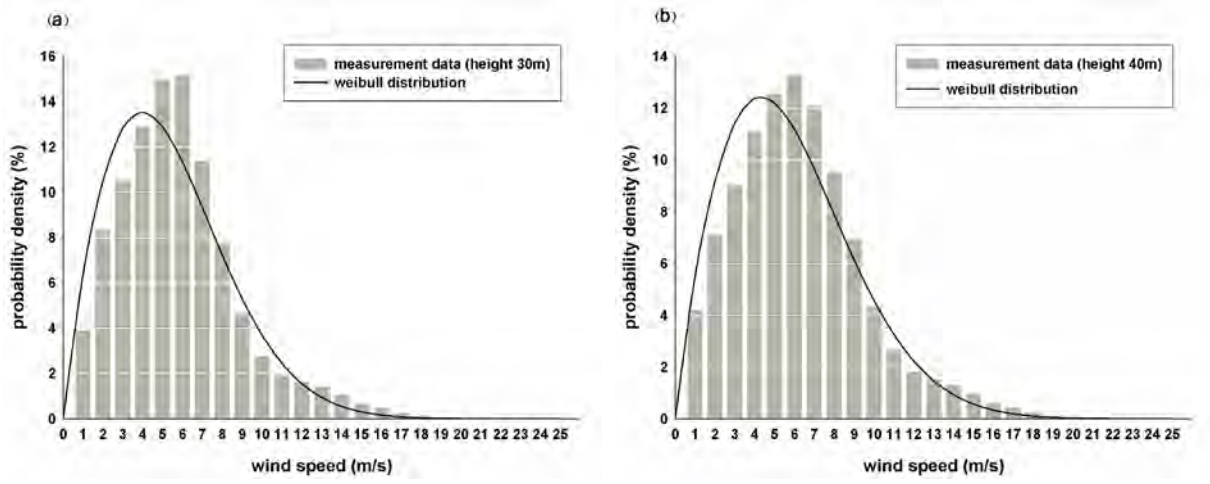

Fig. 1. Weibull probability distribution function at (a) 30m (b) 40m

Fig. 2(a) illustrated the Weibull distribution function at the height of 10m. The distribution of measured data can be seen in this figure. The Weibull distribution reaches to the maximum

frequency of 15.61% at the wind speed around 3.00m/s. The cumulative distribution functions at three given heights are shown in Fig. 2(b). According to this figure, the cumulative density at 40m gets up to 56.50% for mean wind speed of 5.83m/s. This probability is 52.62% and 50.47% for mean wind speed of 5.36m/s and 4.50m/s at 30m and 10m heights, respectively.

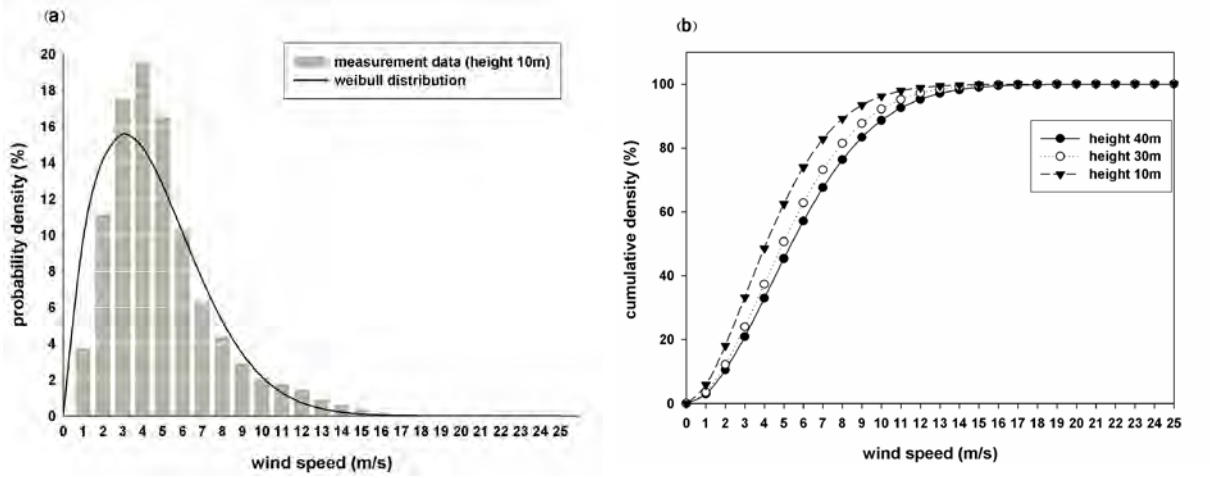

Fig. 2. (a) Weibull probability distribution function at 10m (b) Cumulative function at three heights

5.1.2. Estimation of monthly wind potential

The monthly distribution of the wind speed measured between January 1, 2007 and December 31, 2007 is plotted in Fig. 3(a). It can be seen from this figure, the wind speeds vary between 3.34 and 7.52 m/s. According to these results, the average speed for 10 m is 4.50 m/s. This is below the minimum speed, 5.0 m/s, required for effective wind turbines, but it is enough for water pumping applications. The monthly average wind power density at height of 40m is illustrated in Fig. 3(b). The wind potential of a site, i.e. average power density, which is proper to run a wind turbine, is qualitatively estimated based on the following [1]: $\overline{P}/A$<100 W/m^2 is a poor potential, $\overline{P}/A\approx$400 W/m^2, is a good potential, and $\overline{P}/A$>700 W/m^2 is a great potential. Here, there is a poor potential in October, September and August, because the power density is near to 100 W/m^2 in these months. For the reminders of the year, there is a reasonable potential.

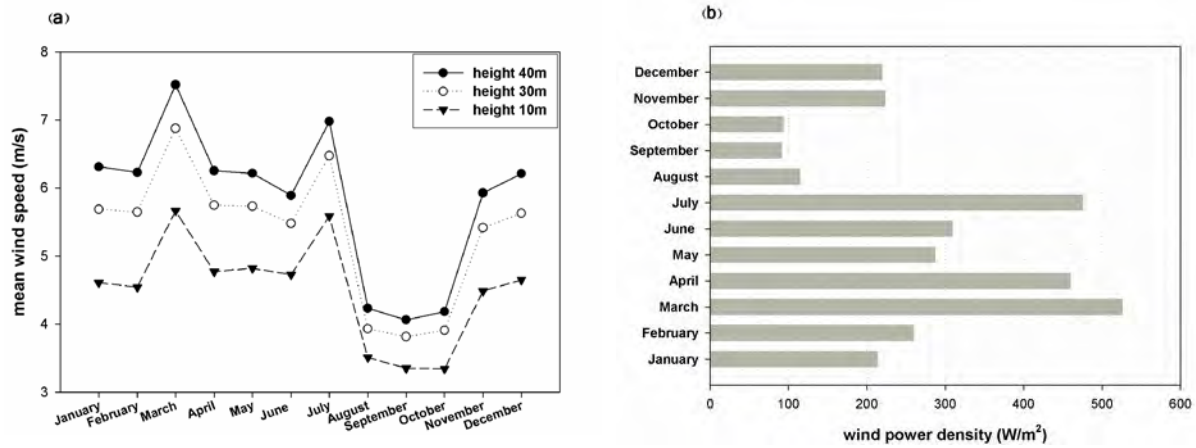

Fig.3. (a) Monthly average wind speed at three heighs (b) Monthly power density at 40m

5.1.3. Wind potential in the site

If annual average wind speeds are known for a certain site, the average wind power density can be found over these regions. Fig. 4 illustrates the power densities per year at three heights. These power densities are drawn for measured data and for the Weibull distribution function. The Weibull distribution function illustrates power density per year a little lower than measured data. The wind power density per year at height of 10m is suitable for water pumping, because it is not actually a good potential. The power density at height of 40m and 30m are more reasonable. A proper wind turbine can be run by the wind at these heights. In the next section, a wind turbine designed and proposed for installation at 40m.

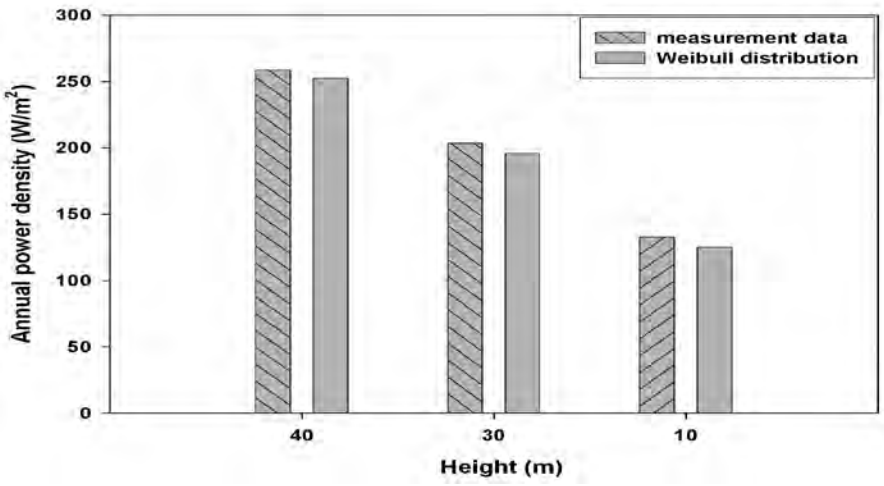

Fig.4. power density per year at three heights

5.2. Wind turbine design and performance results

In order to utilize the wind energy potential for the mentioned site, a power of 50kW is needed at 7.50m/s wind speed (mean cubic wind speed at 40m height). For this purpose, a 3-blade, stall-regulated and upwind horizontal axis wind turbine (HAWT) has been designed based on the BEM theory. The blade has NACA 4415 airfoil and has a tip speed ratio of λ=6.

5.2.1. Blade geometry

To develop the maximum possible power coefficient (C_p) requires suitable blade geometry. The geometrical parameters for blade design are shown in Table 2. Assume the mechanical efficiency and the overall rotor power coefficient are 0.99 and 0.40, respectively. With these assumptions, the radius of rotor will be R=13m. The blade is divided into *N* elements (usually 10-20). The first column, r/R, is fraction of rotor radius. The straight line connecting the leading and trailing edges is the chord line of the airfoil, and the distance from the leading to the trailing edge measured along the chord line is designated as the chord, *c*, of the airfoil (second column in Table 2). The section pitch angle (θ_p) is the angle between the chord line and the plane of rotation. $\theta_{p,0}$ is the blade pitch angle at the tip. The relative wind is the vector sum of the wind velocity at the rotor and the wind velocity due to rotation of the blade. The angle between the chord line and the relative wind is the angle of relative wind ($\varphi = \theta_p + \alpha$).The blade twist angle is the difference between section pitch angle and the blade pitch angle at the tip, i.e. $\theta_T = \theta_p - \theta_{p,0}$. The design aerodynamic condition occurs when C_d/C_L is at a minimum for each blade section. The aerodynamic properties of the airfoil at each section, i.e. C_L-α (lift coefficient vs. angle of attack) and C_d-α (drag coefficient vs. angle of attack) can be obtained from the empirical curves.

Table 2. Blade design of a 26m-diameter Rotor

r/R	Chord (m)	Twist angle (degree)	Angle of relative wind (degree)	Section pitch (degree)
0.0500	2.0091	42.5590	48.8672	42.8672
0.1000	2.6631	33.0493	39.3575	33.3575
0.1500	2.6778	25.7003	32.0085	26.0085
0.2000	2.4742	20.2288	26.5370	20.5370
0.2500	2.2268	16.1518	22.4600	16.4600
0.3000	1.9939	13.0615	19.3696	13.3697
0.3500	1.7907	10.6673	16.9753	10.9756
0.4000	1.6174	8.7717	15.0793	9.0799
0.4500	1.4704	7.2405	13.5474	7.5488

0.7000	0.9903	2.6201	8.8820	2.9283
0.7500	0.9225	2.0443	8.2625	2.3525
0.8000	0.8558	1.5373	7.6712	1.8455
0.8500	0.7825	1.0876	7.0541	1.3958
0.9000	0.6856	0.6861	6.2952	0.9943
0.9500	0.5029	0.3255	4.9618	0.6338

5.2.2. HAWT performance curves

The Betz limit, $C_{P,max} = 0.59$, is the maximum theoretically possible rotor power coefficient. In practice three effects lead to a decrease in the maximum achievable power coefficient: rotation of the wake behind the rotor, finite number of blades and associated tip losses, and non-zero aerodynamic drag [1]. Although the blade has been designed for optimum operation at a specific design tip speed ratio, the performance of the rotor over all expected tip speed ratios needs to be determined. The results are usually presented as a graph of power coefficient versus tip speed ratio, called a C_P-λ curve, as shown in Fig. 5(a). The maximum value of C_P in C_P-λ curve, Fig. 5(a), is 0.4586 at λ=6. C_P-λ curves can be used in wind turbine design to determine the rotor power for any combination of wind and rotor speed. They provide immediate information on the maximum rotor power coefficient and optimum tip speed ratio.

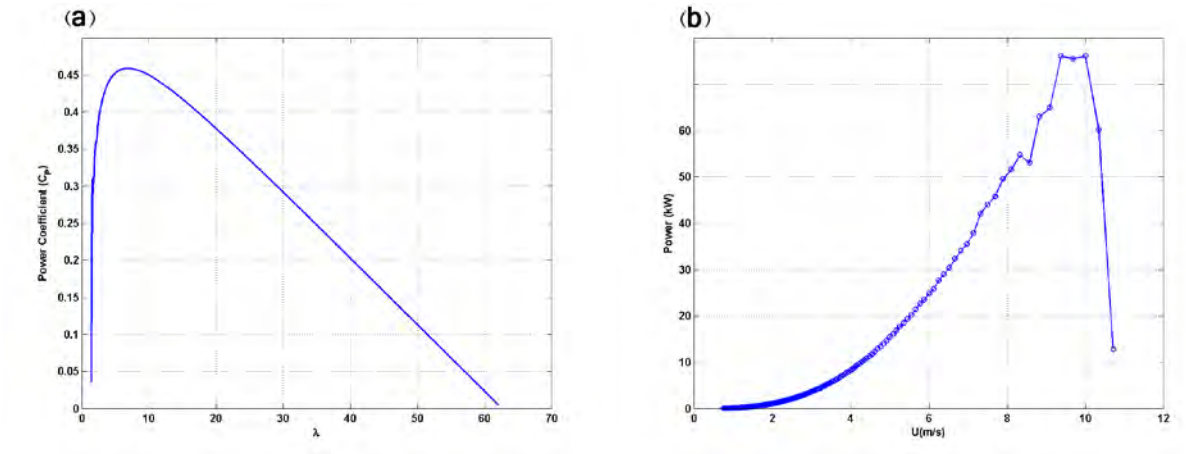

Fig. 5 (a) C_P-λ curve (b) Rotor power vs. wind speed

Fig. 5(b) illustrates the power produced by the wind turbine in various wind speeds. In order to estimate the energy captured per year by this wind turbine, $p(U)$ and $P_w(U)$ are obtained from Fig. 1(b) and Fig. 5(b) respectively and are put in the Eq. (5). So, the energy of the wind turbine per year will be 155 MWh.

6. Conclusions

In this study, a site in the coasts of Persian Gulf was evaluated for wind potential. Statistical analysis of wind data at three heights, 10m, 30m and 40m, showed that there is a promising wind potential for installing wind turbine at height of 30 and 40m. The power density per year at these two heights was 253 and 196 W/m^2, respectively. In the second part of paper, a 50kW horizontal axis wind turbine was designed for installing at 40m. The energy produced per year by this turbine was 155MWh. The wind potential in this coastal region can be utilized for both water pumping and electricity generation by small wind turbine. It might be suitable for the rural parts of Bushehr.

Abstract: In the Baltic countries interest to the renewable energy is growing. Government support and availability of large unpopulated areas on the coast makes attractive use of these lands for the placement of large wind power plants (WPP). For successful implementation of planned projects reliable information about distribution of the resource of wind energy is needed. Researches in this area are carried out by collaboration IPE with VUC. The paper presents the results of years-long observations on the density fluctuations of wind energy at heights of 10 to 60 *m* in the area in the Baltic Sea coast in the north and the south-west of Latvia. The velocity observations from 2004 till 2010 years have been obtained by measurements complex of the LOGGER 9200 Symphonie type. The results presented in the form of tables, bar charts and graphs. The graphs of seasonal fluctuations of wind speed have been obtained for the heights up to 60 *m* by measurements over the period of 2007 – 2010. The histograms have been composed for the relative frequency of repetition of wind speed. The wind speed distribution on heights up to 60 *m* was analysed and coefficients of approximating functions for the two areas with different terrain types were calculated. Extrapolation results of the distribution curves of wind velocity and density mean values on heights up to 150 *m* were shown.

1. Introduction

The availability of large unpopulated coastal areas and the developed infrastructure of electric power networks in the Baltic countries make attractive the use of these areas for siting large wind power plants (WPP). In the coastal territories of western Estonia, in the Ida-Virumaa region at the site of the former shale quarries the construction of WPPs is planned whose power will be over 600 *MW*. Further it is also planned to start offshore WPP construction. In Latvia, projects on the construction of 450 *MW* coastal WPPs have been approved; there are also projects as to the construction of a 900 *MW* wind park offshore. In Lithuania, the total power of wind parks in 2010 has made up 200 *MW*, with 1000 *MW* to be reached; after 2020 it is planned to start works in the offshore territories. In Latvia, planned preparation of the infrastructure is going on: construction of thermal power plants and of the transmission line "Kurzeme Arc" (by 2017), which would allow for construction of a ~900 *MW* WPP in the sea near Liepaja (by 2020). The governmental support is confirmed by working out administrative and legislative regulations as well as by creating a favourable tariff policy that would encourage the construction of large WPPs. At the same time, for the territory of the Baltic countries there are no databases of long-term measurements of wind speeds at different heights that can be used to compose an atlas of wind energy resource distribution in this region. The systematic long-term measurements of wind speeds in Latvia since 2007, taking into account the wind speed distribution on several levels, have been carried out in the two sites: on the south-west coast of the Baltic Sea in the Ventspils region and on the north of the country in the Ainaži region in 35 *km* from the shore [1]. The places where the metrological masts are situated are shown on the map of Fig. 1 by black stars. On the same map, by dark grey colour the regions are indicated which, according to the forecasts of meteorological observations and being territorially remote from populated areas, could be promising for siting WPPs.

Fig. 1. The coastal map of Baltic countries with the places of interest for siting WPPs indicated.

2. Research on the cyclic behaviour of wind energy fluctuations

The measurements of wind speed were carried out using certified sensors of wind speed of the NRG #40 type and sensors indicating the direction of the air stream of the NRG #200P type. The sensors are arranged on metallic masts with the height of 53 and 60 *m* above the ground. The periodicity of the information read-out from the sensors at all the height levels was 10 *s*. For storing information an NRG LOGGER Symphonie complex was employed, which has independent supply from batteries and is able to store information from nine sensors in the memory card during a year.

In the observation period a database has been built up containing the wind speed values at heights of 10, 20, 30, 40 , 50 and 60 *m*, wind temperature and direction in two regions in the Latvian territory. At the present time, the database contains more than 3'000'000 records of measurements. To compare the wind energy flow levels on the sea shore in the Ventspils region and in the area remote from the sea in the Ainaži region, in Table 1 average wind speed values, V_a, are given, with standard deviations *SD*, and the wind energy density values, P_d, W/m^2. Dark colour in the table corresponds to a larger value of wind speed or energy density for the month.

The charts of seasonal fluctuations of average wind speed *V* (*m/s*) for the measurement period *T* (*a month*) at the heights 20, 30, 40, 50 *m* in the Ventspils region and 10, 30, 50, 60 *m* in the Ainaži region are shown in Figs. 2 and 3. The results of wind speed measurements taken in the Ventspils and Ainaži regions are systematized and presented in the form of histogram in Figs. 4 and 5. The envelope of the histogram shows the wind speed *V* distribution in the relative frequency of repetition *F*, which corresponds to the relation $F = \frac{T_V}{T} \cdot 100\%$, where T_V is the total duration of wind with the speed *V* in the whole measurement period *T* for the heights 20, 30, 40, 50 *m* in the Ventspils region and 10, 30, 50, 60 *m* in the Ainaži region.

Table 1. Distribution of average wind speed values with standard deviations and corresponding power density values at the height 50 (m) in the observation period.

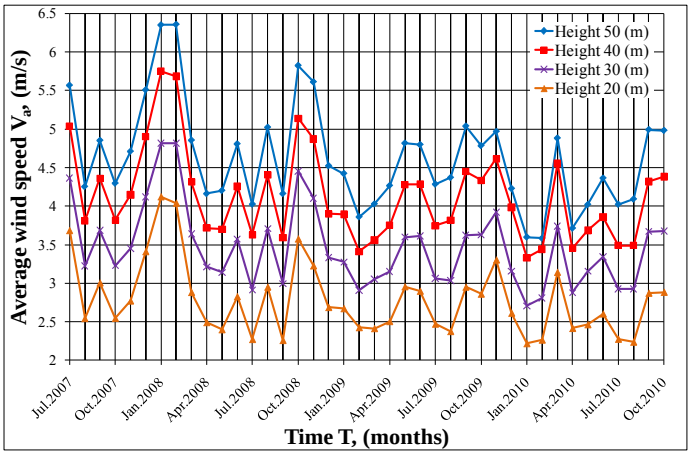

Fig. 2. Average wind speed values V_a in period T (2007/2010) at heights 10, 30, 40 and 50 (m) in the Ventspils region.

The histogram allows determination of the wind energy flow density, which is calculated by the equation:

$$P_d = \rho \frac{V_{a.c.}^3}{2} = \rho \frac{\sum_{n=0}^{n} V_n^3 F_n}{2 \cdot 100}, \qquad (1)$$

where $V_{a.c.}$ – is the average cubic wind speed, *m/s*,

$\rho = 1.23\ kg/m^3$ – is the air density at atmosphere pressure *101.325 kPa* and temperature *15° C*,

V_n – is the wind speed, *m/s*,

F_n – is the relative frequency of repetition, %, corresponding to wind speed V_n and determined by curves on the histograms of Figs. 4.

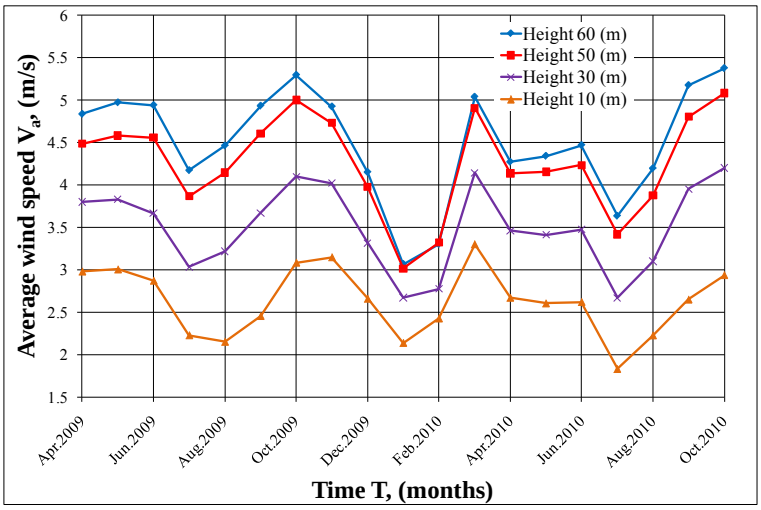

Fig.3. Average wind speed values V_a in period T (2009/2010) at heights 10, 30, 50 and 60 (m) in the Ainaži region.

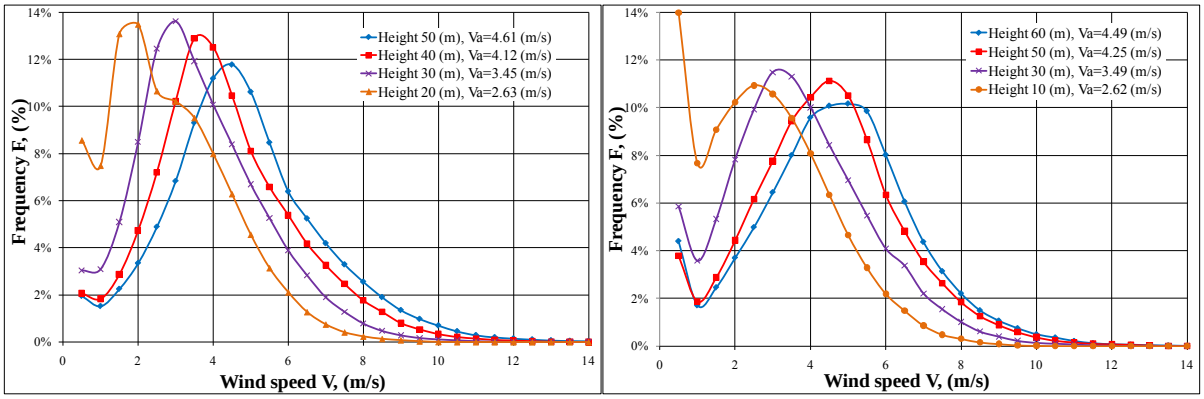

Fig. 4 (left). Distribution of wind speed in relative frequency of repetition F= f(V) at heights 10, 30, 40 and 50 (m) in the Ventspils region and Fig. 4 (right). Distribution of wind speed in relative frequency of repetition F= f(V) at heights 20, 30, 50 and 60 (m) in the Ainaži region.

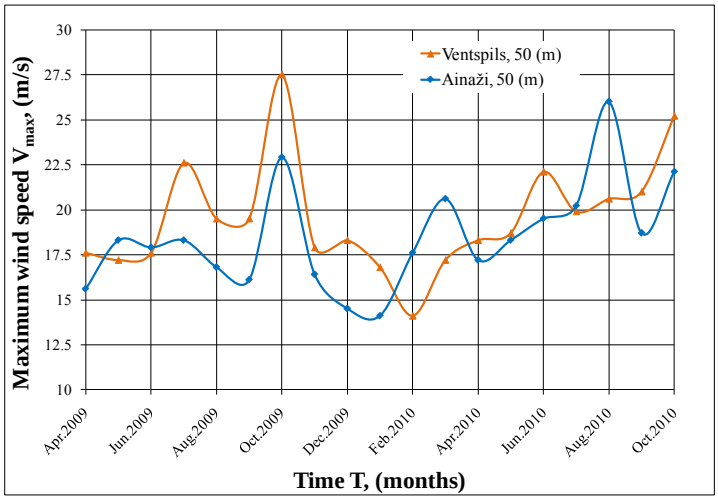

Fig.5. The maximum values of separate wind gusts, V (m/s), with duration 10 (s) in the regions Ventspils and Ainaži, at height 50 (m) above the ground level in the period of 2009/2010.

From analysis of statistical data for 2009/2010 shown in Fig. 5 it follows that in the coastal zone winds are gustier, whereas farther from shore their speeds are more uniform. The maximum value for separate wind gusts lasting not less than 10 *s* in the Ventspils region is not much higher than in Ainaži, with the situation changing in individual months. In January of 2005 the wind gusts in the Ventspils region at a height of 50 *m* reached 34.1 *m/s*.

3. Approximating functions for calculation of the wind speed and wind energy density up to 150 m

The distribution curves of the average wind speed V_a *(m/s)* in height *h (m)* above the ground level in the regions Ventspils and Ainaži obtained based on the data accumulated for a long time are presented in Fig. 6. The measured values of wind speed in the Ventspils region are shown by two curves. Curve 1 corresponds to the average wind speed values in the period of 2007/2010, curve 2 – to the average wind speed values in the period of 2009/2010, and curve *3* – to the distribution of the average wind speed in the Ainaži region in the period of 2009/2010.
Analysis of the distribution curves in Fig.6 obtained for the average wind speed V_a shows that the wind speed distribution in height up to 30 *m* is to a considerable extent determined by the topography of the terrain. In the Ventspils region it is represented by 8 - 10 *m* high tract of forest, whereas in the Ainaži region – an open plain remote from the sea. The points on the curves corresponding to the measured values of wind speed at a height over 30 *m* could be well approximated by the exponential function of the form:

$$V_a = kh^{\alpha}. \qquad (2)$$

For the curves of Fig. 7 the following values for approximating functions have been obtained:

For curve *1* – $V_a = 1.19\ h^{0.37}$, the coefficient of determination $R^2 = 0.9941$;
For curve *2* – $V_a = 1.11\ h^{0.37}$, the coefficient of determination $R^2 = 0.9937$;
For curve *3* – $V_a = 1.02\ h^{0.37}$, the coefficient of determination $R^2 = 0.9977$,

hereafter R^2 – reveals how close is modelled approximation function to actual measured values, most reliable when is at or near 1.

Fig. 7 shows curves *1, 2, 3* for measured values of the average wind speed V_a *(m/s)*, calculated using the corresponding values of approximating functions and extrapolated up to the height *h* of 150 *m*. From analysis of the distribution of the average cubic wind speed depending on the height above the surface $V_{a.c.} = f(h)$ for curves *1, 2, 3* the following coefficients and exponents have been obtained for approximating function in Eq. (2):

For curve *1* – $V_{a.c.} = 1.69\ h^{0.31}$, the coefficient of determination $R^2 = 0.9877$;
For curve *2* – $V_{a.c.} = 1.61\ h^{0.31}$, the coefficient of determination $R^2 = 0.9883$;
For curve *3* – $V_{a.c.} = 1.59\ h^{0.29}$, the coefficient of determination $R^2 = 0.9994$.

With due regard for the relationship in Eq. (1) the distribution curves for the average cubic wind speed values in height $V_{a.c.} = f(h)$ are calculated up to the height of 150 *m* and are presented in Fig. 8 (left). Correspondingly, the distribution curves for the wind energy density $P_d = f(h)$ are presented in Fig. 8 (right). For calculation of the wind energy density in the coastal area and in the regions remote from the coast by 30 - 40 *km* the following functions have been used:

For curve *1* – $P_d = 3.17\ h^{0.93}$ the coefficient of determination $R^2 = 0.9874$;
For curve *2* – $P_d = 2.64\ h^{0.94}$, the coefficient of determination $R^2 = 0.9882$;
For curve *3* – $P_d = 2.57\ h^{0.88}$, the coefficient of determination $R^2 = 0.9995$.

For flat territories typical of the Baltic countries the approximating function Eq. (2) could be reduced to the form more convenient for the use as shown in the Eq. (3) & Eq. (4):

$$V_{a.h} = V_{a.h_1}\left(\frac{h}{h_1}\right)^{\alpha}, \quad (3)$$

$$V_{a.h} = V_{a.h_1}\left(\frac{h - h_0}{h_1 - h_0}\right)^{\alpha} \quad (4)$$

where $V_{a.h}$ – is the calculated value of the average wind speed *(m/s)* at height *h*, *(m)*;

$V_{a.h_1}$– is the measured value of the average wind speed *(m/s)* at height h_1, *(m)* for a flat area;

h_0 – is the height of the surface relief at the installation point of the measuring set,

α – is the approximation coefficient (depending on the remoteness from the sea shore is 0.37 – 0.31).

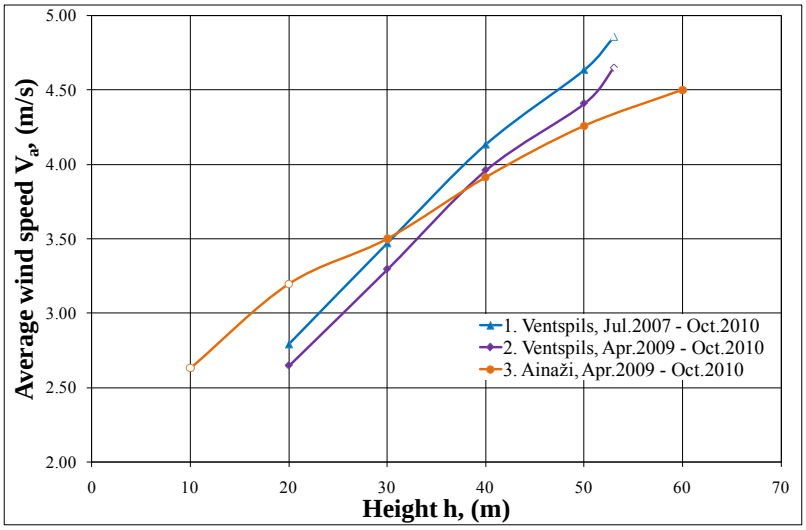

Fig. 6. The curves of the average wind speed vs. height V_a = f(h) in the Ventspils and Ainaži regions obtained by measurements.

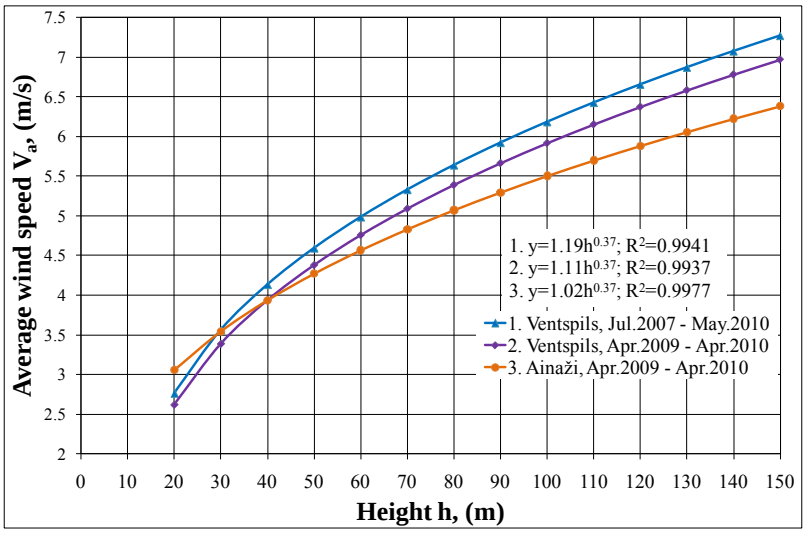

Fig. 7. The curves of the average wind speed vs. height V_a = f(h) in the Ventspils and Ainaži regions extrapolated up to the height of 150 (m).

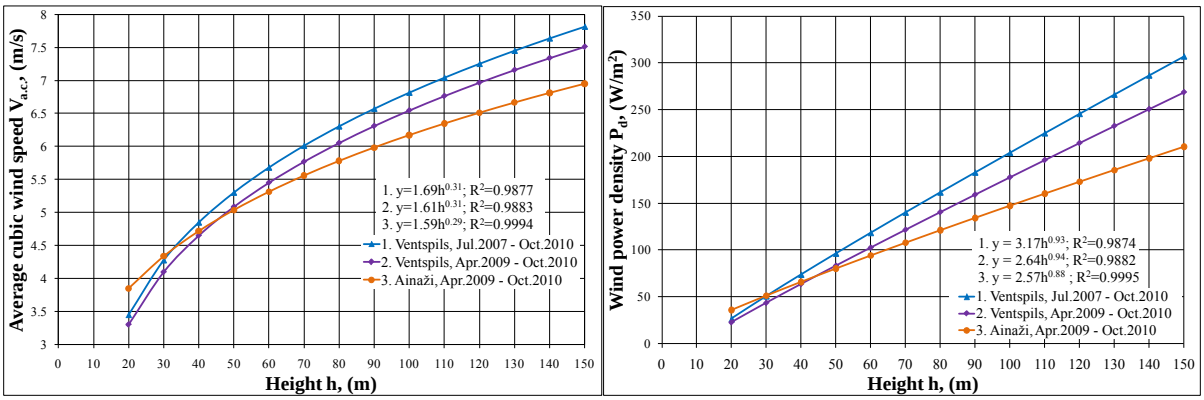

Fig. 8 (left). The curves of the average cubic wind speed vs. height $V_{a.c.}$ = f(h) in the Ventspils and Ainaži regions extrapolated up to the height of 150 (m). Fig. 8 (right). The curves of the wind energy density vs. height P_d = f(h) in the Ventspils and Ainaži regions extrapolated up to the height of 150 (m).

4. Estimation of the acoustic noise level distribution around a WPP

One of the negative aspects of WPP operation is emission of low-frequency noise that acts on humans and disturb comfortable life conditions. Calculations allow to define a zone of noise influence on environment and to determine if the planned projects are in accordance with requirements of the Law of Republic of Latvia, which establishes acceptance standards of noise level in populated areas. In compliance with the sanitary norms in Latvia the noise level accepted at the places of permanent residence of people must not exceed 40 *dB(A).* This means that the construction of WPPs in the proximity of settlements is not allowed.

Fig. 9. The map of noise level distribution around a WPP consisting of 32 generators with the total power of 80.0 (MW) in the territory 8000x5000 (m).

Figure 9 s hows the map of noise level distribution in the territory surrounding a WPP consisting of 32 generators with the total power of 80.0 *MW* in the Ainaži region. The maximum value of the noise level in the WPP territory is 50.14 *dB(A),* the noise level of a generator being 99.0 *dB(A)* [3].

5. Conclusions

1. Availability of large unpopulated areas on the coasts of the Baltic countries, along with the developed infrastructure of electric power networks, makes attractive the use of these lands for siting large wind power plants (WPPs).

2. During long-term observations a statistical database has been accumulated on the distribution of speeds and directions of winds at different heights: 10, 20, 30, 40, 50 and 60 *m* in the Ventspils and Ainaži regions on the Baltic Sea shore.

3. The graphs of seasonal fluctuations of wind speed have been obtained for the heights up to 60 *m* by measurements over the period of 2007 - 2010.

4. The histograms have been composed for the relative frequency of repetition of wind speed over the period of 2007 - 2010.

5. The values of approximating functions have been obtained allowing for the calculations of the wind speed at a height up to 150 *m* above the ground level in coastal zones of the Baltic Sea and in a territory remote from the sea by 35 *km*.

6. The wind speed measurements are noticeably affected by the terrain features, therefore to raise the precision at determination of approximating functions it is worthwhile to dispose the measuring sensors at a height over 30 *m* above the surface level.

7. During the period of observations it has been revealed that in 2009 the average yearly wind speed on the Baltic Sea shore decreased 5% with respect to 2007. To compose the atlas of the wind energy resources it is necessary to investigate the period of cyclic yearly fluctuations of the wind speed.

8. The maximum values obtained for separate wind gusts lasting not less than 10 *s* are not much higher in the Ventspils region than in Ainaži. In January 2005 the wind gusts at a height of 50 *m* in the Ventspils region reached 34.1 *m/s.*

9. In the places of WPP location the level of acoustic noise can be higher than 50.14 *dB(A),* while in compliance with the sanitary norms the noise level allowable for residential areas must not exceed 40 *dB(A).*

Abstract: Various studies investigating the future impacts of integrating high levels of renewable energy make use of historical meteorological (met) station data to produce estimates of future generation. Hourly means of 10m horizontal wind are extrapolated to a standard turbine hub height using the wind profile power or log law and used to simulate the hypothetical power output of a turbine at that location; repeating this procedure using many viable locations can produce a picture of future electricity generation. However, the estimate of hub height wind speed is dependent on the choice of the wind shear exponent α or the roughness length z_0, and requires a number of simplifying assumptions. This paper investigates the sensitivity of this estimation on generation output using a case study of a met station in West Freugh, Scotland. The results show that the choice of wind shear exponent is a particularly sensitive parameter which can lead to significant variation of estimated hub height wind speed and hence estimated future generation potential of a region.

Keywords: *Wind shear exponent, Wind profile, Renewable energy, Variability, Intermittency*

Nomenclature

α	*wind shear coefficient*..... *dimless*	k	*von Karman constant*.....*dimless*
u_1	*horizontal velocity component at* z_1 .....ms^{-1}	z_0	*surface roughness factor*.....*m*

u_*	*friction velocity*.....ms^{-1}	z_2	*vertical measurement height 2* .....*m*

1. Introduction

Various influential studies investigating the impacts of the variability of renewable resources begin with meteorological (met) station data, as this is often readily available over a wide geographic area [1-3]. Alternative studies instead rely on statistical methods, e.g. [4], have direct access to wind farm generation data, e.g. [5], or take a black box approach and consider the impact of wind at a system level, based upon industry forecasts and policy targets, e.g. [6].

A typical weather station will log hourly mean horizontal wind and gust speeds at a standard height of 10m, which may be extrapolated to estimate the wind speed at a standard wind turbine height. By applying a wind turbine power curve, the wind speed can be converted into a hypothetical generation output, and repeating this process to a greater number of turbines and to a wider geographical area can give insight into how a future involving a high penetration of renewable energy may look.

Two common analytical models are used to map the wind velocity profile with height, and hence allow the calculation of horizontal wind speed at a certain elevation over the earth's surface: the log law and the power law [7]. In reality, the complex and dynamic nature of the atmospheric boundary layer means that one single profile will not provide a consistently reliable extrapolation of wind speed from one height to another. The variables in the log and power laws therefore are particularly important to consider when performing the kind of future resource study suggested above. This paper investigates precisely this sensitivity by

carrying out a resource analysis of hourly mean wind data for a met station in West Freugh, Scotland, in the same manner that other influential resource studies [1-3] have used.

First, the relevant background literature and the methodology used in this research are presented, with particular focus given to the assumptions made in the analysis. The findings of the research are then discussed, the implications identified, and avenues for future research are highlighted.

2. Background literature

There are two main analytical models used to extrapolate wind speeds to greater heights: the log law and the power law. In general, the two models have been shown to perform equivalently in shear extrapolation predictions on average, although at any particular site one model may be better than another [8]. However, for either approach, large errors in the predictions are common and this error is exacerbated further when energy production is estimated. This section introduces the theory and assumptions behind these two approaches, and indicates some of the previous work into better understanding and applying them.

2.1. The Logarithmic Law

The log law's origins lie in boundary layer fluid mechanics and atmospheric research [7]. For determining the horizontal velocity u at a height z is commonly expressed

$$u(z) = \left(\frac{u_*}{k}\right)\ln\left(\frac{z}{z_0}\right) \tag{1}$$

Where u_* is the friction velocity, k is the von Karman constant and z_0 is a measure of surface roughness known as the roughness length; u_* and k are generally determined from a graph of experimental data [9].

There are cases where wind velocity u_1 is known at a reference height z_1, and required at another z_2, in which case it can be derived from equation 1 that

$$u_2 = u_1 \frac{\ln(z_2) - \ln(z_1)}{\ln(z_1) - \ln(z_0)} \tag{2}$$

This is a simpler expression to solve, as it eliminates the need to calculate the friction velocity and von Karman constant, which can be difficult to estimate in the atmosphere. A neutral wind profile is assumed [9], where convection is negligible, the lapse rate (the fall of temperature in the troposphere with height) is nearly adiabatic and stratification is nearly hydrostatically neutral (i.e. there is no *vertical* wind flow in the atmosphere without excitation).

Seasonal variations in local terrain characteristics can have a profound influence the on estimation of z_0 (due to changes in foliation, vegetation, snow cover etc.). Table 1 extracts some guideline roughness lengths for different types of terrain as given in the European Wind Atlas [10].

Table 1- Typical Surface Roughness Lengths z_0

Terrain	z_0 (m)
Water areas (lakes, fjords, open sea)	0.0001
Airport runway areas	0.01
Airport areas with buildings and trees	0.02
Farmland with very few buildings and trees	0.03
Farmland with closed appearance	0.10
City	1.00

2.2. The Power Law

The power law [9] is an empirical equation, expressed

$$u_2 = u_1\left(\frac{z_2}{z_1}\right)^{\alpha} \tag{3}$$

Where α is the wind shear coefficient or power exponent, an empirically derived constant applied over the height range that the power law is applied. Calculating the wind shear coefficient becomes trivial if the wind speeds at two heights are known, as equation 3 may be rearranged in terms of α

$$\alpha = \frac{\ln(u_2) - \ln(u_1)}{\ln(z_2) - \ln(z_1)} \tag{4}$$

The exponent α is a dynamic value that is dependent upon the stability of the atmosphere. The wind shear exponent may be taken as constant for a given height in a given height range, but a different α should be chosen depending on the height range over which the power law is applied [9]. For neutral stability conditions, α is approximately 1/7, or 0.143 (this rule of thumb is known as the "1/7^{ths} power law"), regarded as a reasonable but conservative estimate [11]. However, various site specific studies have found that the coefficient is actually greater, and that this leads to underestimation of the energy resource available [12-14].

2.3. Usage of the two laws

Each method requires knowledge of a wind speed at a reference height, and one further coefficient: a roughness length z_0 in the case of the log law and a wind shear coefficient α in the case of the power law. Both may be calculated using on site measurements, but the power law is common engineering practice [15] favoured by the wind industry and consultants, as the wind shear coefficient is a dynamic value that varies according to a large number of factors including time of day, season, atmospheric stability and regional topography [11]. The log law on the other hand is only valid under certain assumptions regarding atmospheric stability, and actual profiles may deviate from the log law. In the wind industry the two methods are generally checked where possible to ensure that they provide similar results [15].

Unlike wind developers, many researchers do not have the resources to conduct field investigations (for example, by erecting weather masts) to determine the horizontal wind characteristics at likely development sites, and instead rely upon available 10m met station data and shear profile extrapolation for their models, often over a large height range and assuming one constant annual value.

3. Methodology

Meteorological data for this study was obtained from the British Atmospheric Data Centre MIDAS database for a station located at West Freugh airfield, Scotland. A wider number of sites were considered, but this site was chosen because it provided a reliable and continuous data set. Five years (2005-2009) of Hourly Climate Messages (HCM) were chosen over Synoptic (SYNOP) data for analysis, as the latter relies on a 10min wind sample to produce an hourly average. HCM readings sample continuously to produce an hourly average mean wind at a standard height of 10m. The readings were recorded to the nearest knot, but converted to SI units for analysis.

The literature identified that the log and power law extrapolations were each dependent on a single parameter: the surface roughness z_0 and the wind shear coefficient α respectively. Four surface roughness lengths were selected for analysis using Table 1, based upon an understanding of the site topography (i.e. an airfield with building and trees being the best description, and hence the starting point) and similarly, a range of four shear coefficients were also selected, using the $1/7^{th}$ power law as a starting point. Both sets of parameters were selected to represent a realistic spread of values that an analyst might take for the site [15].

A Vestas V80 2MW wind turbine power curve was used for calculation of generation output, with an assumed hub height of 60m. The generation outputs were calculated each year for each of the extrapolated profiles of 10m wind speed, producing an apparent indication of the site's annual capacity factor, energy production, zero generation hours and the proportion of time when a hypothetical turbine would be producing no power output.

4. Results

Annual capacity factors, based upon wind speed extrapolation to 60m, are shown in Figure 1, with all other results summarised in Table 2. A sample week (from June 2005) has been extracted from the analysis and used to illustrate the change in estimated 60m wind speed and generation outputs under each law; this is shown in Figure 2.

Figure 3 maps the profile of wind speed with height from a starting height of z_1=10m, using the log and power law with the variables specified in the methodology. A typical wind speed of u_1=5ms^{-1} was a chosen to illustrate this behaviour. The extrapolated wind speeds at z=60m are emphasised for discussion, as this was the height of interest in this study.

Table 2 - Summary of mean values attained under log and power law

5 year average	power law (α)				log law (z_0)			
	0.100	0.143	0.200	0.300	0.010	0.020	0.030	0.100
Capacity Factor	0.266	0.307	0.364	0.463	0.293	0.306	0.314	0.348
Zero prod hrs	1777	1779	1785	1468	1778	1779	1779	1782
% non gen time	20.4%	20.4%	20.5%	16.9%	20.4%	20.4%	20.4%	20.5%
Total GWh	4.623	5.348	6.344	8.057	5.105	5.320	5.470	6.053

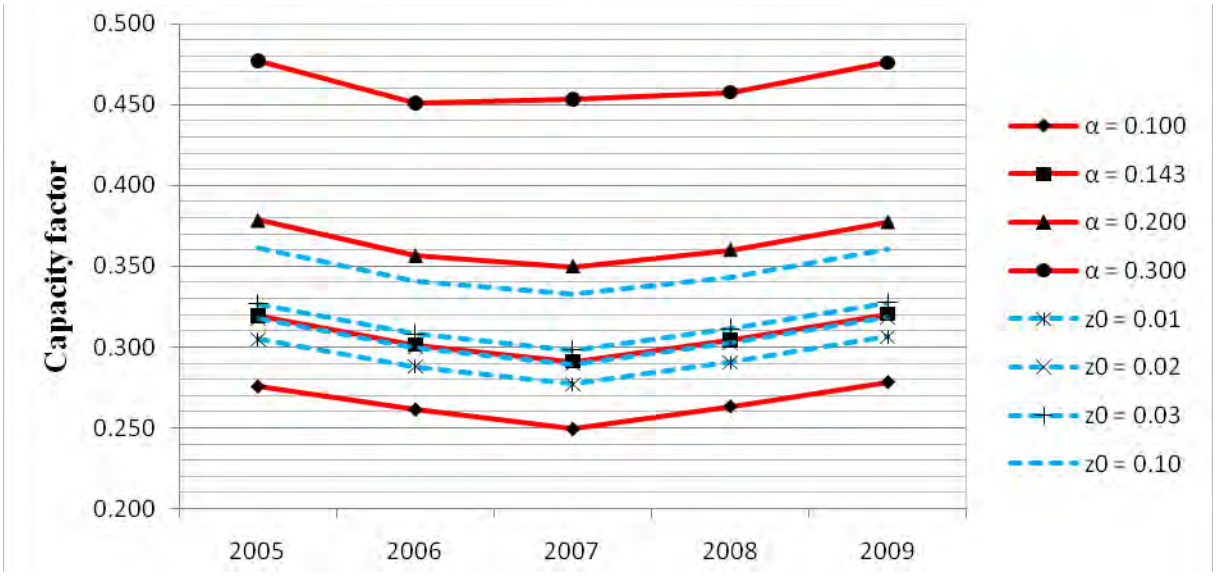

Figure 1 - Graph of extrapolated annual capacity factors

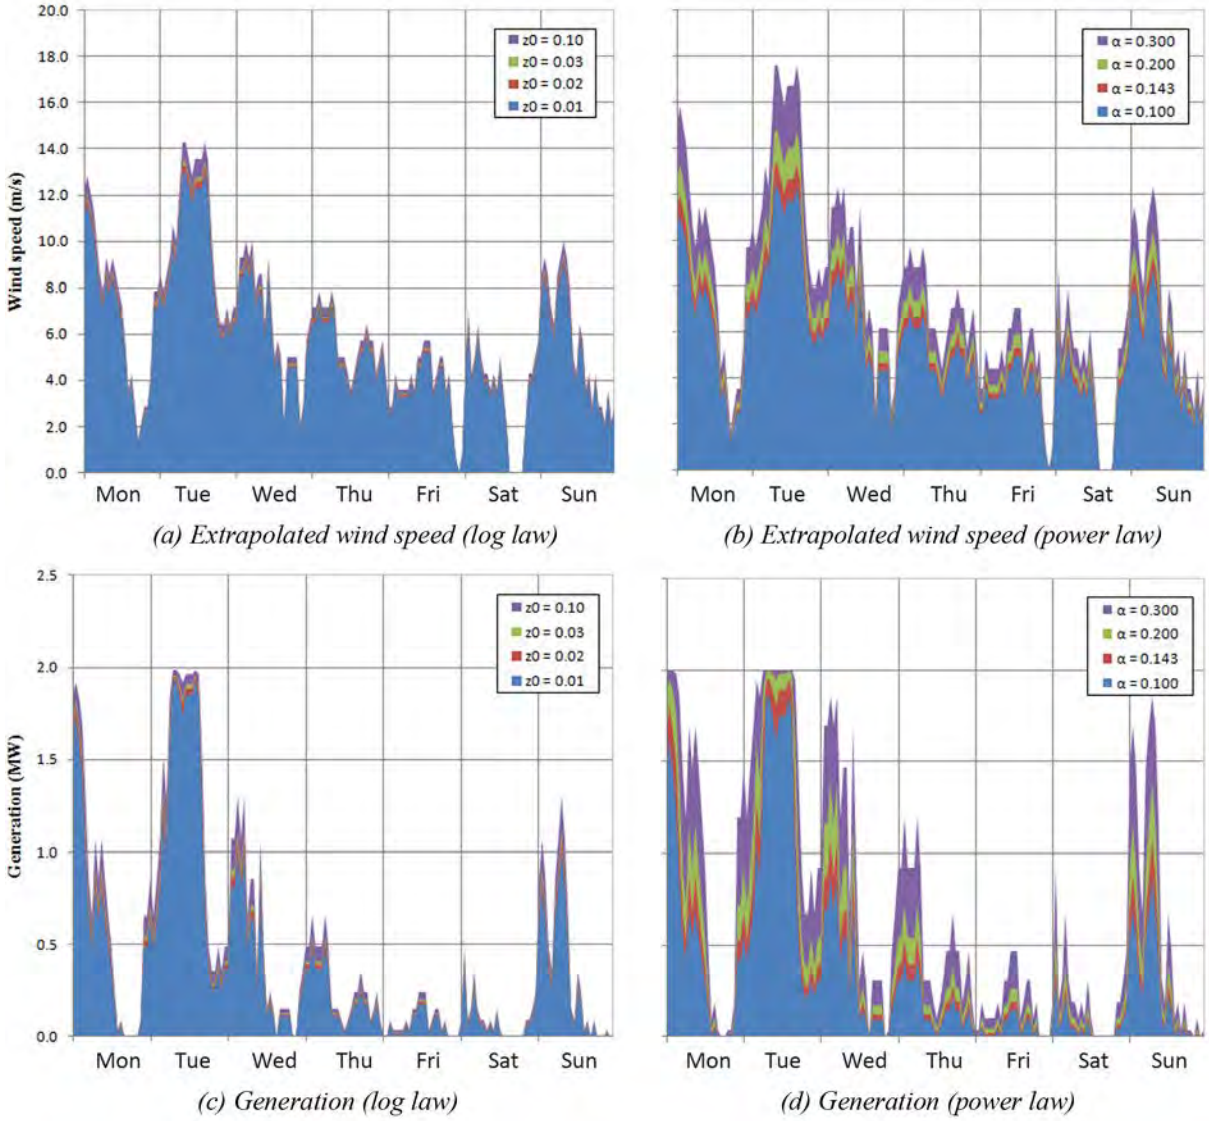

Figure 2 - Sample week of wind extrapolation and estimated generation using the log and power law

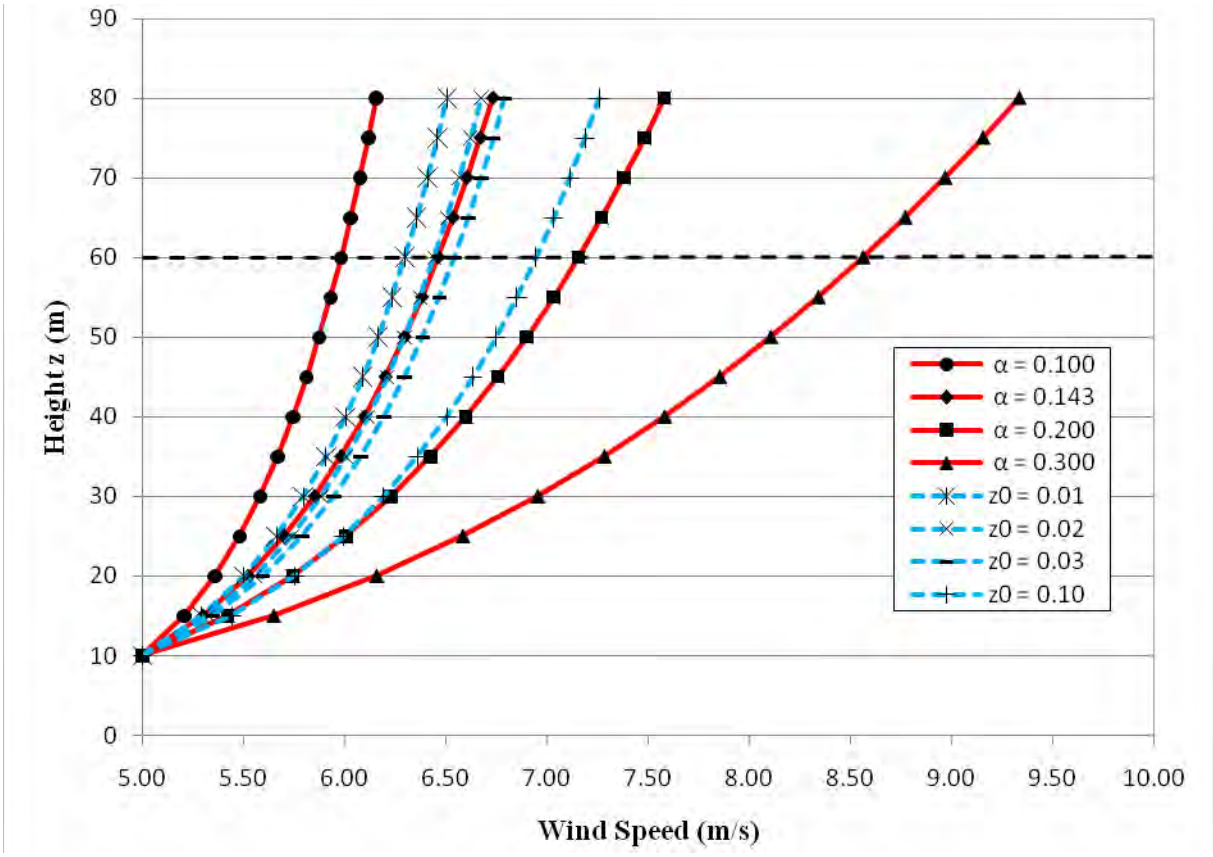

Figure 3- Graph illustrating the wind shear profiles under various log and power law parameters

5. Discussion

It is clear that the base case parameter choices (z_0 = 0.02m and α = 0.143) follow a near identical profile (Figure 3), and hence produce very similar capacity factor estimates and total amounts of energy annually (Table 2). T his is to be expected, as both represent neutral stability conditions. The parameter values in this study were selected to represent the realistic values an analyst might take for the West Freugh site, as discussed earlier in the methodology. Through these choices a wider range of surface roughnesses than shear coefficients were applied (a percentage change of 1000% in z_0 and 300% in α respectively, from the lowest to highest values). Regardless of this disparity, which would be expected to favour a tighter knit set of results for the power law, Figure 3 shows that the range of extrapolated wind speeds at 60m was in fact considerably larger for the power law than the log law (0.65ms^{-1} and 2.58ms^{-1} respectively). This trend is also clearly observed in Figure 2(a) and (b); in the former, the wind speeds for each series are banded close together, in the latter they are considerably more widespread.

Figure 2 also very clearly illustrates the variable nature of the wind resource and the importance that it has on the output of a wind turbine. The sensitivity of the power output is pronounced for different shear coefficients, though relatively similar generation profiles are produced for the range of surface roughnesses, as shown in Figure 2(c) and (d). This is similarly observed in the clustered nature of the log law annual capacity factors in Figure 1, compared to a considerably wider range for the power law.

The reason for the pronounced difference in generation outputs, observed particularly strongly using the power law, is that wind turbine power is related to the cube of wind speed, so a

difference in the wind speed error becomes far more significant in a generation calculation. This is best illustrated with an example; the mean 60m wind speed calculated for West Freugh in 2005, using $\alpha = 0.100$ and $\alpha = 0.200$, together with the limits of one standard deviation, is overlain onto a Vestas V80 power curve in Figure 4. As the cumulative energy generated is calculated by integrating under the area of the curve, it is clearly illustrated how a small change in mean wind speed estimate equates to a significantly larger area under the curve, and hence a large change in total generated energy.

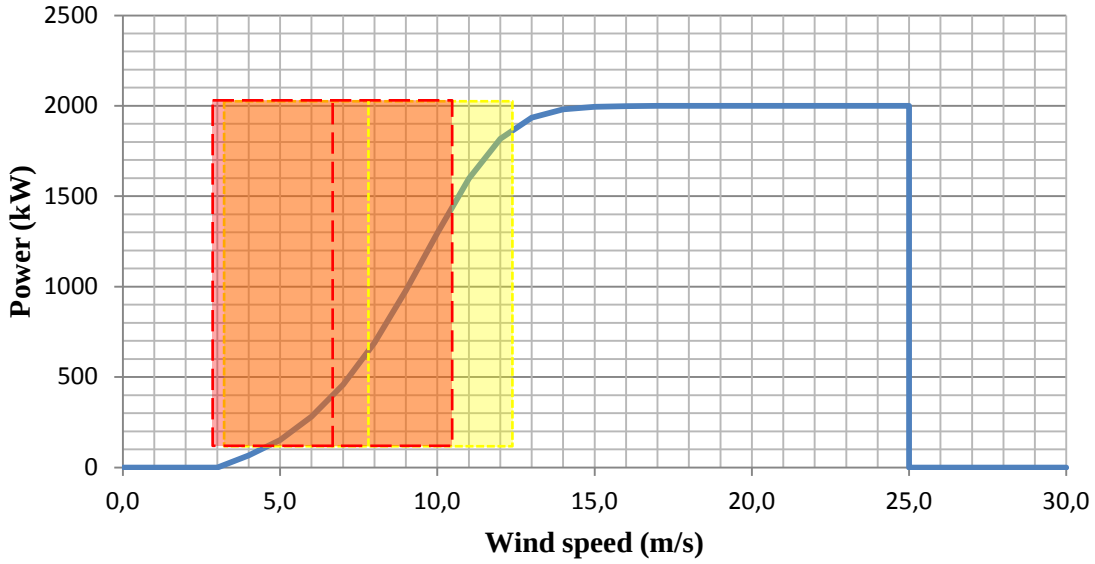

Figure 4- Vestas V80 power curve, annotated. The long red dashes indicate the mean wind and range of one standard deviation for α=0.100, and the short yellow dashes for α=0.200.

6. Conclusions

It is clear from the results that the wind shear coefficient is a more sensitive parameter than surface roughness, and that an equivalent percentage change to each value will impact the wind speed and generation estimates more robustly than when using the log law. However, if properly used, the power law can provide a more accurate idea of the renewable energy output of a particular site or area than the log law, which requires neutral stability conditions to be scientifically exact.

This study is not suggesting that either the power or log laws are intrinsically good or bad, but rather highlights the importance of the quality of information that goes into a model. It is important that there is a good understanding of the site before attempting to apply a single parameter to characterise the system, particularly as in reality the wind shear coefficient is a dynamic value dependant on a large number of parameters.

In order to understand the accuracy of using a single wind shear for the power law model, it is important to compare this theoretical generation data to the output for a real wind farm. Without this information, a critical analysis of this type of approach to future resource estimate cannot be made. Another interesting topic for future research will be to look into how different wind turbine designs, with different power curve characteristics, may change the energy yield of a site. Both of these are aspects of research that the authors intend to investigate in future studies.

Abstract: Generating energy with clean and renewable sources of energy has become imperative due to the present days' energy crisis and growing environmental consciousness. The objective of the present study is to assess the wind power, wind shear exponent, air turbulence intensity, energy yield, plant capacity factor and effect of hub height on energy yield and PCF for the site under consideration. To achieve the set objectives, wind speed measurements at different height made during the evaluation period were utilized. The site under consideration was found to be feasible for developing grid connected wind farms in the area with annual energy yield of 11.75GWh with plant capacity factor of 48.8% from one wind turbine of 2.75MW rated power with a hub height of 100m from Vestas.

Keywords: *Wind Energy, Saudi Arabia, Plant Capacity Factor, Wind Speed, Weibull Parameters, Wind Shear, Wind Turbulence*

1. Introduction

The adverse effect of climate change such as tsunami, floods, forest fires, have become common in the recent years due to alarmingly increasing pollution levels and increasing global population and thereof increasing power demands. Each megawatt of electricity generated using fossil fuel adds around half a ton of green house gases equivalent CO_2 in to the atmosphere. The accumulating effect of fast depletion of fossil fuels, alarmingly rising environmental pollution levels, and at the same time gradually emerging awareness of environmental degradation has given rise to the use of renewable sources of energy such as wind, solar, small and large hydro, geothermal, tidal, and bio-energy. Of these clean sources, the rapid development in wind energy conversion technology has made it an alternative to conventional energy systems in recent years. Wind energy is the fastest growing source of energy and is getting worldwide attention due to the technological advances for harnessing the wind power and its competitive cost of production compared to other traditional means. In order to conserve the conventional energy resources and to address the environmental problems, the wind power utilization is the answer to these problems. The worldwide wind power installed capacity is increasing rapidly due to new projects being commissioned in different parts of the world. United States of America (USA) is leading the world with regard to global wind power installed capacity. The other countries contributing towards wind power sectors are Germany, Spain, Denmark, India, China, United Kingdom, Egypt, and others.

Various wind speed and wind power characteristics studies have been reported in and around the Middle East region. Some of these studies include Marafia and Ashour [1] for offshore/onshore wind power project development in Qatar; El-Osta and Kalifa [2] for a proposed 6 MW wind farm in Zwara, Libya; Al-Nassar et. al. [3] showed that the annual mean wind speed in Kuwait lied in the range of 3.7 to 5.5 m/s with mean; Hrashyat [4] reported wind resource assessment of the south western region of Jordan; Elamouri and Amar [5] for Tunisia; Ucar and Balo [6] for Manisa, Turkey; Bagiorgas et. al [7] for Western Greece; Shahta and Hanitsch [8] studied the technical and economic assessment of wind power for Hurghada in Egypt; Toğrul and Kizi [9] for Bishkek, Kyrgyzstan; Jowder [10] reported wind resource assessment for Bahrain; and Himri et. al [11] provided review of

renewable energy in general and the wind in particular for Algeria. Sahin and Bilgili [12] studied the wind characteristics of Belen-Hatay province of Turkey using hourly wind speed records between years 2004 and 2005.

The work on wind resource assessment in Saudi Arabia dates back to 1986, when Ansari et. al [13] used hourly wind speed data to develop a Wind Atlas for Saudi Arabia. In Saudi Arabia, work on wind speed data analysis such as Weibull parameter determination and distribution, wind speed prediction using different methods such as auto-regression and neural network, wind power generation cost determination, and so on has been reported in the literature. Rehman et. al. [14] presented the Weibull parameters for ten anemometer locations in Saudi Arabia and found that the wind speed was well represented by Weibull distribution function. Rehman and Halawani [15] presented the statistical characteristics of wind speed and diurnal variation. The autocorrelation coefficients were found to be matching with the actual diurnal variation of the hourly mean wind speed for most of the locations used in the study. Some of the other studies include Rehman et. al [16], Rehman and Aftab [17] and Rehman et. al [18].

The objective of the present study is to assess the wind power, wind shear exponent, air turbulence intensity, energy yield, plant capacity factor and effect of hub height on energy yield and PCF for the site under consideration.

2. Site, equipment and Data Description

The 40 meter tall tower was installed at Juaymah power plant, a site located in the eastern part of Saudi Arabia. The latitude, longitude and altitude of the measurements site were 26°47' N, 49˚53' E and near sea level, respectively. The data was collected for a period of 33 months stretching from July 01 2006 to April 01, 2009. The area is surrounded by government and private industries and power plants which are connected to the national electric grid. In order to assess the wind potential at the site, an instrumented 40 m tall wind tower, was installed. The meteorological data (wind speeds, wind direction, air temperature, relative humidity, surface station pressure, global solar radiation) were collected for a period of more than two years. The details of the equipment installed at the site are provided in Table 1.

Table 1. Details of the equipment installed at an isolated village.

Item Description	**Technical Information**
Wind speed sensor, NRG#40 Three cup anemometer	AC sine wave, Accuracy: 0.1 m/s, Range: 1-96 m/s Output: 0-125 HZ, Threshold: 0.78 m/s
Wind direction vane, NRG#200P Potentiometer	Accuracy: 1%, Range: 360^o Mechanical, Output: 0-Exc. Voltage, Threshold: 1 m/s, Dead band: Max - 8^o and Typical 4^o
Temperature sensor #110S Integrated circuit	Accuracy: ±1.1 ^{o}C, Range: -40 ^{o}C to 52.5 ^{o}C, Output: 0 – 2.5 volts DC, Operating temperature range: -40 ^{o}C to 52.5 ^{o}C
Barometric pressure sensor BP20	Accuracy: ±15 mb, Range: 150 – 1150 mb, Output: Linear voltage
Relative humidity sensor RH-5 Polymer resistor	Accuracy: ±5%, Range: 0 – 95 % Output: 0 – 5 volts, Operating temperature range: -40 ^{o}C to 54 ^{o}C
Pyranometer Li-Cor #LI-200SA Global solar radiation	Accuracy: 1%, Range: 0 – 3000 W/m^2 , Output: Voltage DC, Operating temperature range: -40 ^{o}C to 65 ^{o}C

3. Results and Discussion

This section provides detailed wind data analysis including calculation of site wind exponent and air turbulent intensity, wind energy yield and cost of energy. Over entire period of data collection the mean wind speeds at 10, 20, 30 and 40 meters AGL were 4.14, 4.84, 5.34 and 5.65 m/s respectively. The climatic parameters like average ambient temperature, relative humidity, barometric pressure, air density, wind shear exponent, roughness, and roughness class were 26.1°C, 17.3%, 1014 mbar, 1.181 kg/m3, 0.228, 0.239, 2.72, respectively.

3.1. Annual, seasonal and diurnal behavior of mean wind speed

The annual mean wind speeds build up a confidence on the amount of energy that could be generated and also provide future trends. In present case, the annual mean wind at 10, 20, 30 and 40 meters above ground level (AGL) were 4.1, 4.8, 5.3 and 5.6m/s, respectively, in the year 2007 and 4.2, 4.9, 5.4 and 5.8m/s, in the year 2008. This shows an increased of about 2% in wind speed in the year 2008 compared to that in 2007. The maximum wind speeds observed during these two years at 10, 20, 30 and 40 meters AGL were 15.9m/s, 17.8m/s, 18.4m/s and 19.5m/s, respectively. The prevailing wind direction was found to be NNW and NW during the data collection period.

Knowledge of monthly variation of wind speed provides confidence on the availability of energy in different months of the year. Monthly changes in wind speed at 10meters AGL, over entire data collection period, are shown in Fig. 2. Highest wind speed was observed in June while lowest in August at all the heights of wind speed measurements. At 40m AGL, the monthly mean wind speed always remained above 5.5m/s except during August to October, which means that a wind turbine with cut-in-speed of 3.5m/s can produce energy during all the months of the year at this site.

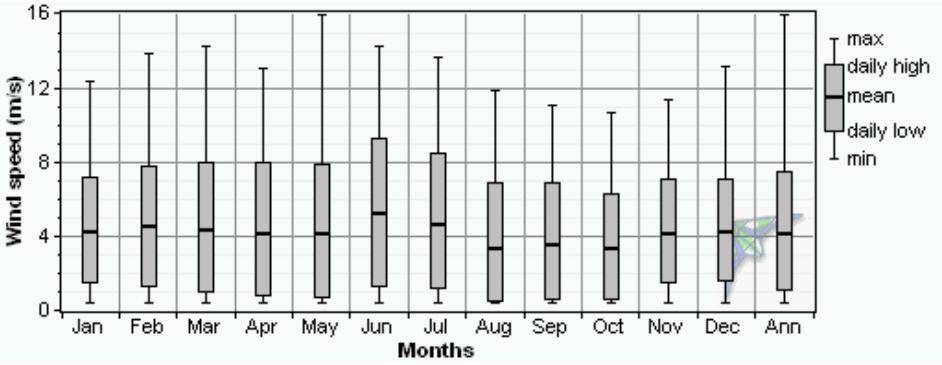

Fig. *1. Seasonal variation of mean wind speed at 10 meters AGL.*

Fig. 3 shows the variation of half hourly mean wind speed at different heights during entire data collection period. It is evident from this figure that as the height of wind measurements increases the wind speed range decreases. At 40m AGL, the half hourly mean wind speed varied from 4.7m/s to 7.0m/s (range=2.3m/s) while at 20m from 3.7m/s to 6.7m/s (range=3.0m/s). At 40m AGL, the wind speed was found above 5.2m/s for most of the time except between 8 P.M. and 12 mid night. This implies that power of the wind can be harnessed during entire day at the measurement site using a wind turbine with cut-in-speed of 3.5m/s and hub height greater than or equal to 40m.

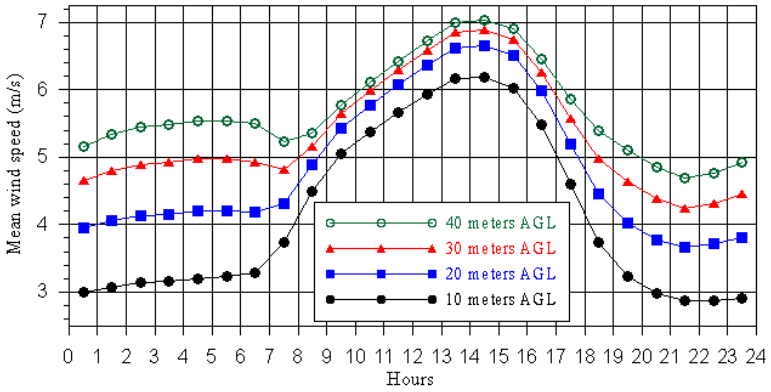

Fig. 2. Diurnal variation of hourly mean wind speed at Juaymah.

3.2. Wiebull parameters and wind frequency analysis

Wiebull distribution function is most widely used function for modeling the wind speed around the globe. The scale factor (c) of the Weibull distribution is related to the average wind speed at different heights and is calculated using the maximum likelihood method. Similarly, the Weibull (k) value is the dimensionless shape factor of the Weibull distribution. This factor reflects the breadth of the distribution. The variation of both scale and shape parameters with measurement heights is shown in Figs. 3 and 4 respectively. Since the wind speed increases with height, hence the scale parameter too follow the trend as can be seen from Fig. 3. The shape parameter also increases with height as shown in Fig. 4. This implies that as height increases, the shape of the distribution tends to be tight which implies less variation in the wind speed. The line of best fit show high values of coefficient of determination (~95%), as given in these figures. The scale parameter increases by about 0.058m/s for each meter increase in measurement height while the shape parameter increases by 0.0157 per meter.

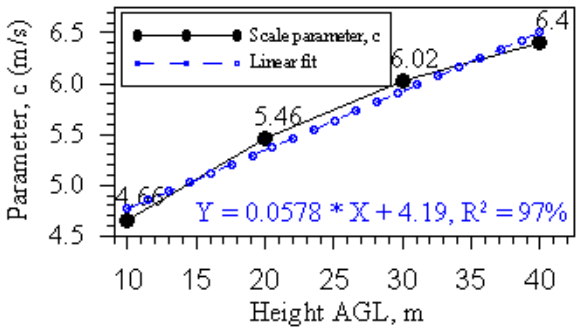

Fig. 3. Variation of scale parameter, c, with measurement height.

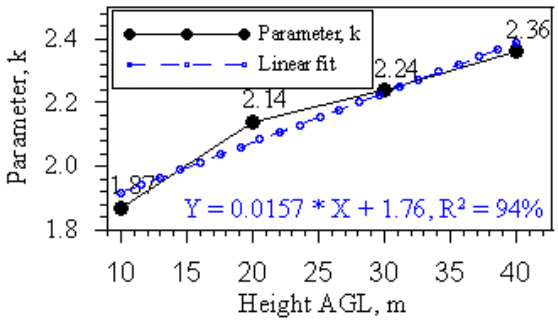

Fig. 4. Variation of shape parameter, k, with measurement height.

Wind speed frequency distribution in different wind speed bins is a very important parameter from energy yield estimation point of view. As the height of wind speed measurement increase, the percent frequency of occurrence of higher winds also increases, as shown in Figures 5(a) and 5(b) at 10 and 40meters AGL. The percent frequencies of 55%, 71%, 78% and 82% at 10, 20, 30 and 40 meters AGL, respectively, were found above 3.5 m/s. An increase of 10 meters in height (from 10 to 20 meters) of the wind speed measurements resulted in an increase of about 16% in the availability of wind speed above 3.5m/s while further increase of 10m in height results only 7% increase in frequency. This analysis confirms that a wind turbine with cut-in-speed of 3.5m/s or more could produce energy for 82% of time at the site of measurements. It is very evident from Figs. 5(a) and 5(b) that as the height increases, the Weibull function fit becomes increasingly better and the wind speed fluctuation also becomes less and less due to decrease in wind turbulence at higher altitudes.

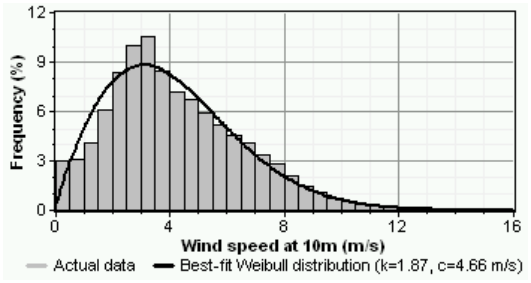

Fig. 5(a). Wiebull fit and frequency distribution of wind speed at 10 meters AGL.

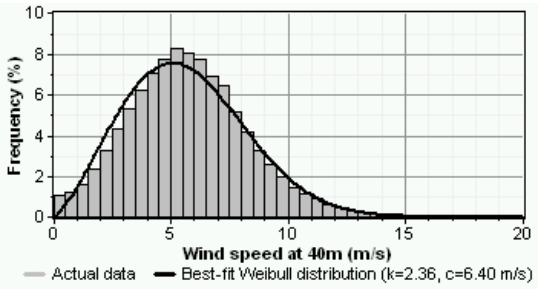

Fig. 5(b). Wiebull fit and frequency distribution of wind speed at 40 meters AGL.

3.3. *Air density and wind power density variation*

In this study, the measured values of air pressure and the temperature were used to calculate the local air density values at Juaymah measurement site. During diurnal cycle, the air density was found to vary between a minimum of 1.159 kg/m^3 during 13:00-14:00 hours and a maximum of 1.201 kg/m^3 during 04:00-05-00 hours. Higher values were noticed during nighttime and lower during day time due to corresponding lower and higher temperatures and air pressure. Around the year, highest mean air density of 1.236 kg/m^3 was obtained in the month of January which characterized by low temperature and relatively high air pressure. On the other hand, lowest air density of 1.136 kg/m3 was recorded in the month of July which is known for high temperature and relatively low air pressure. The mean wind power density values calculated using the local air density and the cube of wind speed during the data collection period at 10, 20, 30 and 40m AGL were 84.7, 119.1, 154.2 and 180.32 W/m^2, respectively. An increase of about 12% was noticed in wind power density in the year 2008 compared to that in 2007 at all measurement heights. The seasonal trends of wind power density values at different heights are depicted in Fig. 6 which indicative of highest values in June and lowest in October.

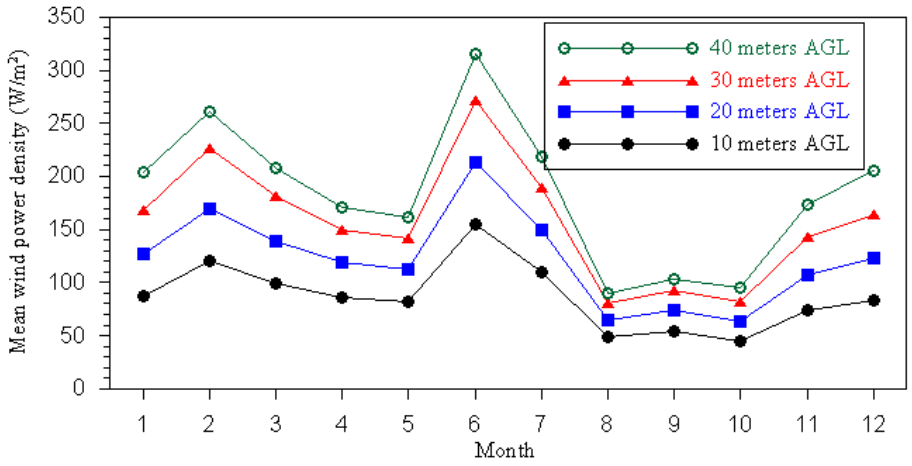

Fig. 6. Seasonal variation of wind power density at different measurement heights.

3.4. Wind shear exponent and turbulence analysis

The power law exponent is a number that characterizes the wind shear, which is the change in wind speed with height above ground. The wind shear exponent (WSE) obtained using all the data values was 0.273 while 0.269 and 0.279 for the data of years 2007 a nd 2008, respectively. Higher values of WSE (~0.285) were observed from October to January and relatively lower (~0.265) during rest of the months with lowest in September. The WSE values are very much dependent on the meteorological changes that take place during 24 hours of day as demonstrated in Fig. 7. It is clear from this figure that higher values of WSE (~0.4) were observed from 7 PM to 7AM and lower (~0.1) from 8:30 AM to 4:30 PM. For precise estimation of wind speed at higher altitudes, different values of WSE during day and

nighttime could be used. The overall surface roughness was estimated as 1.124 m with highest of 1.386 m in October and lowest 0.995 m in June.

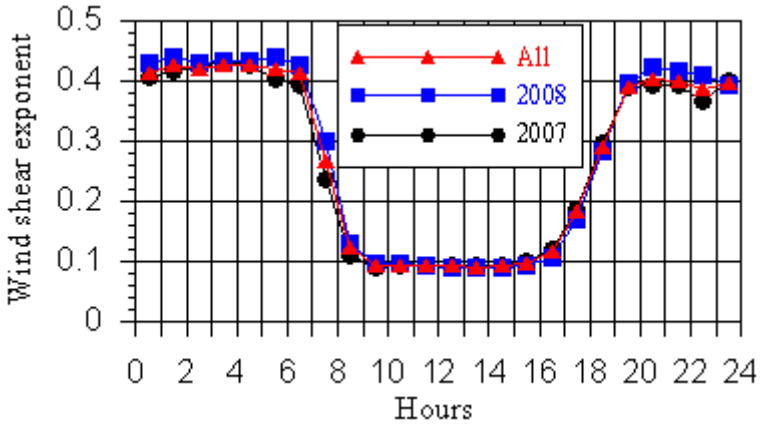

Fig. 7. Diurnal variation of wind shear exponent at Juaymah.

Wind turbulence intensity is critical parameter and dictates the durability or the operational life of the wind turbines. It is highly site dependent and should be well understood before any real time installation. According to International Electrotechnical Commission (IEC, IEC Standard 61400-1) there are standard category A and B values of the turbulence intensities. Any value between these two or below is said to be safe for the normal operation of the wind turbine. The characteristic turbulence intensity, which is another important parameter, is defined as the sum of mean turbulence intensity and the standard deviation of mean turbulence intensity in a wind speed bin. The overall mean turbulence intensity values over entire period of data collection were 0.172, 0.142, 0.127 and 0.122 at 10, 20, 30 and 40m AGL, respectively. The mean turbulence intensity decreases with increasing height AGL as the near ground turbulence effects minimize with height. The mean turbulence intensity along with IEC and characteristic turbulence values is given in Fig. 8. It is evident from this figure that the mean turbulence intensity at the site of measurements is much below even the category C of IEC limits and hence will be safe for normal operating life of the turbines.

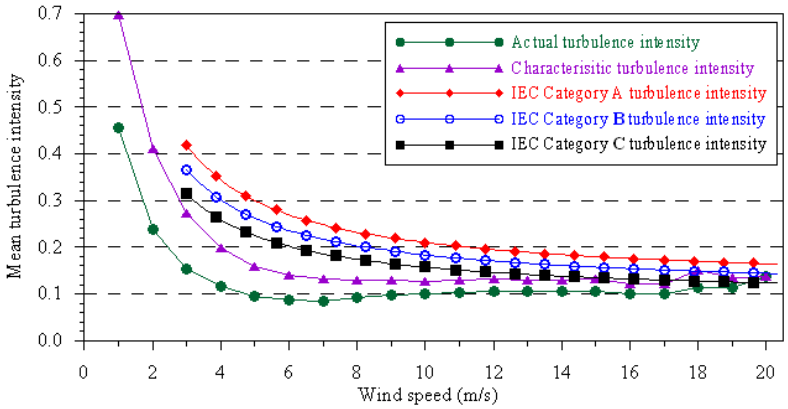

Fig. 8. Varitaion of mean turbulence intensity with wind speed.

3.5. Wind energy yield analysis

For energy yield estimation, a three bladed wind turbine of 2.75MW rated power with rotor diameter of 100m from Vestas was chosen. The net energy yield was calculated by considering the down time, array, soiling and other losses as 4, 5, 1 and 4%, respectively. For energy yield estimation, three hub heights of 60, 80 and 100 meters were considered. The

Annual average wind speed at 60, 80 and 100m AGL was found to be 6.3, 6.8 and 7.2m/s, respectively. The chosen wind turbine could produce average net power of 1,103; 1,239 and 1,341kW corresponding to wind speed at hub heights of 60, 80 and 100m; respectively. Furthermore, the annual net energy equivalent to 9,664; 10,851 and 11,747MWh could be produced with an average plant capacity factor (PCF) of 40.1, 45.0 and 48.8% corresponding to hub heights of 60, 80 and 100m, respectively, from the chosen wind turbine. On an average, the rated power could be produced for only 4% of the time during the year with a hub height of 100m. There will be certain times when the wind turbine will have zero output. It is evident that on annual basis, only 3.6% of the times there will be no power with a hub height of 100m and around 3.9% of the times for 60m hub height. Since wind is an intermittent source of energy, one has to bear with this type of situation.

4. Conclusions

The analysis of the measured data showed that the annual average wind speeds were 4.1, 4.8, 5.3 and 5.7 m/s at 10, 20, 30 and 40m AGL, respectively. The prevailing wind direction was found to be NNW and NW during measurement period. Highest wind speed was observed in June while minimum in August and October at all the heights of wind speed measurements. During entire data collection period, the average wind power density values at 10, 20, 30 and 40m AGL were 85.5, 119.1, 154.2 and 180.3W/m^2, respectively.

The wind shear exponent (WSE) obtained using all the data values was 0.273 while 0.269 and 0.279 for the data of 2007 and 2008, respectively. No definite seasonal trend could be noticed in the values of WSE. The overall mean turbulence intensity values over entire period of data collection were 0.172, 0.142, 0.127 and 0.122 at 10, 20, 30 and 40m AGL, respectively.

The monthly average minimum energy of 526, 600 and 661MWh was generated in August while a maximum of 1,034; 1,127 and 1,192MWh in June corresponding to hub heights of 60, 80 and 100m, respectively. The monthly mean plant capacity factor (PCF) varied between 25.7 and 52.2% for 60m hub height, 29.3 and 57.0% for 60m and between 32.3 and 60.2% for 100m hub height in the months of August and June, respectively.

A wind tunnel method for screening the interaction between wind turbines in planned wind farms

Mats Sandberg[1,*], Hans Wigö[1], Leif Claesson[1], Mathias Cehlin[1]

[1] *University of Gävle, Gävle, Sweden*

Abstract: The energy captured by wind farms is reduced if there is an interaction between the individual turbines. In the paper a novel method for studying the interaction between wind turbines is presented. It is based on recording the static pressure on ground in a wind tunnel provided with wind turbine models.
The assumption is that the pressure distribution at ground reflects the pressure distribution at hub height. The pressure distribution at hub height is a result of the flow in the vicinity of the turbine.
The pressure at ground is recorded with a pressure plate provided with 400 pressure taps. The wind turbine model is a porous disk giving a non rotating wake.
At first the pressure response to one wind turbine is recorded. This is the reference case giving the characteristics of a non disturbed wind turbine. Its region of influence can therefore be determined. This provides important information on how to avoid any interaction between turbines. A nearby turbine should not be placed within the region of influence. In the paper we show how the pressure response varies with different distances between two turbines. The agreement between the static pressure on ground and at hub height has been tested by recording the static pressure at hub height with a small Prandtl tube.

Keywords: *Wind farms, Wind tunnel, Pressure distribution on ground, Pressure distribution at hub height, Region of influence*

1. Introduction

To benefit of economies of scale, wind turbines are arranged in wind farms. As wind energy capacity expands, the size of individual wind farms continues to increase requiring tens to hundreds of wind turbines typically arranged in a large array. While organizing wind turbines in wind farms help in reducing the cost of energy production they introduce another problem, aerodynamic interaction. One of the research challenges is to accurately model interactions between the individual turbines to accurately predict power output before wind farm construction. In a wind farm with *N* turbines the wind farm efficiency is defined as

$$\eta_A = \frac{E_{A_i}}{E_T N} \qquad (1)$$

Where E_A is the annual energy captured by the wind farm and E_T is the annual energy captured by one isolated turbine. If there were no aerodynamic interaction the energy captured by the wind farm would be NE_T and the efficiency would subsequently be 100 %. Figure 1 shows a wind turbine with rotor diameter *D*. Array losses can be reduced by optimization of the downwind spacing and the cross wind spacing.

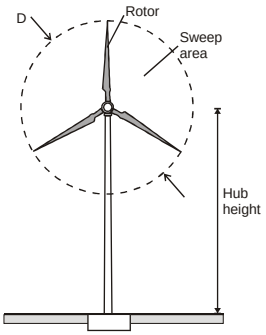

Fig. 1. Definition of some concepts

Behind a wind turbine there is rotating wake with a velocity deficit with respect to the approaching free wind U_∞. If we set the reference pressure (static pressure) in the undisturbed wind to zero there is an under pressure in the wake (compare Figure 5). After a relatively short distance there is pressure recovery. However the velocity deficit goes on for a long distance behind the turbine.

With a too short distance between wind turbines the wind turbines upstream will lower the exposed wind speed of the turbines downstream. Subsequently the power generated by the wind farm will be reduced. This calls for the need of methods for predicting the risk of interaction. Providing such methods in the planning process is the purpose of this research. The importance of accurate design models increases since the turbines gets larger and larger by time. If there is an interaction between wind turbines one can minimize the loss in power generated by suitable control of the wind turbines [1].

It is extremely difficult to predict the power output from wind farms, due to atmospheric turbulence, wind shear, changes in wind directions, wake effect from neighboring turbines etc. In recent times, CFD (Computational Fluid Dynamics) simulations have been performed on wind turbines. Recent wake studies based on CFD using various turbulence models have been presented by e.g. Ivanell [2], Sørensen et al. [3], and Wußow et al.[4]. CFD methods for simulating wake flows and wake interactions need to resolve many different length scales, ranging from the thickness of the blade boundary layer to the distance between the turbines. Hence, there are still limitations in CFD to simulate an entire park, due to computer limitations.

1.1. Basic assumption behind the method

Our approach for studying the aerodynamic interaction between individual wind turbines is based on the assumption that with a plain ground the static pressure distribution on the ground reflects the pressure distribution at hub .Aand the pressure distribution at the hub height reflects the air flow pattern at this height. For natural ventilation the relation between the static pressure in air and on the ground has been explored in [5]. The results were encouraging and are the impetus for this work.

2. Methodology

2.1. Wind tunnel

The experiments were conducted in the atmospheric boundary layer wind tunnel at University of Gävle. The pertinent details of the wind tunnel are shown in Figure 2. Within the empty wind tunnel there is a pressure gradient, see Fig 9. To equalize the pressure within the wind tunnel with the ambient pressure the wind tunnel is provided with a slot of width 6 cm located 255 cm downstream of the centre of the turning table. The slot is running along the whole perimeter of the wind tunnel.

During the tests the wind speed at half height in the test section was about 20 m/s.

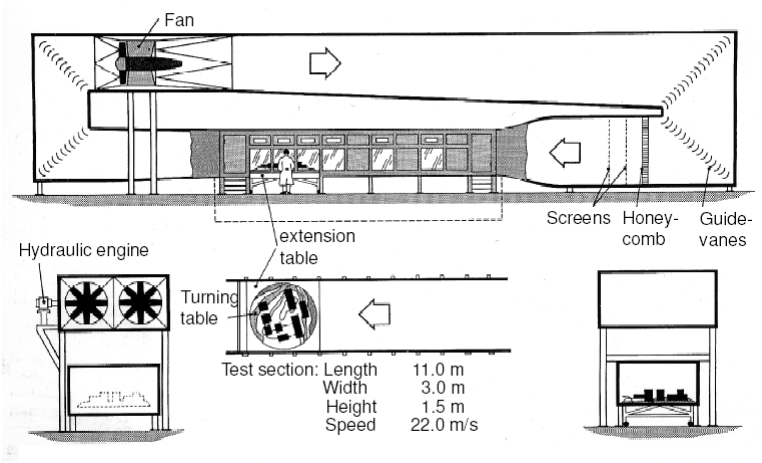

Fig. 2. Atmospheric boundary layer wind tunnel

2.2. Wind turbine model

The wind turbine model used in this study was in scale 1:2000 and had a diameter of 45 mm and the hub height was 45 mm. This corresponds to a wind turbine with 90 meters diameter and a hub height of 90 meters. In the model the rotor where replaced by a porous disc, which was used to simulate the wake behind the wind turbine Medici & Alfredsson [6] .The disc porosity was 42% and the corresponding drag coefficient was 0.85. This value of the drag coefficient is approximately the same as the value obtained for a turbine at high tip speed ratios.

2.3. Technique for measurement of static pressure at hub height and on the ground

The static pressure at hub height (45mm above ground in the wind tunnel) was measured with a Prandtl tube of 3 mm diameter. The static pressure on ground was measured with a pressure plate provided with 400 pressure taps organized in a quadratic pattern with a distance of 37 mm between the centers of the taps, see Figure 3. The pressure was recorded with a pressure transducer connected to a scanner valve. Measuring the pressure in all 400 pressure taps takes about 5 hours

Figure 4 shows the wind tunnel with one wind turbine model placed on the pressure plate. In this picture the wind tunnel was provided with roughness elements and spires to generate a turbulent boundary layer.

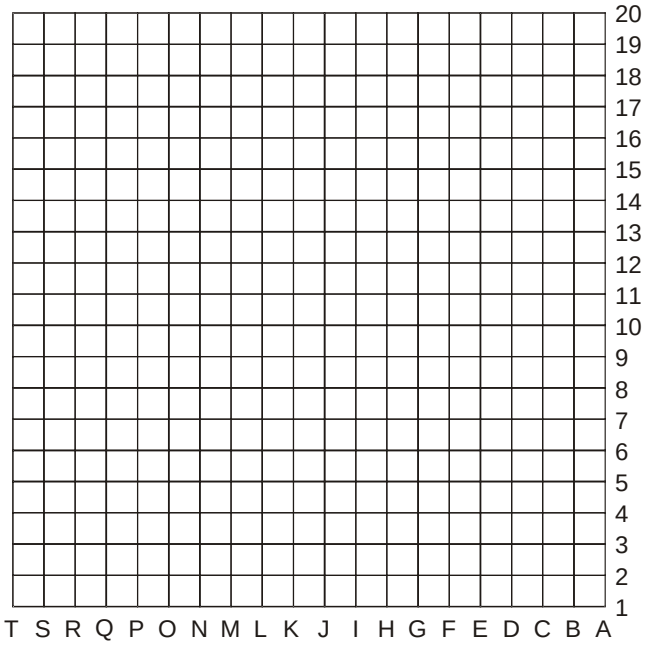

Fig. 3 Notation for the pressure plate

Fig. 4 Wind tunnel with one wind turbine model placed on the pressure plate along line 10 in Fig.3

To eliminate the effect of the pressure gradient along the wind tunnel a measurement was first made with an empty wind tunnel. These data were then subtracted from the pressure readings obtained with a turbine model present.

3. Results

3.1. Pressure response on ground due to one wind turbine

To begin with one wind turbine was placed on the pressure plate along line 10 in Figure 3 and the pressure was recorded. Figure 5 shows the recorded pressure (raw data) quantified as a pressure coefficient.

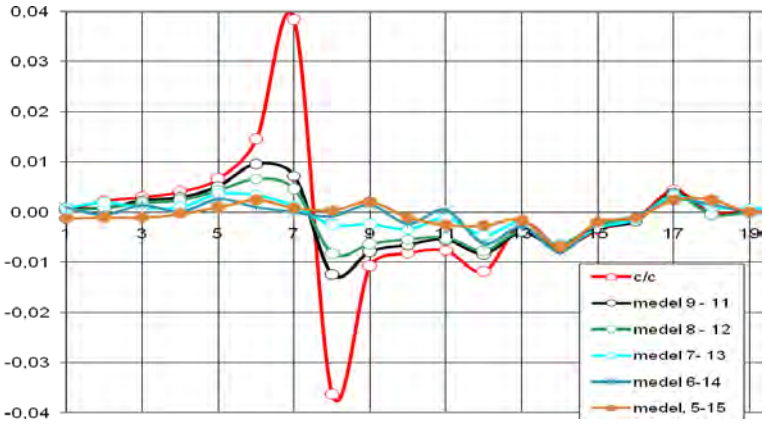

Fig. 5. Recorded pressure coefficients at different positions with one wind turbine on the pressure plate. (medel = average).

The pressure is shown as the pressure distribution along line 10 (center line) in Figure 3.. The pressures in the surroundings are shown as the mean value of the lines 9-11, 8-12, 7-13, 6-14 and 5-15 respectively .

Upwind the pressure reflects the deceleration of the flow when approaching the disk. The highest pressure corresponds to the stagnation pressure on a solid disk. Then there is an acceleration of the flow when passing through the openings of the disk. After reaching the minimum pressure in the wake the static pressure is recovered relatively fast.

3.2. The region of influence of one wind-turbine

The gray area in Figure 6 shows the region of influence, of a wind turbine located on the center line.

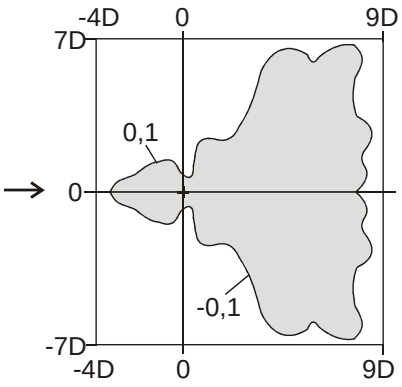

Fig. 6. Region of influence from one wind turbine located at the cross based on static pressure readings on the pressure plate. The pressure has been normalized with the highest pressure..

The region of influence on the upwind side is defined by the line representing 10% of the highest pressure (0.1 line) an on the downwind side by the line representing -10% of the highest pressure (-0.1 line). The pressure has been normalized with the highest pressure which occurs just before the wind turbine.

3.3. An example of interaction between wind turbines

The interaction between two wind turbines was explored by placing two wind turbines with a separation distance of 6.66 D. The wind turbines were located along the center line.
Figure 7 shows the response from one isolated wind turbine which is the reference case.

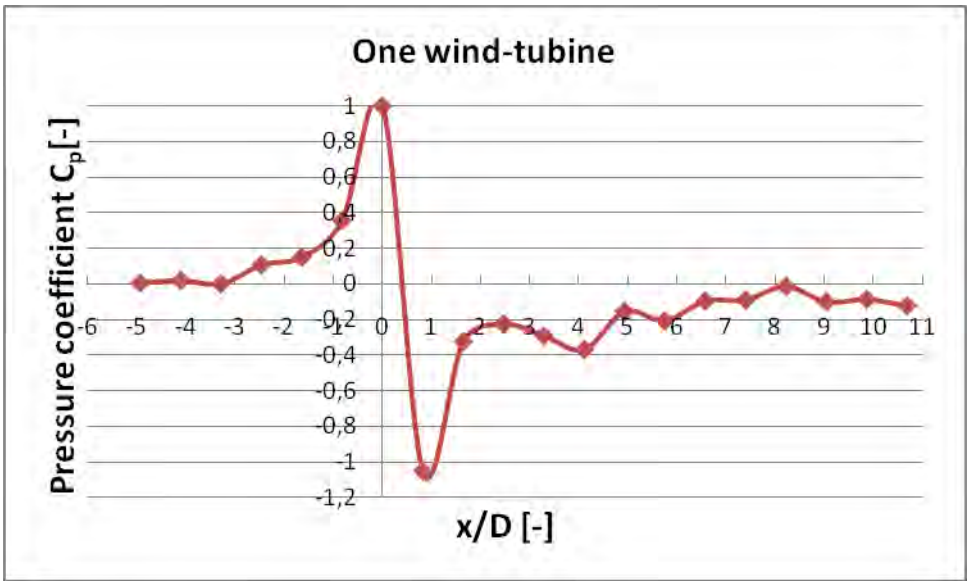

Fig. 7. One undisturbed wind turbine.

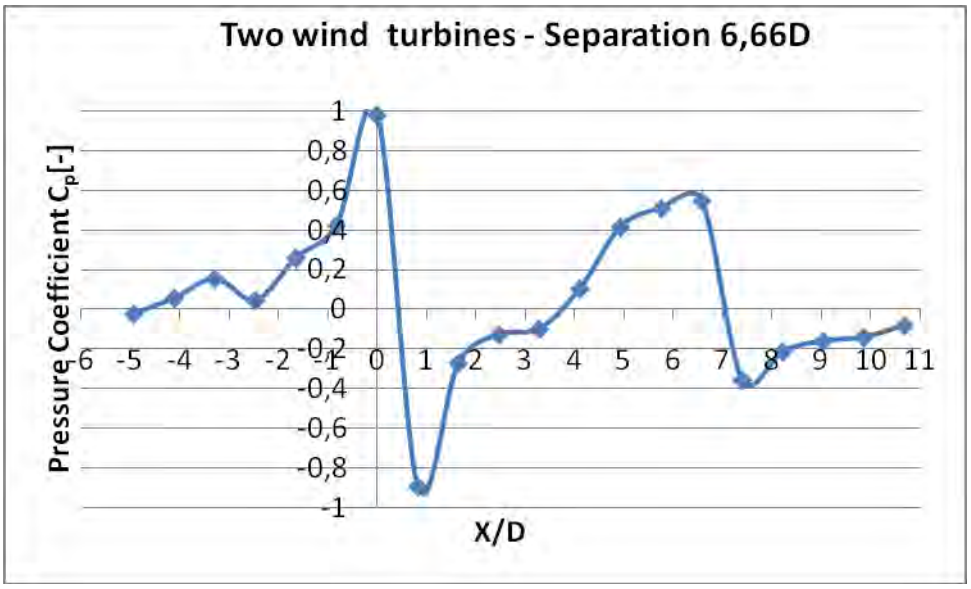

Fig.8 Two wind turbines

By comparing the pressure response of the undisturbed wind turbine in Figure 7 with the pressure response of the wind turbine located downstream in Figure 8 one sees clearly that the wind turbine located downstream is disturbed by the one located upstream.

3.4. Comparison between static pressure at hub height and on the plate

Our method is bases on that that there is a close relationship between the static pressure at hub height and on ground. This has benne tested by measuring the static pressure at hub height with a Prandtl tube. The result is shown in Figure 9.

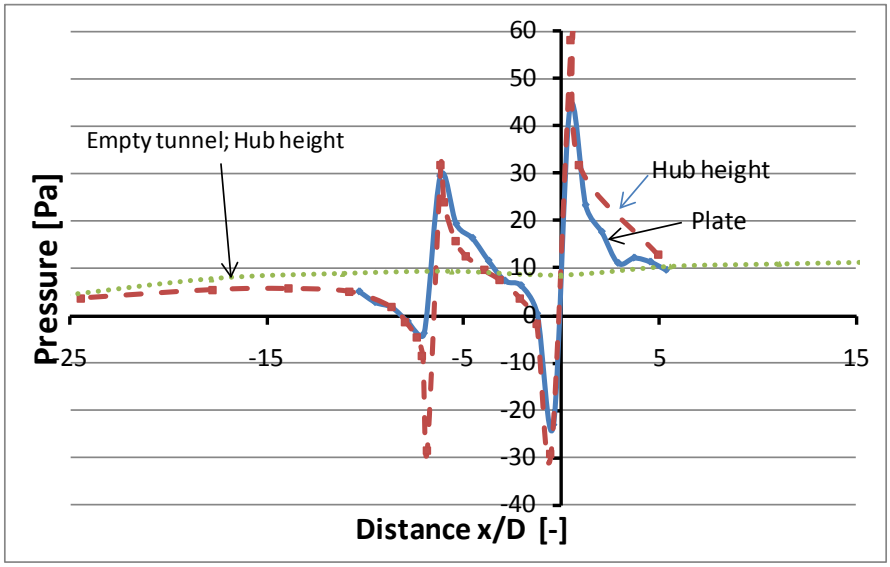

Fig.9 Static pressure at hub height and on ground (pressure plate).

There is a god correspondence between the pressures at the two levels.

4. Discussion

There is a clear response in the static pressure on the pressure plate due the presence of wind turbine models. This makes it possible to quantitatively explore the interaction between wind turbines. There is also a good correspondence between the static pressure on the ground (pressure plate) and the static pressure at hub height recorded with a Prandtl tube. Downstream of a wind turbine there is a relatively fast recovery of the static pressure. Therefore the response in static pressure may underestimate the length of the wake in terms of the velocity recovery. This will be explored by measuring the total pressure at hub height and to in detail investigate the velocity field in the wake region with Particle Image Velocimetry.

5. Conclusions

This is a new method, which is fast and economic, for exploring the interaction qualitatively between wind turbines. The next step is to develop it into a quantitative method that makes prediction of energy production possible.

Abstract: The stress on demand and supply gap of electricity has lead the globe to face acute problems. Further use of fossil fuel based energies for improved life and development have lead to adverse environmental effects, like climate change. Offshore wind farms have great potential as sustainable energy source. This accentuates to focus attention on technical issues such as selection, requirements, characteristics and power production from wind turbine. This paper presents a methodology developed for selection of optimum windmill for a specific site based on capacity factor approach by proper analysis of wind data. Offshore wind data for the purpose is obtained from, INCOIS Hyderabad- India for a particular site under proposal in India. The wind data is used to generate mean wind speeds for a typical day in a month by using MATLAB program. The windmill with the highest average capacity factor is the optimum one and to be recommended. The results of said analysis are presented. Such analysis at the planning and development stages of installation will enable the wind power developer or the power utilities to make a judicious choice of potential site and wind turbine generator system from the available potential sites and wind turbine generators respectively.

Keywords: *Offshore wind, Climate change, Capacity factor, Wind data.*

1. Introduction

A Number of potential wind power sites are available all over the world. Of these, not all sites have wind turbine generators installed. The observation with the existing wind farms shows that some of the wind power plants have performed poorly probably due to improper site matching. Hence there arises a n eed for a systematic approach toward the problem of optimum siting of wind turbine generators. [4] The production of electricity by a wind turbine generator at a specific site depends upon many factors. These factors include the mean wind speed of the site and the speed characteristics of the wind turbine itself namely, cut-in, rated, and furling wind speeds including the hub height. Commercially many models of wind turbine generators available, with similar MW and KW ratings. Each of these wind turbines has their own specifications and speed parameters. These speed parameters affect the capacity factor at a given specific site, and subsequently affect the choice of optimum wind turbine generator for the site. In this paper the method to determine capacity factor of different offshore wind turbine under different tower heights, rated wind speeds, is discussed for Mumbai offshore region.

1.1. Capacity Factor

It compares the plant's actual production over a given period of time with mean wind speed the amount of power the plant would have produced if it had run at rated wind speed for the same amount of time and hence can be defined as ;

- The ratio of average power output to the rated power output [1]
- An indicator of how much energy a particular wind turbine makes in a particular place.

$$C.F. = (Pa / Pr) \quad (1)$$

2. Methodology

2.1. Offshore Wind Turbine Site Matching Based On Capacity Factors

The methodology for the selection of the optimum windmill for a specific site is developed the flowchart is shown in Fig 1. The selection is based on the capacity factors (CF) of the available windmills. The long term wind speed data recorded at different hours of the day for many years is used. The particular steps used to determine C F for the mean wind speeds for at different hours of the day are generated with the manufacturer's specifications. The windmill with the highest capacity factor for the specific site is the optimum one and to be recommended.

- Step1: Calculation of Mean Wind Speeds

  The mean wind speed for a typical day of a month need to be generated by averaging all the recorded wind speeds for regular interval of long term data of the wind speeds for the site to be considered.
- Methodology Of Determination Of Capacity Factor

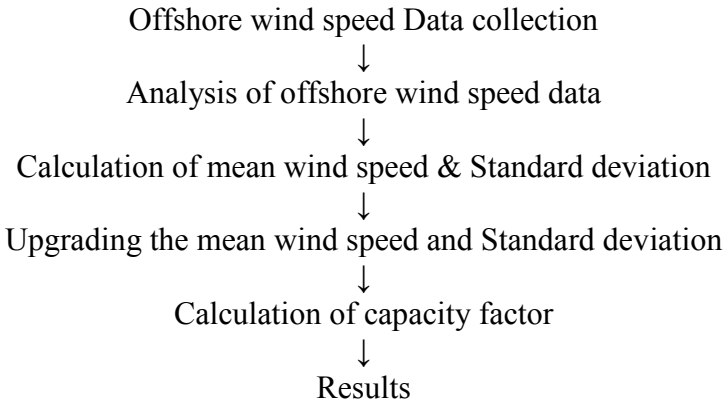

Fig 1 Methodology for determination of capacity factor

The mean wind speed is then calculated using the equation below

$$V_i = \left(\frac{\sum_{j=1}^{N_j} V_j^{\,3}}{N_j} \right)^{1/3} \qquad (2)$$

Where

V_j =observed wind speed
N_j =number of wind speed observations
V_i =mean wind speed

- Step 2 Upgrading the Mean Wind Speed

$$V_z = V_i \left(\frac{Z}{Z_i} \right)^x \qquad (3)$$

Where

V_z= mean wind speed at projected height, Z

V_i= mean wind speed at reference height, Z_i
Z= projected height (or hub height)
x=power law exponent depends upon the roughness of the surface. For open land, x is usually taken as 1/7.

- Step 3 Generation of the Wind Speed Probability Density Functions

$$f(v)=\left(\frac{v}{C_i^{\,2}}\right)\exp\left(-\left(\frac{v}{2C_i^{\,2}}\right)\right) \tag{4}$$

Where

$C_i = v_i/1.253$
v= wind speed
The Weibull probability density function is represented by

$$f(v)=\left(\frac{k}{c}\right)\cdot\left(\frac{v}{c}\right)^{k-1}\exp\left(-\left(\frac{v}{c}\right)^{k}\right) \tag{5}$$

Where;

c=scale factor, unit of speed
k=shape factor, dimensionless
v=wind speed
The Weibull parameters c and k can be found using the following acceptable approximations

$$k=\left(\frac{\sigma}{v}\right)^{-1.086} \qquad 1\le k\le 10$$

$$c=\frac{v}{\Gamma\left(1+\frac{1}{k}\right)}$$

In both the probability density functions, the wind speed v will be the mean wind speed V_Z, calculated at hub height from equation (3)

- Step 4 Calculation of Capacity Factors

The average power output from a wind turbine is the power produced at each wind speed multiplied by fraction of the time that wind speed is, experienced integrated over all possible wind speeds. In integral form the equation is [2,4]

$$P_a=\int_0^{\infty} P_w\cdot f(v)\cdot dv \tag{6}$$

Capacity factor can be defined as the ratio between average power output given by equation (6) and rated power of the wind turbine P_r can be obtained from the manufacturer's details. In equation(6) the power at various wind speeds can obtained from the following equation

$$P_w = \begin{cases} P \cdot \dfrac{v^k - v_c^{\,k}}{v_R^{\,k} - v_c^{\,k}} & for\ v_c \le v \le v_R \\ P & for\ v_R \le v \le v_f \\ 0 & elsewhere \end{cases} \quad (7)$$

Where

P is the rated electrical power,
v_c is the cut in wind speed,
v_R is the rated wind speed
v_f is the cut off wind speed
k is the Weibull shape parameter defined under the equation(5), the relationship betweenpower and wind speed is as under,

$$P = \frac{1}{2} C_p \cdot \rho \cdot A \cdot v^3 \eta$$

For which considering value of air density factor ρ = 3.485 P/T

Where P=101.3 kpa and T=273K the power equation thus can be written as

$P=0.646\ C_p .\ A\ .\ v^3.\eta$ (8)

Thus the capacity factor defined above can be expressed as

$$CF = \frac{1}{P_r} \int P(v) \cdot f(v) \cdot dv \quad (9)$$

- Step 5 Choice of the Optimum Wind Turbine Based on Capacity Factor
  The capacity factors of different turbines are computed from the wind speeds (v_c, v_R, v_f) and rated power data obtained from manufacturer details. Now detailed table for the capacity factor for each turbine is prepared from which it can be clear that certain turbine will have a maximum value of capacity factor. This becomes the candidate which can produce the optimal power for the chosen site and wind data. [4, 5, 6]

3. Computation and Results

3.1. Data Analysis:

The wind speed data that is obtained from Indian National Centre for Ocean Information Services (INCOIS) has been first arranged on the hourly basis. The mean wind speed and standard deviation on the hourly basis and daily basis is computed. The results of computed mean wind speed data has been presented year wise for the year 1998 and 2005 respectively in Figure 2 to 5.

3.2. Computation Of Capacity Factor

The capacity factor of a machine indicates the ability to generate the mechanical energy by utilizing the wind power. This solely depends upon how the wind speed utilized to spin the rotor of turbine. The mean wind speed data that has been obtained from INCOISIS is used to determine the hub height wind speed as per the equation 3 . Further wind turbine data of the

selected machine is used for the computation of capacity factor for each of the machine the details of which are shown in table 1.the computation of capacity factor has been carried out by using MATLAB program.

Table 1. Offshore wind turbine specification

Company Name	Power Rating MW	Cut in wind Speed (m/s)	Rated wind speed (m/s)	Cut out wind speed (m/s)	Rotor diameter in meter	Turbine Height in meter
RE Power	5	3	11.4	25	126	90
GE	3.6	3.5	14	27	111	90

Fig.10. Vestas 112/3.0 MW offshore wind turbine layout for 50MW

3.3. Conclusions

The paper presents a methodology for assessment of offshore wind data and the capacity factor of wind turbines for their suitability to be used for harnessing offshore wind energy in a better fashion as depicted by the results. This not only helps to choose a better turbine but also to maximize the system performance. Further the illustration presented for a specific site in Konkan region of Maharashtra exemplifies the suitability of method presented.

Abstract: In urban areas, the evaluation of the energy outcome of a horizontal axis micro wind turbine depends on several factors such as mean wind velocity, location, turbulence, etc. To maximize the micro wind turbine efficiency it is important to define the best location. The present paper focuses on the definition of common rules for micro siting in urban areas.

In this work, the efficiency of a 1 kWp horizontal-axis wind turbine has been evaluated, by means of CFD and experimental data. The numerical results have been compared with the experimental data collected over a period of time of three years, by using a measurement equipment installed on the roof of the Engineering building at the University of Salento. The results have shown that horizontal axis wind turbines suffer from wake effect due to buildings, therefore best sites in urban area have to be identified by a careful fluid dynamic analysis aimed at evaluating all causes that can reduce significantly the performance of the generator.

Keywords: *Micro wind turbine, best location, experimental and fluid-dynamic analysis*

1. Introduction

In the last years, prices of oil have achieved strong variations on international markets. These occurrences have underlined the very important role of energy as fundamental factor for human activity [1,2,3]. In this scenario, small/micro wind generators are gaining an important role due to both the low environmental impact and the possibility to avoid big electrical networks.

Several authors have studied the topic of microgeneration, by taking into account both technical and social aspects [4,5,6]. Kelleher e Ringwood [7] developed software to estimate the economic performance of small/micro solar and wind plants. Watson [8] carried out studies about the microgeneration management techniques considering power supply issues. Besides, in order to estimate micro wind turbine performance several studies have been carried out by using computational fluid dynamic models (CFD), since they can show an exhaustive draft about the wind flow around the micro turbine in any meteorological conditions, allowing saving time and costs [9,10].

For evaluating the economic convenience about the installation of a micro wind turbine in urban area, it is important to calculate positive and negative effects of buildings or other obstacles on the aerogenerator performance. For this reason, the present work focuses on the best siting of small horizontal-axis wind turbines in urban area. Particularly, an aerogenerator has been installed on the roof of the Engineering building at the University of Salento and monitored over a period of time of three years.

During experimental testes it was observed a perpetual transient condition of the microturbine that reduces its performance. Then CFD simulations have been carried out to fully understand the relationship between the aerogenerator performance measured under several meteorological conditions and the shape of the building where the plant is installed. In this way, a useful rule for best placing of horizontal-axis wind turbines in urban areas has been obtained.

2. Experimental setup and numerical model

2.1. Description of the experimental setup

In this work, an experimental apparatus has been developed for monitoring the performance of a horizontal axis micro wind turbine (1 kWp).

Anemometer, PLC, analogic/digital conversion unit, web server, voltage transducers and current transducers composed the measurement apparatus. Table 1 reports the main technical specifications of the experimental setup.

Table 1. Mean technical features of the plant

Elements	Technical features
Aerogenerator	- power: 1 kWp - cut-in velocity: 2.5 m/s - Electric generator: 24 VDC (alternator + rectifier) - n. 4 batteries: Trojan T105, 6VDC - inverter: 24 VDC-220 VAC - fiberglass rotor: D=2.5 m - Pole: 9 m
voltage transducer	R_M 0.47 Ω - Precision T_A=25 °C 0.7%
current transducer	V_{OUT} 0÷10 V - Precision T_A=25 °C 1%
anemometer	optical encoder (precision +0.3m/s up to 3m/s, ±1% over 3m/s)
PLC	8 input-PNP,NPN /8 output-Transistor PNP, interface RS232 COM-Port
analogical/digital conversion unit	8 analogical input 12 bit
Web-server	Ethernet - 10 Mbit/s

The whole system was controlled by a PLC that acquires and processes several signals and monitors all parameters under investigation. Besides the measures were viewable in real time on an Internet web site and stored on a remote hard disk.

2.2. CFD Model

In order to study the wind microturbine performance, a 3D model of the building has been drawn, as Fig. 1 shows. The total height from the ground of the aerogenerator is equal to 20 m.

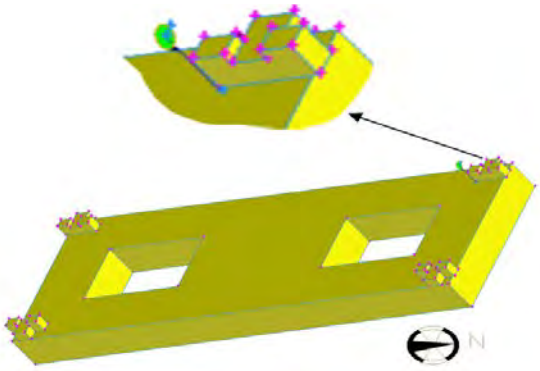

Fig. 1. 3D model of the building where the aerogenerator has been installed.

The fluid dynamic simulation domain has been obtained by subtracting the building volume to a parallelepiped sufficiently large to consider undisturbed fluid-dynamic conditions on the boundary.

For meshing the volume, tetrahedral elements whose size was in the range between 0.2 and 2 m have been used. The computational cell size has been selected to reduce the maximum computational error and to obtain grid-independent solutions.
The mesh sensitivity analysis has been performed by comparing the results from several simulations carried out with different mesh resolutions.

Table 2. Sensitivity analysis results

Cells (n)	Mean wind velocity close to the aerogenerator (m/s)	Variation (%)
579'596	7.93	-
1'084'494	8.16	2.8%
2'552'154	8.26	4.1%

As Table 2 shows, by incrementing the number of cells from 579'596 to 2'552'154 the mean wind velocity close to the aerogenerator changes within 4.1% and this difference outcomes equal to 1.3% switching the number of cells from 1'084'494 to 2'552'154. So it is reasonable to use the denser grid, since further incrementing the number of cells, advantages shouldn't be enough to justify the relative increment of calculation time.

Numerical simulations have been carried out by using FLUENT software and studying eight wind directions with an angular difference equal to 45° and wind velocity within the range 4÷8 m/s. This range has been fixed by taking into account the following considerations:

- Up to 4 m/s, the electric power is lower than 5% of the nominal power and the data statistical dispersion is much large with respect to the measured values: this issue does not allow to do a comparison between experimental and numerical data;
- Over 8 m/s, there are not enough data (less than 2%).

Turbulence has been evaluated using the standard k-ε turbulence model.

3. Discussion of results

3.1. Measured data analysis

The aerogenerator was installed on the roof of the Engineering building at the University of Salento. The following coordinates individuate the exact location: 40°20'03" N, 018°06'51" E and 35 m with respect to the mean sea level.

The wind microturbine has been monitored over a period of three years (2005, 2006 and 2007), measuring several parameters: wind velocity and direction, electric current, voltage and generated power. All parameters have been registered each 10 minutes.
For modeling wind data the Weibull function has been used in accord with following equation.

$$P(v < v_i < v + dv) = P(v > 0)\frac{k}{c}\left(\frac{v_i}{c}\right)^{k-1} \exp\left(-\left(\frac{v_i}{c}\right)^{k}\right)dv \quad (1)$$

Where c is the scale parameter, k is the shape factor, v_i is a generic wind velocity value, dv is the wind velocity increment, $P(v<v_i<v+dv)$ is the probability to register a wind velocity within the range v e $v+dv$ and $P(v>0)$ is the probability to register a wind velocity major to zero.

Weibull function is completely defined if c and k are known: these coefficients have been calculated by using the modified maximum probability method and considering a wind velocity step equal to 0.1 m/s. Table 3 reports the values of c and k for the period under

investigation (2005÷2007), whereas Fig. 2 shows the comparison between experimental data and the Weibull curve.

Table 3. Weibull function parameters for the period under investigation (2005÷2007)

Year	*k*	*c* (m/s)	Most probable velocity (m/s)	Mean velocity (m/s)	Standard deviation (m/s)
2005	1.658	3.457	1.98	3.09	1.91
2006	1.649	3.420	1.94	3.06	1.90
2007	1.669	3.444	1.99	3.08	1.89
Mean values	1.659	3.440	1.97	3.08	1.90

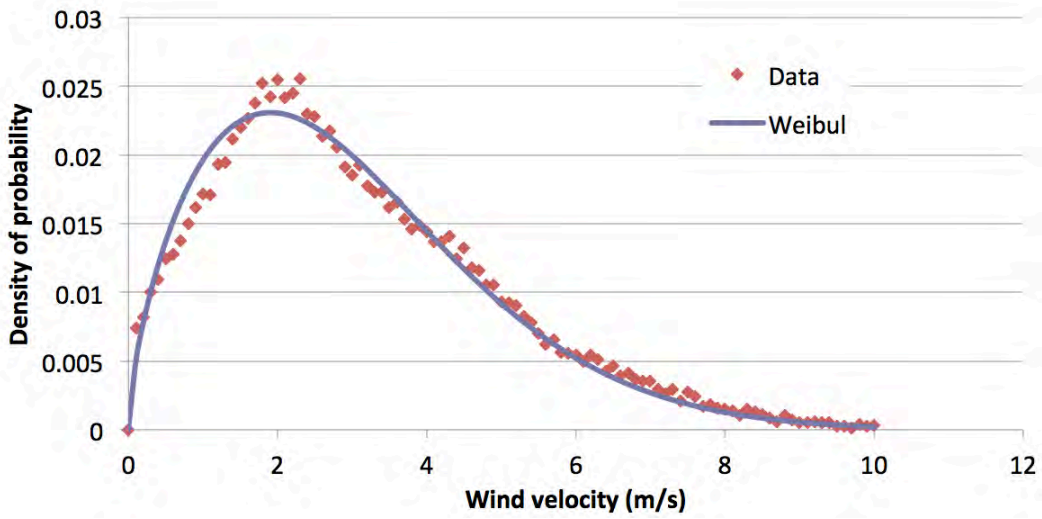

Fig. 2. Comparison between experimental data and the Weibull curve.

The anemometric analysis shows that the mean wind velocity at 20 m from the ground is equal to 3.08 m/s. This value is comparable with the aerogenerator cut-in velocity (2.5 m/s) and so it demonstrates that the site does not have a good wind potential. Nevertheless it is important to remark that at 35 m from the ground the mean wind velocity is equal to 4.9 m/s as the Wind Atlas of Apulia Region [11] shows. In other words, the mean wind velocity has to be halved going from 20 m to 35 m of height from the ground: this issue is common to many sites in urban area and it represents a big problem in order to achieve good performance from micro wind turbines.

Over experimentation time, more parameters have been measured as voltage, current and electric power. These data have been organized and analysed as function of wind direction. In this way it has been possible to study the influence of the shape of the building on the aerogenerator performance.

Fig. 3 shows the measured electric power for wind direction North as a function of wind velocity. Besides it is possible to see the comparison between the mean electric power (best fit of the measures of power - red curve) and the nominal electric power (orange curve). Particularly, for wind velocity up to 3 m/s the mean power curve is higher than nominal one, within 3 and 4 m/s the two curves are about similar and over 4 m/s the mean power curve is lower with respect to the nominal one. Moreover it is possible to observe a noticeable variability of measures due to the irregularity of wind velocity in the site under investigation.

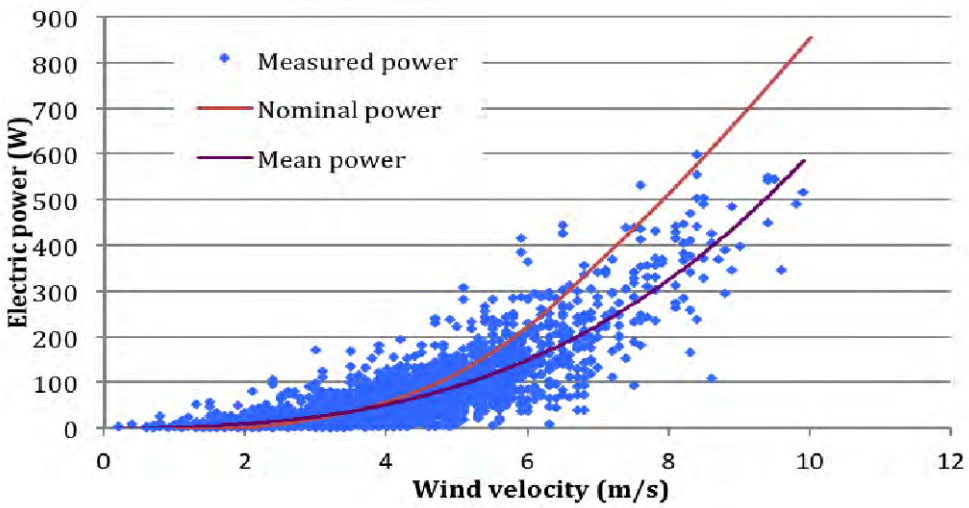

Fig. 3. Electric power output as function of wind velocity (wind direction North). The blue points indicate the measures of power, the red curve indicates the mean power (best fit of the measures) and the orange curve indicates the nominal power.

In order to complete the experimental data analysis, the measured electric power has been examined for each wind direction as Fig. 4 shows.

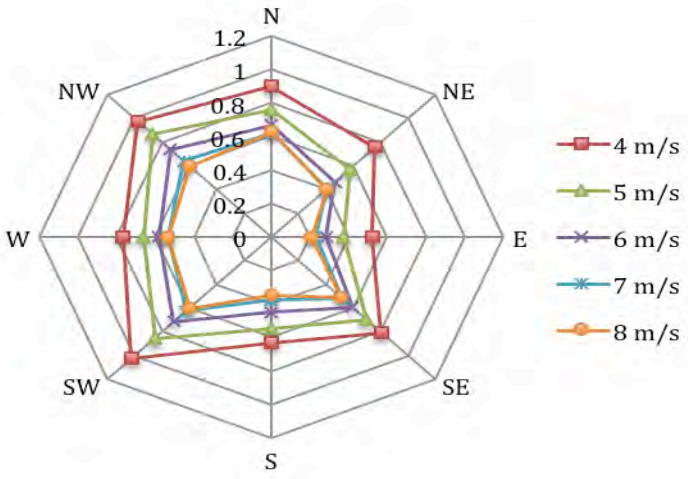

Fig. 4. Ratio between measured electric power and seminal electric power as function of wind direction and intensity

Fig. 4 demonstrates that electric power is very influenced by the wind direction, or in other words, this parameter strictly correlate with the intensity of the wake due to the shape of the building. These effects are more evident by observing the ratio between mean power and nominal power that decreases for high values of wind velocity and for all the considered directions.

3.2. CFD analysis

To fully understand the fluid-dynamic phenomena that influence the wind turbine performance several numerical simulations have been carried out by using the software FLUENT. All results are reported next.

The CFD post-processing analysis was developed taking into account for each wind direction four sections of the calculation domain. Particularly, three sections were positioned

transversely to the wind direction (the first one was placed ten meters forward the building, the second one close to the aerogenerator and the third one ten meter rear the building) and one longitudinal section was placed parallel to the wind direction. This section is very interesting because it shows the flow evolution along the building.

Numerical simulations have been carried out considering the wind velocity within the range 4÷8 m/s like to experimental analysis. Fig. 5 shows the results along the longitudinal sections for wind directions N-S (North is the prevalent wind direction), in the case of wind velocity equal to 6 m/s (mean velocity within the range 4÷8 m/s). It is important to notice that in the other cases under investigation (wind velocity equal to 4, 5, 7 and 8 m/s and other wind directions) the results are qualitatively similar to the case shown next.

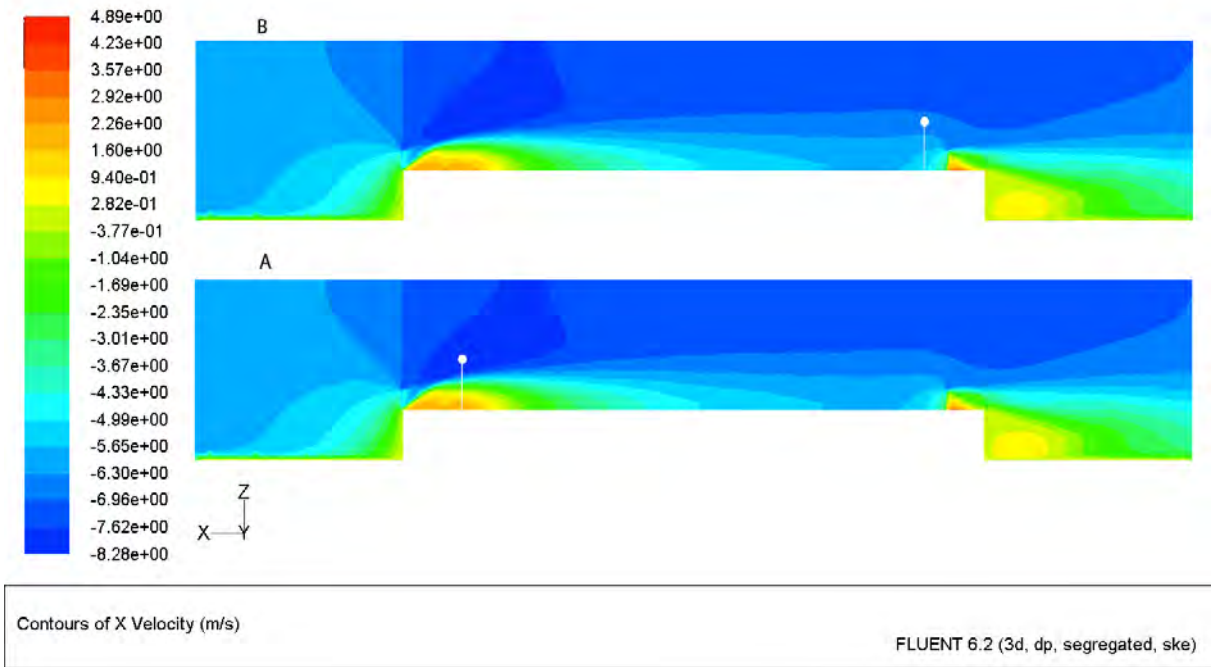

Fig. 5. Contours of X wind velocity: wind intensity on the boundary: 6 m/s; wind direction: North (A) and South (B); the pole is sketched by a line and a white circle

As the contours of X wind velocity demonstrate (Fig. 5), close to the aerogenerator there is a very strong vorticity phenomenon, whereas above this area the wind velocity rise quickly over to 8 m/s, against an inlet wind velocity equal to 6 m/s.

These results allow achieving a possible understanding of the experimental results reported in Fig. 3 and Fig. 4: the building generates an increment both of wind velocity and of vorticity influencing the aerogenerator performance; in fact the electric power results meanly lower than the nominal one, due to the strong vorticity, but in some cases the higher values of wind velocity results in a higher electric power output with respect to the nominal one. For example, under meteorological condition with wind velocity equal to 6 m/s the maximum measure of electric power matches the nominal power curve for a wind intensity equal to 8 m/s, as the analysis of Fig. 3 and Fig. 5 reveals.

Changing wind direction from North to South (Fig. 5B), the wind velocity distributions are similar to the previous case (wind direction North - Fig. 5A), with an opposite relative position of the aerogenerator.

According to experimental results, the longitudinal sections North-South show bigger wind intensity when the direction is North and so also the experimental electric power results bigger than the case South.

Another important consideration can be done taking into account the results shown in Fig. 3. As it is described before, for wind velocity up to 3 m/s the mean power curve is higher than nominal one: in this case the wind intensification effects due to the building are predominant on the vorticity. Instead, when the wind rises over to 4 m/s the vorticity generated by the wake of the building becomes prevalent on t he wind intensification effects, cutting the aerogenerator performance.

To define the best location for the horizontal axis micro wind turbine has to be take into account the turbulence intensity, defined as the ratio of the magnitude of the root mean square turbulent fluctuations to the reference velocity:

$$I = \frac{\sqrt{\frac{2}{3}k_e}}{v_{ref}} \qquad (2)$$

where k_e is the turbulence kinetic energy and v_{ref} is the mean velocity magnitude for the flow. Fig. 6 shows the comparison between the contours of X wind velocity and turbulence intensity. This evaluation allows defining the best location for the horizontal axis micro wind turbine in urban area. In fact, by overlapping areas of higher X velocity with areas of lower turbulence intensity it is possible to individuate an area where the aerogenerator can gives maximum performance.

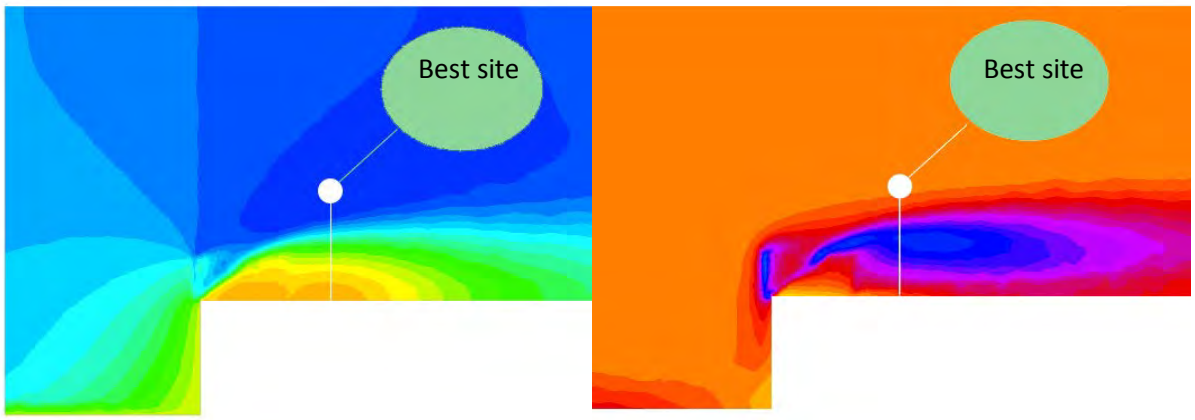

Fig. 6. Comparison between contours of X wind velocity and turbulence intensity. The pole is sketched by a line and a white circle. The best site in sketched by a green ellipse

4. Conclusions

This work focuses on experimental and numerical analysis about the electric power generation from a 1 kW horizontal-axis aerogenerator installed on the roof of the Engineering building at the University of Salento in urban area. Particularly the influence of the building on the micro wind turbine performance has been studied.

Experimental data were collected over a p eriod of time of three years during which it w as observed a perpetual transient condition of the microturbine that reduces its performance. Then to fully understand this occurrence and in order to value the performance of the

horizontal axis wind turbine, several CFD calculations have been carried out, taking into account different meteorological conditions. Numerical simulations calculated wind velocity fields and turbulence intensity above the building due to fluid-dynamic effects.

The experimental and numerical results of this study reveal that the siting of the horizontal-axis micro wind turbine on a building should allow to exploit bigger wind intensity, but often this advantage is neglected from turbulence phenomena; in fact, in the case under investigation, the measured aerogenerator efficiency appears lesser in comparison with the nominal performance curve. But, the best site can be found by crossing the contours of wind velocity with the turbulence intensity fields. In this way it is possible to localize an area (best location) where the aerogenerator can gives maximum performance.

In conclusion, the result presented in the present investigation showed that horizontal axis wind turbines suffer from wake effect due to buildings, therefore best sites in urban area have to be identified by a careful fluid dynamic analysis aimed at evaluating all causes that can reduce significantly the performance of the generator.

Abstract: The eddy viscosity in the buffer zones of the turbulent boundary layers was limited to investigate its effects on the points of incipient separation for flows over wind turbine airfoils. The $k-\omega$ SST turbulence model was used as the base model within the framework of a finite volume CFD scheme. Flows over two different wind turbine airfoils were computed and compared with experimental results. Much improvements in the lift and drag coefficients in the stall regions were observed when compared with the results of the original turbulence model.

Keywords: *Turbulence model, $k-\omega$ SST turbulence model, Airfoil stall prediction, Stall in wind turbine*

1. Introduction

Practical flows over wind turbine blades at large angles of attack are very complicated, thus difficult to predict accurately by numerical methods. The difficulties stem from the fact that the boundary layers separate from the blade's suction surfaces due to adverse pressure gradients and its interaction with turbulence. Several investigations have been conducted by various researchers to compute these separated flows; the results have been hitherto only partially successful. Some investigations have over-predicted the lift coefficients [1-3] while some have under-predicted them [4-6]. Moreover, all computations missed the characteristic dips and rises of the lift coefficients in the regions right after the onsets of stalls [1-8]. The reasons for the inaccurate numerical predictions were invariably attributable to the inaccuracies incurred by the turbulence models used in the computations.

Early computations employed the $k-\varepsilon$ turbulence model [9] but later on the $k-\omega$ turbulence model [10] became more acceptable; at present the $k-\omega$ SST model [11-12] seems to be more preferable among wind turbine researchers. This model utilizes both the $k-\varepsilon$ and the $k-\omega$ models under a strategy of a blending function. Like it predecessors this model employs the fully turbulent flow condition as its basic assumption, i.e. the flow devoid of a transition region. The performances of this model in the predictions of separated flows over airfoils were only partially satisfactory since substantial inaccuracies of the lift and drag coefficients predictions were still prevailed in the stall regimes [1-8].

In particular, the $k-\omega$ SST turbulence model had been demonstrated to over-predict the lift coefficients beyond the stall points [1,5,6,8]. It is believed by the authors that these over-predictions were due to the fact that the turbulence levels (hence, turbulent eddy viscosities) in the boundary layers were too high, thus enhancing a momentum transfers to the near wall regions which helped the boundary layer to push through the adverse pressure gradient regions more easily than otherwise. The resulting delayed separation then caused the low pressure on the suction side to spread over more area than normal which thus increased the lift. The turbulence levels that were too high, in turn, were caused by the fully turbulent assumptions that were employed in the turbulence model.

To this end, it should be noted that the buffer zone which bridges the laminar sub-layer and the log-law region in a boundary layer is very important to the physic of turbulence in the boundary layer. This zone is very difficult to model numerically. A small 'model error' in this relatively thin region could induce a large overall error.

The objective of this study was to improve the accuracy of the numerical prediction of separated flows on airfoils by an adjustment of the turbulence intensity in the buffer zones of turbulent boundary layers. The $k-\omega$ SST turbulence model [11,12] will be used as the basis for this investigation.

2. Methodology

In order to limit the eddy viscosities in the regions from the buffer zones to the log-law zone a damping function f_{SST} is proposed. The limited eddy viscosity for the $k-\omega$ SST model thus becomes,

$$\mu_t = f_{SST} \min\left[\frac{\rho k}{\omega}; \frac{a_1 \rho k}{SF_2}\right] \tag{1}$$

The damping function f_{SST} was defined as a function of y^+ (a scaled normal distance from the wall),

$$f_{SST} = f \ (<1.0) \quad ; \quad a \le y^+ \le b \tag{2}$$

$$f_{SST} = 1 \quad ; \quad y^+ < a,\ y^+ > b \tag{3}$$

For simplicity, the damping function was initially defined as a step function as shown in Figure 1 (solid line). Later, it was modified to be a continuous function. The constant a was set in the range 5-30 and the constant b was set in the range 50-300 for a parametric study. The values selected correspond to the edges of the buffer zone and the log law zone of a turbulent boundary layer.

The CFD code used in this study was the FLUENT Code [13]. The computational mesh was an O-type extending approximately to 35 chord lengths away from the airfoil and 250 points were employed along airfoil surfaces. The first cell at any surface point was sized such that $y^+ \le 2$ whereas grids away from it were expanded at a rate less than 20%. This grid system was found to be suitable for a RANS simulation of turbulent boundary layer flows [14,15].

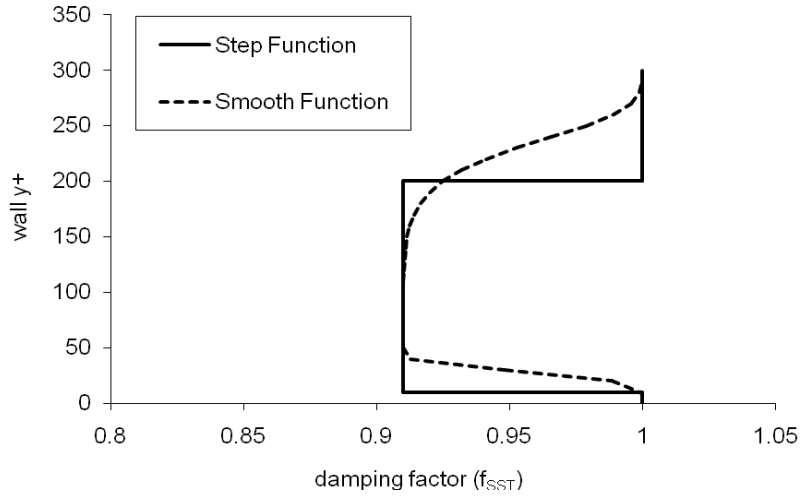

Fig. 1 Example of the step damping function and the hyperbolic (smooth) damping function.

Computations of flows over NREL's S809 airfoil [16] and NACA 63-215 [17] were conducted. An initially parametric study was performed to find out as to how sensitive a boundary layer would respond to changes in the values of a, b and f, using the step function. For this purpose, only some values of angles of attack, namely: 9^o, 11^o, 15^o and 20^o were selected; these are critical points on the lift curve of the S809 airfoil.

3. Results

Figure 2 compares the various computed results with the experimental data at angles of attack 9^o and 11^o. It can be seen that the lifts are quite sensitive to small changes in the values of a, b and f. Actually, several numerical experiments had been performed to weed out the unreasonable ones; only the more meaningful results are demonstrated here.

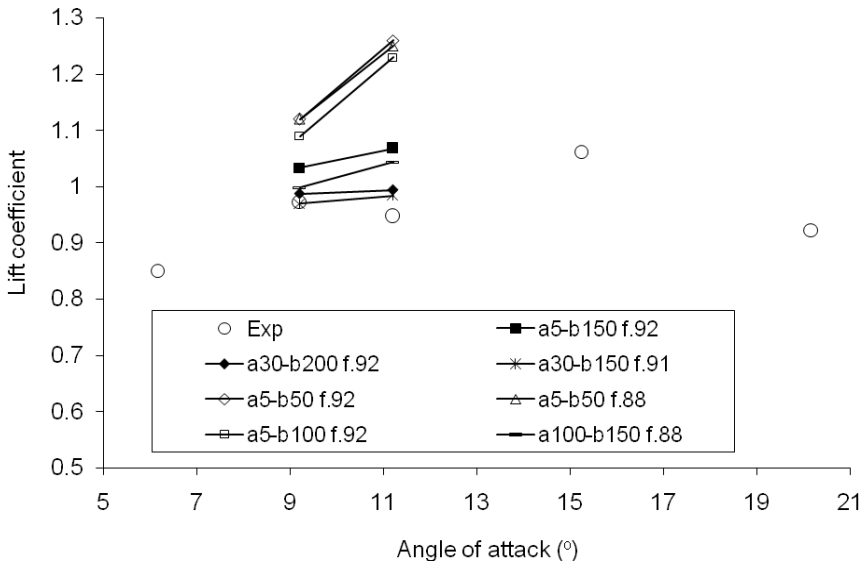

Fig.2 Effects of a, b and f in the step damping function on the lift coefficients.

After getting the feel for the sensitivity of the response, more numerical experiments were performed; the results of which are shown in Fig. 3 wherein it is observed that the characteristic dip and rise of the lift distributions are captured. The value of f a and b in the

ranges 0.90-0.91, 5-10 and 100-200, respectively, were found to be acceptable. Note that the range of acceptable f is very narrow.

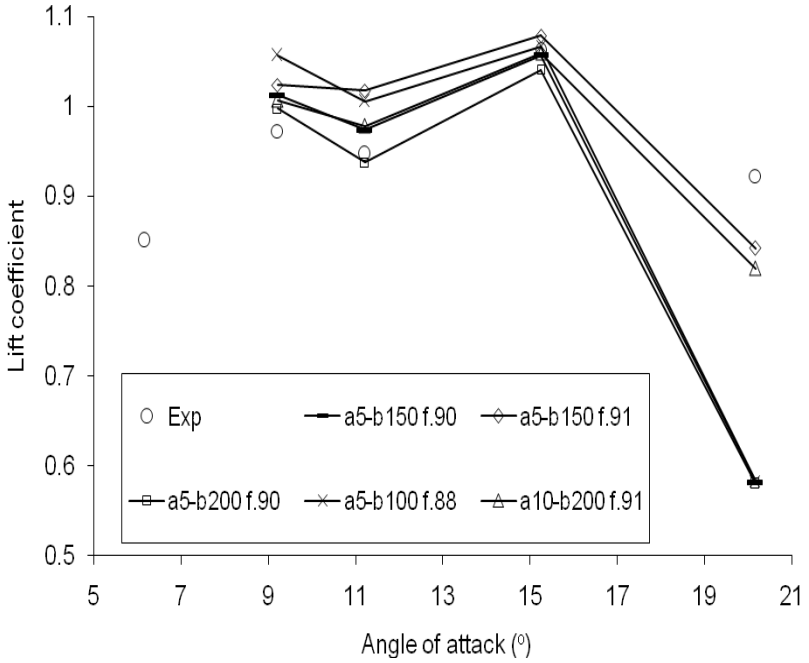

Fig. 3 Effects of a, b and f in the step damping function on lift at high angles of attack.

From the knowledge and experience gained in the parametric study of the step damping function, a continuous function is now proposed as,

$$f_{SST} = 0.1 + \{1 - 0.1\tanh[(0.03y^+)^4]\} \times \{0.9 + 0.1\tanh[(0.005y^+)^8]\} \qquad (4)$$

This damping function is the product of two hyperbolic functions; it was designed (by trial and error) for a rapid rise in the buffer zone and a gradual decrease in the log-law zone, as shown in Fig. 1 (dash line.)

Figure 4 compares the experimental results for lift on the S809 airfoil [16] to three computations, namely: 1) the present model by using the continuous damping function (denoted as SST+), 2) the 2-equation $k-\omega$ SST model (denoted as SST) and 3) the 4-equation $k-\omega$ SST turbulence model with transition [8] (denoted as SST-T.) This last turbulence model is an enhanced version of its 2-equation counterpart wherein a model for transition to turbulence is also incorporated. It is clearly seen that, in the stall region, the SST+ results compare much more favorably to the experiment than those of the other two models. The improvements are not only in a quantitative manner but also in a qualitatively manner, notably the dip and rise of the distribution right after the incipient point of stall at about 10 degree angle of attack. Drag coefficient plot, shown in Fig. 5, also indicates that SST+ results are superior to other models.

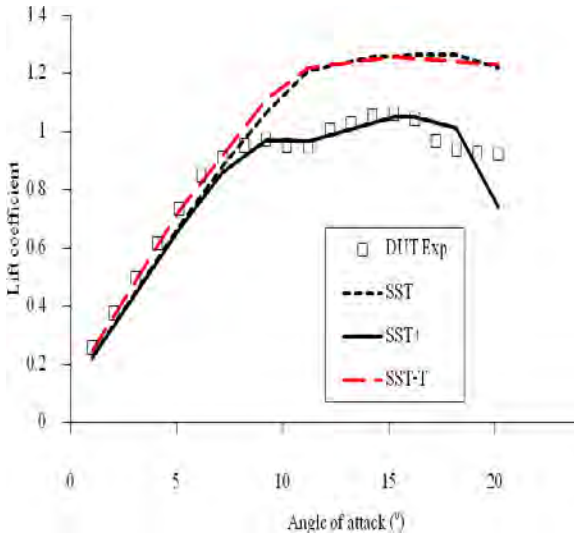

Fig. 4 Lift predictions on S809 airfoil using present and original turbulence models

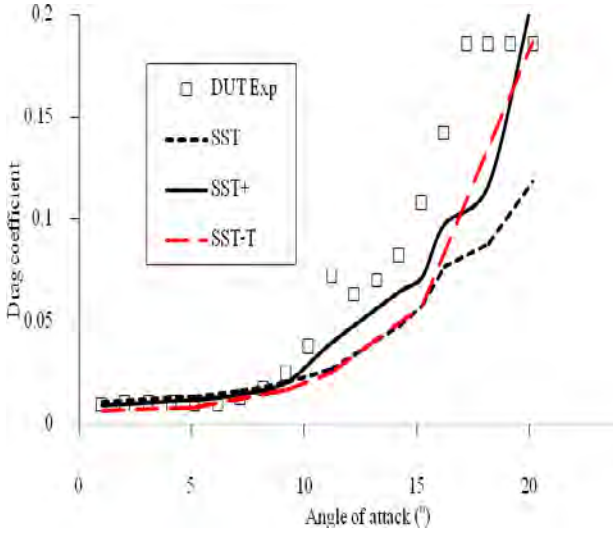

Fig. 5 Drag predictions on S809 airfoil using present and original turbulence models.

It is evident that in the low angle of attack region where the flow is still attached, SST-T gives best results but from the stall point onward SST-T exhibits over-predictions much in the same trend as SST. This perhaps is due to the fact that when flows separate on the suction side there is no transition regions left to give an advantage point to SST-T.

The predicted pressure distributions on the S809 airfoil surfaces at 14^o and 20^o angles of attack are shown in Figs. 6 and 7, respectively. The figures confirm that SST+ gives better overall agreements to the experiment than SST and SST-T. Specifically, the points of separation predicted by SST+ agree better with the experimental results; this is the main reason why it can predict aft-stall lift coefficients more accurately.

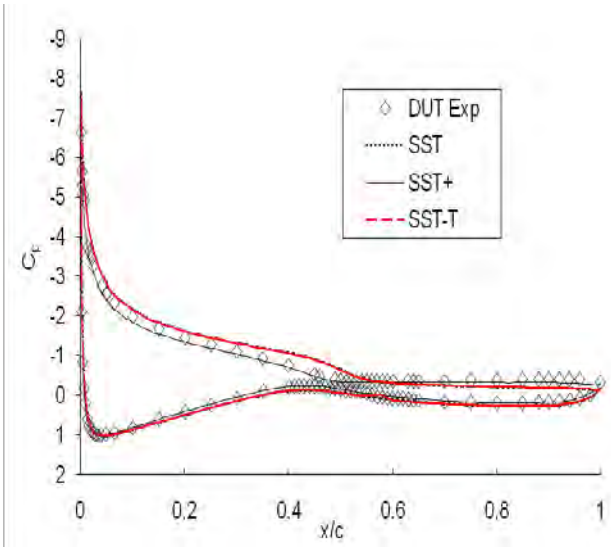

Fig.6 Comparison of pressure distributions on S809 airfoil at 14^o angle of attack

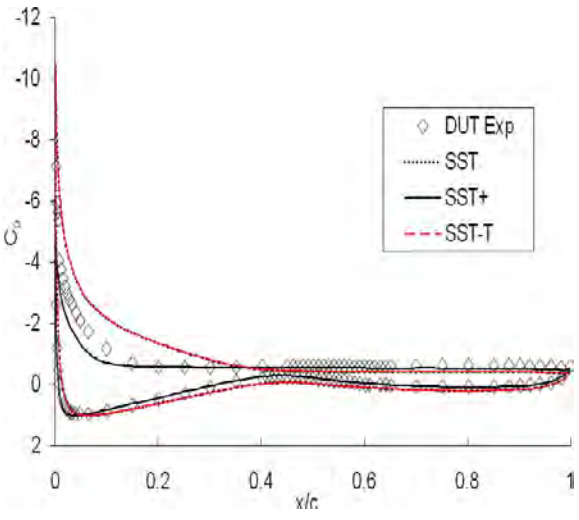

Fig.7 Comparisons of pressure distributions on S809 airfoil at 20^o angle of attack

The incipient of separations can be noticed as the point where the pressure distributions on the suction side are leveled off. Again, SST and SST-T give almost identical results.

To verify that the improved results obtained by the adjustment made to the buffer zone was not specific to an airfoil, flows over another airfoil, the NACA 63-215 [17] were solved under similar conditions. The results are shown in Figs. 8 and 9. Again, SST+ gives much better results than the original models, both quantitatively and qualitatively.

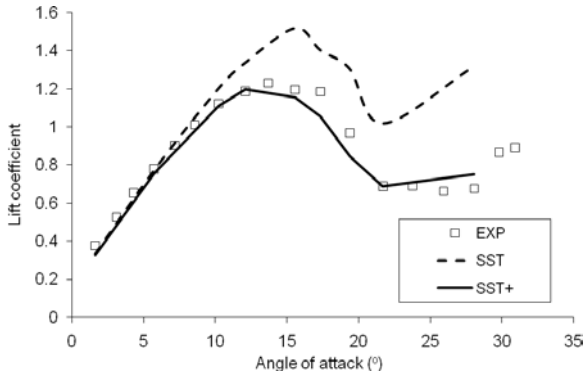

Fig.8 Comparison of lift between modified and original turbulence model.

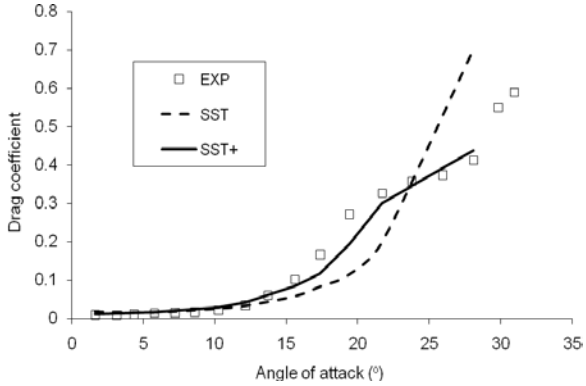

Fig.9 Comparison of drag between modified and original turbulence model.

4. Discussion and Conclusions

It could perhaps be reasoned that the improvements in lift and drag predictions over airfoils after stall were caused by the eddy viscosities in the buffer zones being reduced to about the right levels so as to compensate for the overall collective effects of the transition regions upstream that were neglected by the fully-developed turbulence model. In addition, compensations were also automatically provided for the local phenomena occurring within the buffer zones.

It has been evident that the behavior of a turbulent boundary layer over an airfoil is very sensitive to events in the buffer zone. A small change in the levels of turbulence intensity in the buffer zone could produce a dramatic change in the overall response of the separated flows on airfoils resulting in large changes on lift and drag.

By limiting the turbulence intensities (eddy viscosities) in the narrow buffer zones of turbulent boundary layers by about 10% together with the use of the $k-\omega$ SST turbulence model, this investigation has demonstrated that predictions of lifts and drags (after stall) on two independent airfoils were much improved. The improvements were evidently due to the reductions in the delay of incipient separation points which in turn were caused by the boundary layer being less energetic since the eddy viscosities (hence momentum transfers) were limited.

Impact of ambient turbulence on performance of a small wind turbine

William D. Lubitz[1,*]

[1] *University of Guelph, Guelph, Ontario, Canada*

Abstract: High resolution measurements of wind speed and energy generation from an instrumented Bergey XL.1 small wind turbine were used to investigate the effect of ambient turbulence levels on wind turbine energy production. It was found that ambient turbulent intensity impacts energy production, but that the impact is different at different wind speeds. At low wind speeds, increased turbulence appeared to increase energy production from the turbine. However, at wind speeds near the turbine furling speed, elevated turbulence resulted in decreased energy production, likely to turbulent gusts initiating furling events. Investigation of measurements recorded at 1 Hz showed a time lag of one to two seconds between a change in wind speed and the resulting change in energy production. Transient changes in wind speed of only one second duration did not impact energy production, however, longer duration changes in wind speed were tracked reasonably well by energy production.

Keywords: *Small Wind Turbine, Turbulence, Gusts, Wind Energy*

1. Introduction

Turbulence in the approaching wind can have a significant impact on the power output of wind turbines. This is particularly important for smaller wind turbines, which in practice are often located near buildings, trees and other obstacles. Some small wind turbine installations may experience inflow turbulence intensity many times greater than an open field site.

Current power curve representations do not account for the impact of turbulence on small turbine energy production. For example, curves based on IEC 16400-12-1 are statistical averages of power measurements binned by wind speed, whereby the variance of the data is lost [1]. This approach cannot properly account for site-varying levels of turbulence [2]. IEC 16400-12-1 does not specifically limit turbulence levels of measurements used in power curves, and the resulting power curves provide no guidance on how differing levels of turbulence will affect the power production of the turbine. It can be argued that the effect of site specific turbulence levels in large turbines is manageable, however small turbines may be tested under this or a similar standard while experiencing a wider range of ambient turbulence levels, creating an immediate need to address the impact of site turbulence and provide useful information in the context of the wind turbine power curve.

Ambient turbulence and wind direction variance both have significant impacts on small wind turbines. The smaller masses and length scales of small wind turbines mean that the impacts of turbulence on small turbines will be different from utility scale turbines [3]. Elevated turbulence levels can result in lower wind energy production and greater mechanical stresses on turbine components [4]. The smaller size, gustier operating environment and passive yaw systems associated with small turbines mean they are much more likely to be operating in a yawed state when the turbine cannot align itself to gusting winds [5]. The power output of a horizontal axis wind turbine falls rapidly when the turbine is not aligned to the wind, with a cos^2 dependence on relative wind angle [6]. Elevated turbulence intensity has been found to be the most important factor in reducing turbine structure fatigue life [4], and turbulence intensity impacts furling behaviour [7].

The effect of turbulence on power output is more difficult to generalize, since turbulent gusts impact wind alignment, airfoil performance and furling/power limiting. A small turbine tested in a high turbulence intensity environment was found to temporarily shut down more often due to high gust speeds exceeding limits [8]. Smith [9] used long term small wind turbine performance measurements collected at the National Renewable Energy Laboratory (NREL) to produce power curves and estimate annual energy production (AEP) for seven small wind turbines at varying levels of observed turbulence intensity. The small wind turbines showed a 9% to 32% difference between AEP at the best and worst turbulence levels. Most of the turbines had lower AEP in both the extreme high and low turbulence levels, although one (Skystream) exhibited a trend of increasing AEP with increasing turbulence intensity..

The goal of this study was to determine the impact of varying turbulence conditions on the performance of a representative small wind turbine. High resolution (1 minute and 1 Hz) data from a Bergey XL.1 1 kW capacity horizontal axis wind turbine were analyzed to explore the impact of turbulence on turbine power output.

2. Methodology

A Bergey XL.1 small wind turbine was used in this study. The Bergey XL.1 is an upwind, horizontal axis SWT with a rated capacity of 1.0 kW. It consists of a three blade, 2.5 m diameter fixed-blade rotor directly coupled to a variable speed permanent magnet alternator. This turbine was chosen due to its mechanical and control system simplicity, and because it has been the subject of a wide body of prior studies documenting its performance and operation [10-13].

The Bergey XL.1 was mounted on an 18 m tall, 0.114 m diameter galvanized steel tubular tilt-up tower. An additional 18 m tall, 0.152 m diameter tubular tilt-up tower was installed 13.4 m to the north of the turbine tower to serve as a meteorological mast for obtaining reference measurements of hub-height wind speed.

NRG 40C cup anemometers and one R.M. Young 81000 three-dimensional sonic anemometer were used for this study. The sonic anemometer was mounted on a short arm such that it's sensing volume was 20 cm directly below the rotor disk when the wind was from the prevailing direction of southwest. One NRG 40C and an NRG 200S wind direction sensor were located at the top of the reference mast 1 m above hub-height on separate 1.53 m booms. All NRG 40C anemometers used in this study were manufactured during the initial months of 2009 and calibrated by Otech Engineering (Davis, CA, USA). These calibrations were verified in the University of Guelph wind tunnel before experiment installation.

Power from the turbine was measured by tracking the voltage across a 2180 W, 2.0 Ω dynamic breaking resistor that dissipated the turbine's electrical power output. The 2.0 Ω resistance was selected to mimic the turbine's intended operation as part of a battery charging system under high load, while keeping the parameters needed to characterize electrical performance to a minimum. Additional sensors were installed to measure the yaw angle and rotor speed of the turbine. Ziter [14] gives further details of the experimental equipment.

The turbine and meteorological tower were installed at a representative SWT site on a farm in Oxford County, southwestern Ontario (43°18'N, 80°33'W). The collocated towers were installed in a field (grass, approximately 0.1 m tall) open for several hundred meters to the west and predominantly open to the north and southwest as well. The prevailing wind was from the southwest. Low rise buildings and trees to the east were all more than 100 m distant.

Other potentially significant obstacles included a small cluster of trees located 160 m to the northwest and a barn located almost 200 m to the southwest. Potentially disturbed direction sectors were determined according to IEC 61400-12-1 criteria [1]. Data from disturbed sectors were not used.

3. Results

3.1. One Minute Data

Fig. 1 shows the overall measured XL.1 power curve, based on binning and averaging of 1 minute averaging period, air density-corrected data from undisturbed sectors. The study turbine exhibited a cut-in speed of 4 m/s, and began furling at 9 m/s. Note that because a constant 2.0 Ω load was used, these power curves are not comparable to the manufacturer's or other power curves measured using a grid connection or battery charging controller. The reduced energy generation above 9 m/s for the study turbine is believed to be due to the addition of a nacelle anemometer and solar panel on the tail boom (that were not used in this study), which resulted in earlier furling than would otherwise occur.

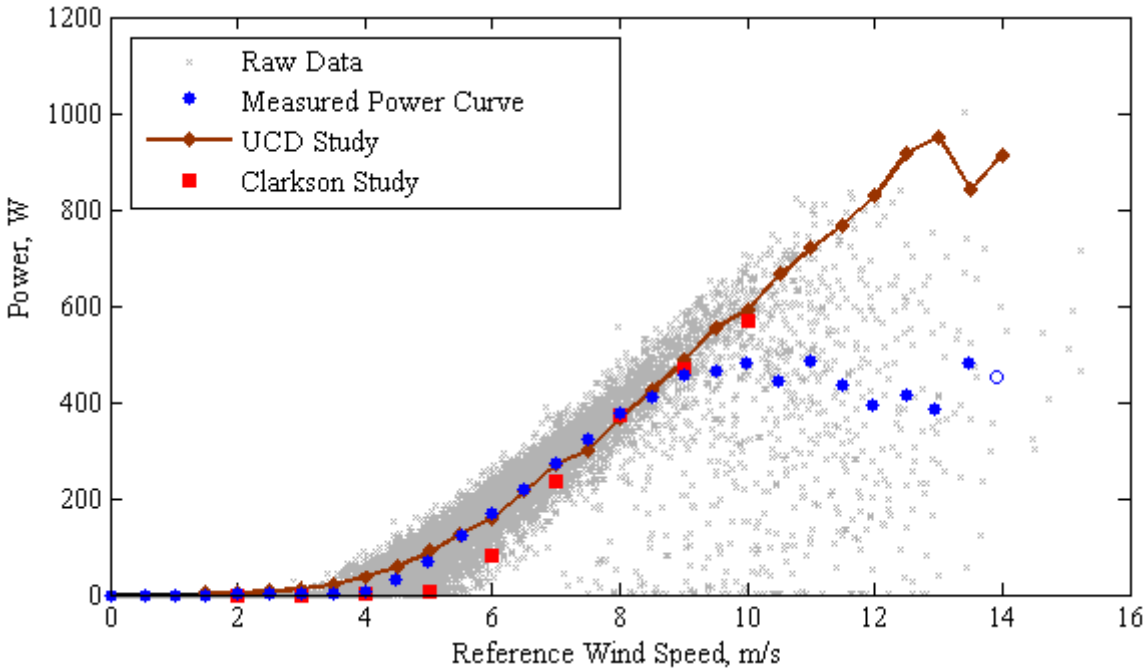

Figure 1. Measured Bergey XL. 1 power curve using a 2 Ω resistive load, with comparisons to UCD [12] and Clarkson [10] XL.1 power curves also measured with a 2.0 Ω load.

Next, the data from the turbine was divided into three categories based on turbulence intensity (which is the standard deviation of the wind speed divided by the mean wind speed during the 1 minute averaging period). The median turbulence intensity for the entire dataset was 0.173. Low turbulence intensity was classified as turbulence intensity less than 0.14. Turbulence intensity greater than 0.18 was considered high. Turbulence intensity between these two values was classified as intermediate. Figure 2 shows the number of observations in each wind speed bin and turbulence category.

Figure 3 shows the percentage difference between the overall power curve and three power curves derived from the categorized data. Low turbulence intensity consistently results in reduced power output (approximately -2%) between 4 m/s and 7 m/s, corresponding roughly to the operating range above cut-in and below the beginning of furling. The results for the

case of high turbulence are less consistent, with the percent increase in power output varying between 0% and +4% in the wind speed bins between 4 m/s and 7 m/s. This variability is likely due to the reduced number of high turbulence intensity observations in individual bins, compared to low turbulence observations. The intermediate differences are almost a mirror image of the low turbulence differences in Figure 3, again supported that these make up most of the observations.

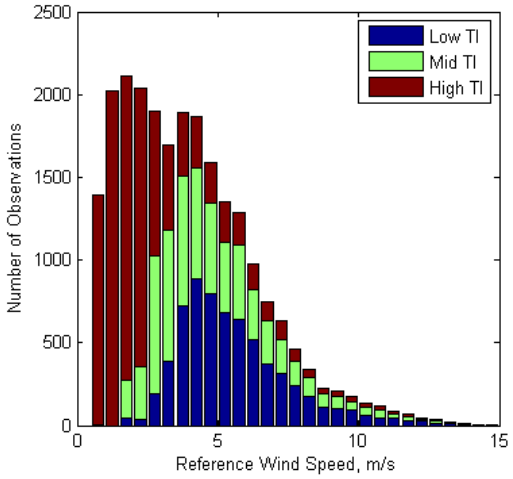

Figure 2. Number of observations by turbulence level and wind speed bin.

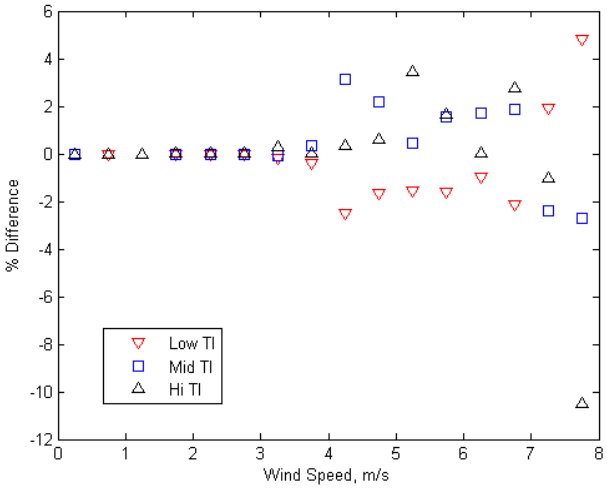

Figure 3. Percent difference between stratified and overall power curves.

The impacts of turbulence on furling were more pronounced. Figure 4 shows the wind percent difference between each of the three stratified turbulence power curves and the overall power curve, over the full range of available data. It is apparent that low turbulence intensity results in increased energy production, likely due to a reduction in intermittent furling and associated hunting. It should be noted that significant variability between bins is likely due to the small number of observations in each bin (Figure 2) at the higher wind speeds.

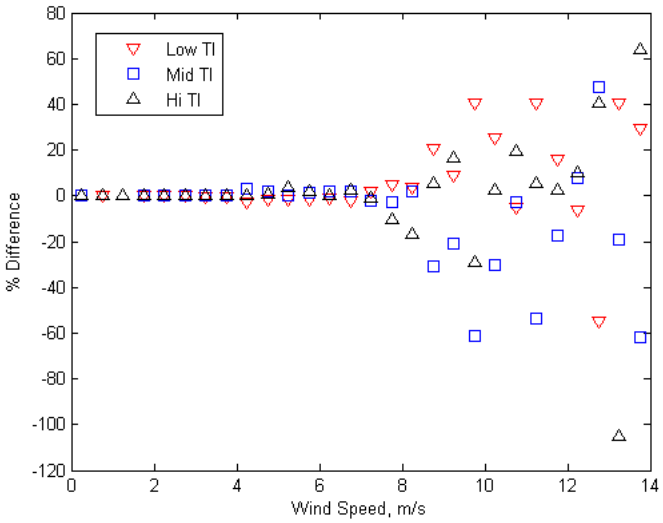

Figure 4. Percent difference between stratified and overall power curves.

Some impact of turbulence was noted at intermediate wind speeds above the cut-in wind speed. The effects of turbulence were found to be most pronounced at wind speeds approaching the furling speed of the turbine, and gusting was observed to cause intermittent

furling and consequently significant hunting and off-axis orientation, reducing power generation.

3.2. One Second Data: Transient Effects

The one second data from the turbine allows direct observation of the turbine response to variations in wind speed. Figure 4 shows 100 seconds of energy production and wind speed. Note that the wind speed shown is that measured by the sonic anemometer immediately below the rotor disk. A prior study [14] found the magnitude of this wind speed to be higher than the reference wind speed, however, turbulence levels were consistent between the two anemometers, and the sonic anemometer is a much closer indication of the wind experienced by the turbine rotor than the reference wind speed, which is over 13 m horizontally distant from the turbine.

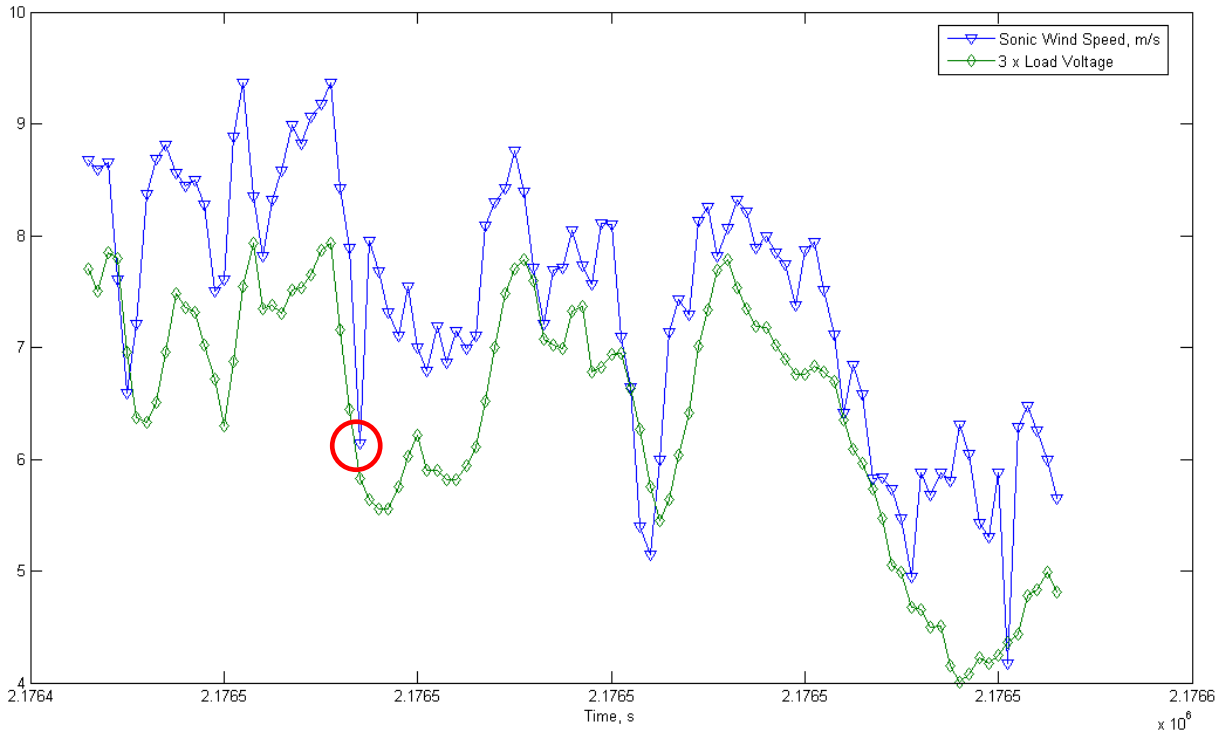

Figure 4. Example of 1 second sonic anemometer wind speed measurements and turbine energy production as measured by voltage across the resistor.

It is apparent that the turbine energy production is approximately one to two seconds delayed relative to the wind at the rotor disk, however, the rate of change and duration of wind speed perturbations appears to influence this. The circle in figure 4 s hows a transient gust of approximately one second duration that is not apparent in turbine energy production. However, changes in wind speed with time constants of many seconds are reasonably well tracked by energy production, factoring in the one to two second delay.

4. Discussion

The UC Davis turbine shown in Figure 1 is mounted on a 9 m mast on the roof of a 3 storey building that contains a penthouse and other roof top infrastructure, on a campus surrounded by other buildings and trees. It would be expected that this turbine would experience higher

ambient turbulence than the Clarkson turbine or the one in this study. With that in mind, it is interesting to note that the UC Davis turbine appears to have a lower cut-in wind speed (at about 3 m/s) than the 4 m/s overall cut-in speed observed for our own turbine, and the 5 m/s cut-in speed of the Clarkson turbine.

Very high turbulence levels resulted in overall decreased performance. It should be noted there are inherent limitations in using a single value of turbulence intensity, which combines all turbulence scales in a single measurement, as the only measure of wind speed variability. It was observed that turbulence impacts depended on the time scale of the turbulence: due to inertia, the turbine had difficulty responding to short time scale turbulence events. This could lead to reduced power output. However longer time period gust events that could be tracked by the turbine would be expected to result in greater overall performance when data was averaged, due to the non-linearity of turbine response to wind speed.

Applying a power curve produced at one level of ambient turbulence to a site with different ambient turbulence is likely to introduce significant errors in site-specific predictions of power output. The results of this study suggest that including additional turbulence information in the performance evaluation of small wind turbines could result in more accurate characterization turbine performance.

5. Conclusions

Measured data from a small wind turbine showed that turbulence has a range of impacts on a small wind turbine. Specifically,

- Turbulence levels had a small but noticeable impact on overall power output at wind speeds between cut-in and furling.
- Low turbulence levels resulted in increased power output at wind speeds associated with furling, likely due delayed onset of furling because of the presence of fewer gusts above the mean wind speed.
- Turbine energy production lagged changes in wind speed by one to two seconds. While changes in wind speed occurring over many seconds were reasonably well tracked by energy production, transient events of approximately one second duration were not tracked by energy production.

The results found here were broadly in agreement with other studies of the impact of turbulence on small wind turbines. The interaction of turbine with turbulent winds is complex and will vary depending on turbine characteristics.

Abstract: Wind energy has the advantage of being a priority sector of the Greek government. Greece has a considerable potential for electricity generation from wind not only in the island area but also in mainland. This paper deals with the current status of wind energy in Greece and the presentation of technical and economical feasibility of a 6.6MW wind farm applied to a potential wind farm site located in Greek mainland (Rentina-Karditsa). Wind speed, prevailing wind direction and temperature measurements are performed for a period of one (1) year (from 11/5/2009 to 11/5/2010). For economic consideration two different technological scenarios based on capacity factor (CF) are investigated and compared with respect to net present value (NPV), internal rate of return (IRR) and payback period (PBP) criteria. The profitability analysis shows that larger installed capacity with larger rated power wind turbines present higher IRR of the investment. The sensitivity analysis backs up the findings.

Keywords: *Renewable energy, Wind energy, Wind farm techno-economic assessment, RES legislation*

1. Introduction

Recently, there has been a considerable expansion of distributed generation (DG) technologies, thanks to progress in reliability, in competitiveness and operation know-how and incentive policies adopted by many developed countries. The presence of DG facilities brings benefits both to the electric power system and the total energy system. With DGs energy can be generated directly where it is consumed. As a consequence, transmission and distribution networks are less charged; safety operation margins increase, and transmission costs and power losses are reduced. The spread of DG technologies enhances supply safety in the energy field by reducing dependence on fossil fuels [1-4].

Wind power is driving growth in the renewables sector and represents a huge investment potential in Greece. The superb wind resources in Greece are among the most attractive in Europe, with a profile of more than 8 m/s and/or 2,500 wind hours in many parts of the country. Capacity increased by an average of 30% annually between 1990 and 2003 and almost 30% of total capacity was installed in the period of 2003-2004. It is estimated that in addition to the 1200-plus MW operating currently at wind farms, a further 7,500 MW will be installed by 2020. A detailed presentation of current and future wind farm installations on Greek islands is given in Ref. [5].

Electricity from Renewable Energy Sources, High Efficiency Cogeneration of Heat and Power and Other Devices». The main scope of the Law 3468 is to establish an adequate legislative and regulatory framework in order to support investments in renewable energy sources (RES) and High Efficiency cogeneration of heat and power (HE-CHP) energy sectors and eventually increase the penetration of these resources in the energy mix of the country. Aiming at conveying to the Hellenic legislation Directive 2001/77/EC of the European Parliament and of the Council of 27 September 2001 on the «Promotion of Electricity Produced from RES in the Internal Electricity Market», the National target is set to a 20.1% RES contribution on the total electricity production by 2010 while for 2020 the target is 29%. In the internal electricity market, the production of electricity from RES and HE-CHP are promoted in priority over other means of power production with specific regulations and principles. Until 2020, in Greece to achieve the target set by EC, the remaining RES

contribution to total electricity (excluding the large hydro) should be 58,37% wind, 2,73% Small Hydro, 2,73% biomass, 1,94% solar thermal, 22,95% photovoltaic energy (PV) and 11,28% other technologies.

On 4 June 2010, the Hellenic Parliament approved Law 3851 referring to "*Acceleration of RES growing facing climate change and other legislation related to Ministry of Environment, Energy and Climate Change subjects*". Law 3851/10 was published in the Official Gazette of the Hellenic Republic and is in effect since then. The main scope of New Law 3851 is the increased utilisation of the vast renewable energy resource of the country together with complying with the environmental targets of the Kyoto protocol. The attraction of large scale energy investments is also envisaged, in parallel with simplification measures for the necessary licensing procedures.

Wind energy has the advantage of being a priority sector of the Greek government. Greece has a considerable potential for electricity generation from wind not only in the island area but also in mainland. This paper deals with the current status of wind energy in Greece and the presentation of technical and economical feasibility of a 6.6MW wind farm applied to a potential wind farm site located in Greek mainland (Rentina-Karditsa). For economic consideration two different technological scenarios based on CF are investigated and compared with respect to NPV, IRR and PBP criteria. The profitability analysis shows that larger installed capacity with larger rated power wind turbines present higher IRR of the investment. The sensitivity analysis backs up the findings.

2. Case study: 6.6 MW wind farm in Greek mainland

The proposed wind farm site is located in the Prefecture of Thessaly (Karditsa-Rentina) in the heart of Greek mainland. The site, known to local people as “Lepouchi”, covers an area of 200.000 m^2 (Photos 1, 2) and is situated 3km from Rentina village. It is near to Rentina-Fourna national road and therefore quite favorable for wind turbines transportation. However, an improvement of an existing 500m forest road would be required to provide easy access to wind farm site. The proposed site is almost a flat-shrubbery area with presence of rocks, suitable for placement of tower foundations, roadways and crane pads. It is also favorable from the environmental point of view due to absence of wildlife, noise and visual issues. However, an important drawback is its distance (25km) from the nearest electrical substation (situated at Makrakomi-Lamia). The excessive cost associated with electrical issues is considered in economic analysis and affected the economic performance of proposed wind farm installation.

2.1. Analysis of wind power generation input parameters

The data was collected for the period from 11/5/2009 to 11/5/2010 with availability 98,7%. The wind speed data was the major parameter for wind energy generation and utmost care was taken in its collection. Two cup anemometers (one as primary and the other as auxiliary), wind direction vanes, temperature sensor and humidity sensor, certified according to ISO 17025:2005, were installed within the wind farm area (latitude 39º 05’ 02,4’’ and longitude 21º 56’ 46,8’’) placed on the top of a 30m metallic pole. A data recorder STYLITIS 40/41 (SYMMETRON) and a PV 10Wp/12V connected to a lead battery 12V/12Ah were also used.

Wind Speed

Significant variations in seasonal or monthly average wind speed are common over most parts of Greece. In the proposed site, the monthly average wind speed (Table 1) is high during

November-February and reaches a maximum of 7,5m/s because of South-West winds. The annual average wind speed is estimated 6m/s ($\pm 0{,}26$m/s) at wind turbine height of 80m.

Fig 1: Geographic location of wind farm site

Fig 2: Wind farm site

Table 1: Monthly average wind speed

Month	Average Wind Speed (m/s)	Data Availability (%)
January	7,3	96,1
February	7,5	97,0
March	5,3	96,0
April	4,4	100,0
May	4,0	98,0
June	5,0	100,0
July	4,0	95,0
August	2,9	100,0
September	2,9	100,0
October	5,2	95,7
November	5,9	97,1
December	7,4	95,2

Relative Humidity

The relative humidity of air depends on the amount of water vapor in the air, which in turn affects the air density. Moist air is less dense than dry air since water molecules is lighter than either a nitrogen molecule or an oxygen molecule, which are the major constituents of dry air. As the relative humidity increases air density decreases. The air density also depends on temperature and pressure and is given as follows:

$$air density = D\left(\frac{273{,}15}{T}\right)\left[\frac{B - 0{,}3783e}{760}\right] \qquad (1)$$

where D is the density of dry air at standard atmospheric temperature (25 C) and pressure (100kPa) (D=1,168kg/ m^3), T is the absolute temperature in Kelvin, B is the barometric pressure in torr and e is the vapour pressure of the moist air in torr. For the proposed site of wind farm installation, the mean yearly temperature is 10,4C and the monthly variation of relative humidity for the given period is between 50% and 70%.

Generation Hours

The generation hour is the period in which the wind turbine produces electric power from the energy available in the wind:

Generation hour = total number of hours in a year – (low wind hours + wind turbine maintenance hours + turbine breakdown hours + grid maintenance hours + grid breakdown hours)

Wind power generation hour is directly governed by the design of wind turbine, especially the cut-in and cut-out speed of wind turbines. A lesser cut-in speed and higher cut-out speed significantly improves the generation hours. Reduction in stoppage hours of wind turbine due to uncontrollable factors such as grid unavailability and mechanical breakdown improves the wind power generation. Periodic maintenance of turbine and grid are unavoidable and if done during off-seasonal period (when the average wind speed is below the cut-in speed) reduces energy loss and increases the total energy generation of wind turbine.

2.2. Wind farm energy generation

In order to calculate the wind farm energy generation is essential to perform the wind flow calculations. This is carried out using the *MS3D3H/3R* model which is integrated to *WindFarm* code. Then the *WindRose* code was used to estimate the total energy production for different capacity wind turbines. Net energy production is calculated using the energy losses related to wind turbine availability due to technical reasons (such as wind turbine malfunction, stoppage time for maintenance etc), wake and transmission losses. Two different technological scenarios were investigated where different capacity wind turbines were proposed.

Technological Scenario I (TS-I)

Four (4) wind turbines VESTAS V82 – 1,65MW were considered forming a 6.6MW wind farm. Table 2 shows the yearly total energy production per wind turbine, the wind direction and wake losses. Figs. 3-4 show the yearly energy yield (net) and the changes of energy yield due to wake losses per turbine respectively. It was calculated that gross energy production of 12,77GWh/year would be delivered to the grid resulting to 1930 generation hours and CF of 22,1%.

Table 2: Yearly total energy production per wind turbine, the wind direction and wake losses (TS-I)

TOTAL ENERGY YIELD

2.3 A systematic economic assessment

The analytical technoeconomic general model is the computerized renewable energy technologies (RETs) assessment tool 'RETScreen' [6] which is used for preliminary evaluation of the technical feasibility and financial viability of potential grid-connected wind

installations anywhere in the world. For Greece in particular, it takes into account the prevailing Greek national development and energy laws, the government's subsidy and the prices applicable for buying or selling energy to the PPC by the electric energy producer.

For the technological scenarios TS-I and TS-II, different economic and financial feasibility indices are calculated such as the year-to-positive cash flow, IRR, ROI and NPV. The results of the installed wind power plants are shown in Figs. 6-7 respectively. The initial capital cost for TS-I is 8.500.000€ and for TS-II is 9.500.000€. The owner covers 25% of initial cost and the rest 75% is provided as a loan by private banks (10-year period and interest rate of 6%). The owner also decided to use the extra bonus 20% increase of feed-in tariff provided by Law 3851/2010 (i.e. 105€/MWh).

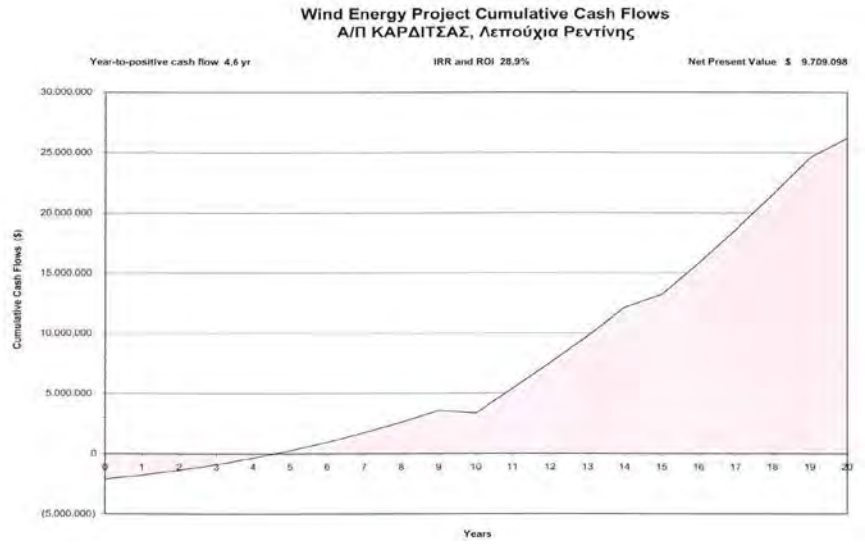

Fig. 6: Wind farm economic analysis (TS-I)

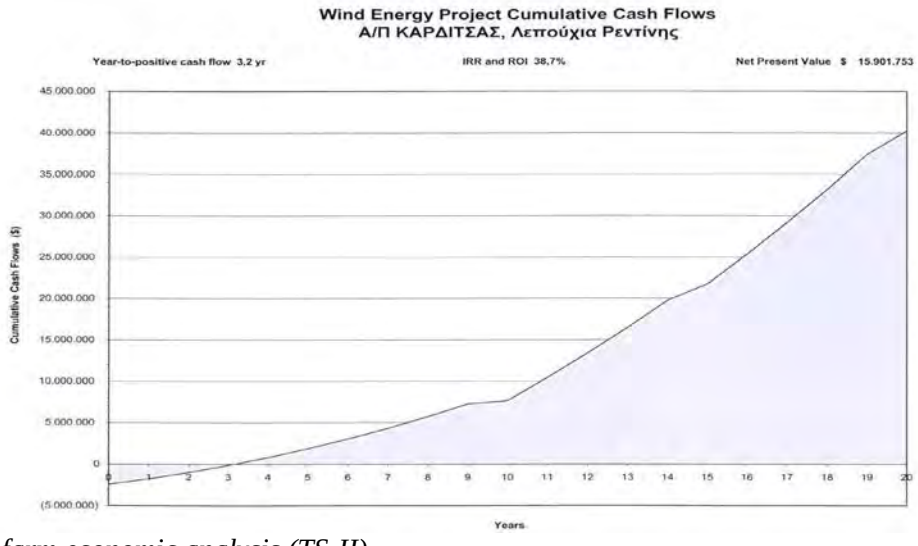

Fig. 7: Wind farm economic analysis (TS-II)

3. Conclusions

Two different technological scenarios were investigated and cash flow economic analysis was performed under the new legislation for RES penetration in Greece. From the results shown in Figs 5-6, it is concluded that Technological Scenario I [four (4) wind turbines VESTAS V82-1.65MW and installed capacity of 6.6MW] constitutes the less profitable investment in comparison to technological Scenario II [larger wind farm of 7.2MW consisted of four (4)

VESTAS V100-1.8MW]. This is due to increased performance of wind turbines in TS-II which compensates for the increased initial cost of the investment. For the particular wind farm installation in the Greek mainland, it was found that larger installed capacity with larger rated power wind turbines presented higher IRR of the investment. Furthermore, the PBP is 7,5 years and 6,2 years for TS-I and TS-II respectively. The results show that the implementation of wind farms in Greek mainland could present a profitable investment despite the fact that the sites are not so favorable compared to the islands. However, the experience of the implementation of wind farms in Greece emphasised the necessity for a simplified licensing procedure and a better coordination through institutions for Environmental Approvals.

The question becomes apparent: where does Greece go from here? According to Greek Ministry of Development, a wind total of 7500MW (including offshore) is planned to be installed until 2020 (while 4000MW of them until 2014). This capacity is limited due to grid stability, due to suggestions from Regulatory Authority for Energy (RAE) for possible excessive charging of consumers and due to public opposition in large scale wind farm installation, particularly in Greek islands. In order to achieve the goal of 7500MW, the Hellenic Parliament approved recently Law 3851 regarding RES electricity. According to this legislation, wind projects can get an extra bonus 20% increase of feed-in tariff, providing that the owner will not apply for a grant to the Greek State. This policy mechanism designed to promote mature wind projects for immediate connection to the grid. Also, the Hellenic State is planning to upgrade the existing grid to overcome grid stability problems and to offer more benefits to local people (such as discounted electricity bills) in order to overcome their opposition.

The main conclusion is that, with respect to electricity supply, wind farm applications will continue to play the most important role in Greece. The country high wind potential through out the year, the increasing environmental sense of Greek population, the elimination of time consuming license procedures, noticed during the implementation of first wind farm installations in Greece, and the improved financial incentives will increase the wind penetration in Greek electricity market.

Optimal spatial allocating of wind turbines taking externalities into account

Jürgen Meyerhoff[1], Martin Drechsler[2,*]

Abstract: Wind power is one of the most promising options for producing energy in a climate-friendly manner. However, besides its environmental benefits wind power generation causes externalities such as impacts on humans and biodiversity. All studies conducted so far show that these externalities can be substantial. The question is how this knowledge translates into a welfare-optimal spatial allocation of turbines that needs to consider both production and external costs. We present a modeling approach for the determination of the welfare-optimal spatial allocation of wind turbines (WT) and apply it to the planning region West Saxony in Germany. The approach combines choice experiments, a non-market valuation method used to measure externalities of wind power, and spatially explicit ecological-economic modeling within an optimization framework. Optimal is understood here as producing a given amount of wind power at lowest social costs. Social costs comprise (i) externalities measured by the (monetized) impact of WT on biodiversity, the distance of the WT to settlements, the height of the WT and size of wind farms, and (ii) the construction and operating costs associated with the WT. We show that the social costs of wind power production can be reduced substantially if externalities are taking into account.

Keywords: *choice experiment, externality, modeling, spatial allocation, welfare-optimal, wind power.*

1. Introduction

Wind power belongs to the most efficient renewable energy sources and constitutes an important component of the energy mix in many countries. In future, wind power is going to expand further to help meeting ambitious energy and climate policy goals. However, despite its doubtless advantages, wind power generation comes along with considerable negative externalities that lead to conflicts with other important policy goals, including human health and biodiversity conservation. Human health is affected because of the shade and noise effects produced by wind turbines (WT) [1]. Visual impacts of WT on landscapes have been considered by [2,3]. Biodiversity is affected especially through increased mortality and habitat loss for birds and bats [4,5]. External costs of wind power have been quantified, e.g., by [6-8]; see [9] for an overview.

The quality and extent of the monetary and non-monetary externalities of wind power considerably depend on the characteristics of the sites selected for wind power development. One the one hand the unit cost of wind-generated electricity depends on the energy produced per year and this depends on the local wind conditions. On the other hand, WT erected in the vicinity of settlements or bird habitats increase the impact on humans and birds. Different sites available for the installation of a WT will have different pros and cons in terms of wind power production costs and external costs. Since the pros and cons of wind power generation vary in space, they can be balanced and conflicts with other policy goals be mitigated through the appropriate spatial allocation of the WT. In the present article we propose a welfare-economic approach that determines the spatial allocation in a way that the social cost of producing a given amount of wind power is minimized. The mentioned balance of the pros and cons is reflected by the fact that the social cost is calculated as the sum of the production cost (e.g., installation and operating costs) and the external costs. The latter comprise the

monetized impacts on human health, biodiversity, etc. and depend on the preferences of the people, i.e. on how they value these impacts.

Despite their advantages such as their analytical clarity and rootedness in economic theory, welfare-economic approaches have been rarely used to optimize the spatial allocation of land use in general, and WT in particular. An example that goes into this direction is found in [10] which explores trade-offs between wind power production and the conservation of two animal species. However, since the analysis does not include any information about social preferences, it cannot determine the welfare-optimal allocation of WT. The above-mentioned studies [6-9] on the other hand, provide the necessary information about social preferences but do not include any assessment or modeling of how the valued impacts depend on the spatial allocation of the WT. As a consequence, they too cannot determine the welfare-optimal spatial allocation. This lack has recently been criticized [11]. The two approaches, spatially explicit modeling of impacts and the economic valuation of impacts have complementary strengths and weaknesses and combining them allows overcoming the weaknesses. In the present paper we follow this route to determine the welfare-optimal spatial allocation of WT in a study region in Germany. For this region we investigate a number of policy relevant questions: (i) how do society's preferences affect the welfare-optimal allocation of WT, (ii) what is the trade-off between the production and the external costs of wind power production, and (iii) what are the consequences of ignoring external cost in the planning of landscapes for wind power production.

The paper is structured as follows. In section 2 we will outline the modeling approach and present the study region. In section 3 we apply the modeling approach to the study region and present the results in section 4. Section 5 discusses the results and draws conclusions for policy design.

2. Methodology

2.1. The modeling approach

The objective of the analysis is to allocate WT in the study region such that a given level of electricity $E_{\min}$ is produced per year at minimal social cost C. The social cost of wind power supply is composed of the production costs C_p and external costs C_e. To determine external costs we define attributes that capture the relevant externalities as identified through stakeholder interviews (see section 3.1 below). The attributes are quantified through spatially explicit models and valued through choice experiments. In the present case the attributes comprise: the loss rate (L) of important species, the minimum distance of WT to settlements (D), the height of the installed WT (H) and the size of wind parks (S). The attributes D, H and S consider the impact of WT on the landscape and ultimately human inhabitants. The disturbance of humans by the noise of a WT depends, among others, on the height of the WT and its distance to the settlement areas. Attribute H considers that WT technologies with different heights may by installed. Attribute S considers that WT may be allocated in larger or smaller wind parks. The production cost and attribute L depend on the time frame. We consider a time frame of 20 years, which is about the life time of a WT, so C_p measures production costs over 20 years and L measures species decline within 20 years. The analysis is carried out in several steps. First we construct the social cost function

$$C = C_p + C_e(L, D, H, S) \qquad (1)$$

where C_e are the external costs associated with the attributes *L*, *D*, *H* and *S*. They are determined through choice experiments (see section 3.1). We further identify the sites that are physically and legally suitable for the installation of a WT. Given these potential sites, WT allocation strategies are formed as described above, considering that the energy target $E_{\min}$ must be fulfilled. For each allocation strategy we determine the associated attributes C_p, *L*, *D*, *H* and *S* and determine the social cost *C*. For given energy target $E_{\min}$, the welfare-optimal allocation of WT, i.e. the allocation that minimizes *C*, is determined through numerical optimization.

2.2. Application of the modeling approach

The approach is applied to the Planning Region West Saxony in Germany that is a part of the Free State of Saxony. The region has about 500,000 households (2005) and covers an area of around 4,300km². Due to its topography the region is fairly suited for wind power production but at the same time belongs to the core distributional area of the endangered Red Kite (*Milvus milvus*). Red Kites have been frequently observed to be killed by WT. The Red Kite therefore forms the focal bird species in our analysis and *L* measures the rate by which the Red Kite population declines as a consequences of the presence of WT in the region [12]. Below we go through the steps of the modeling approach.

2.2.1. Construction of the external cost function through choice experiments

We consider an external cost function which is the sum of the partial external costs $C_y(y)$ associated with the attributes $y \in \{L,D,H,S\}$:

$$C_e(L,D,H,S) = \sum_{y\in\{L,D,H,S\}} C_y(y) \cdot \sum_{t=1}^{T} (1+r)^{-t} \qquad (2)$$

The partial external cost $C_y(y)$ represents the cost for a single year. Since we are considering a time span of T=20 years, we have to aggregate the costs over these 20 years. We discount the external costs at annual rate *r*. We assume that $C_y(y)$ has the shape $C_y(y)=a_y/(y-b_y)+g_y$ (which can describe concave or convex increases or decreases of C_y with *y*) and carry out choice experiments (CE) [13] to determine the parameters a_y, b_y and g_y for all $y \in \{L,D,H,S\}$. CE are based on the assumption that the utility to consumers of any good (i.e., also public goods such as a landscape) is derived from its attributes or characteristics. Due to this focus CE are particularly useful for valuing multidimensional changes. In a CE, respondents are asked to make comparisons among environmental alternatives characterized by a variety of attributes and the levels of these. Typically, respondents are offered multiple choices during the survey, each presenting alternative designs of the environmental change in question and the option to choose the status quo. The record of choices serves as a basis to estimate the respondents' willingness to pay. Changes in welfare due to a marginal change in a given attribute are calculated using the MWTP. It is defined as the maximum amount of income a person will pay in exchange for an improvement in the level of a given attribute provided and can be identified as the difference in C_y associated with the change in *y*.

In the present study we consider the four different attributes *L*, *D*, *H* and *S* with three levels for each attribute to characterize changes in the environment. They are combined to choice sets using an experimental design that allows determination of the independent influence of the attributes on respondents' choices (details of the CE can be found in [9]). The choices of 353 randomly chosen inhabitants from the study region were considered.

2.2.2. Specifying the decision space and modeling the attributes

We start our analysis by identifying which parts in the landscape are physically and legally qualified for the allocation of WT with the help of a geographical information system (GIS) of the region. Broadly speaking, these are open areas distant enough from infrastructure, settlements and nature conservation areas. The analysis focuses on two WT technologies k=1,2. The k=1 type has a hub height of 78m and rotor diameter of 82m, yielding a nominal power of 2MW, while the k=2 type has a hub height of 105m and a rotor diameter of 90m, yielding a nominal power of 3MW. The suitable parts of the landscape are subsequently filled with a grid of points with each point in the grid representing a potential site for the allocation of a WT, taking technical minimum distances between individual WT into account. The number of potential sites is N=1098. Allocation scenarios are defined by deciding for each potential WT site i=1,…,N whether it should contain a WT of type 1 or type 2 or no WT.

The energy yield E_{ik} for each site i and WT type k is calculated by using the technical parameters of the WT and the relevant frequency distribution of wind speeds observed at the spatial location and altitude of the WT hub (for further details see [12]). The wind speed data were obtained from Eurowind GmbH (Köln, Germany). The total energy E_{tot} produced per year in the region is obtained by summing E_{ik} over all installed WT.

The production cost $C_{p,k}$ (over a time frame of 20 years) associated with a WT of type k comprises the construction and operating costs. The construction costs are composed of selling prices, taken from the companies' price lists, and a 10 percent mark-up to cover on-site construction costs, including grid connection. Annual operating costs are typically estimated at five percent of the construction costs (information provided by interviewed WT operators).

Ecological externalities are partly taken into account by prohibiting the erection of WT in areas protected by nature conservation laws. However, protected areas are by no means sufficient to reach the ambitious goals of biodiversity policy. So the impacts of WT on biodiversity have to be considered even if the WT are installed outside the protected areas. We consider L, the percentage of the regional Red Kite population that is lost due to WT over the modeling time frame of 20 years. We model this loss rate as the sum of "marginal" loss rates l_i over all sites i=1,…,N that contain a WT. We assume that the contribution l_i of site i to L is determined by the probability of an individual of the focal species being found at the site. This depends, e.g., on how close the site is to a nest, whether the site is located within a migratory bird route, etc. In the case of Red Kites we assume that l_i is a declining function of the distances of site i to known nests (i.e., WT close to a nest cause a higher collision risk for the Red Kite with the WT than WT at more distance to a nest).

The modeling of the remaining three attributes is straightforward. Attribute D represents the minimum distance of WT to settlements, considering all settlements and installed WT in the region. Attribute H is modeled as the average over the heights of all installed WT in the region. To determine attribute S we apply the wind park method [14] that clusters all WT into wind parks. S is then the average size of those wind parks.

3. Results

3.1. Construction of the social cost function

The choice experiments yield the following MWTP (in Euros per household per month)[1]: 2.13 for an improvement in the Red Kite loss rate L from 10% to 5% per 20 years; -2.18 for a worsening in L from 10% to 15%; 3.18 for an increase in the settlement distance D from 800m to 1100m; and 3.94 for an increase in D from 800m to 1500m. Changes in the other two attributes, H and S, did not lead to a statistically significant MWTP.

The partial cost functions $C_y(y)$ (eq. 2) are fitted to these measured MWTP to obtain the external cost function $C_e(L,D)$ shown in Fig. 1. One can see that external costs increase with increasing externalities, i.e. with increasing Red Kite loss rate L and decreasing settlement distance D.

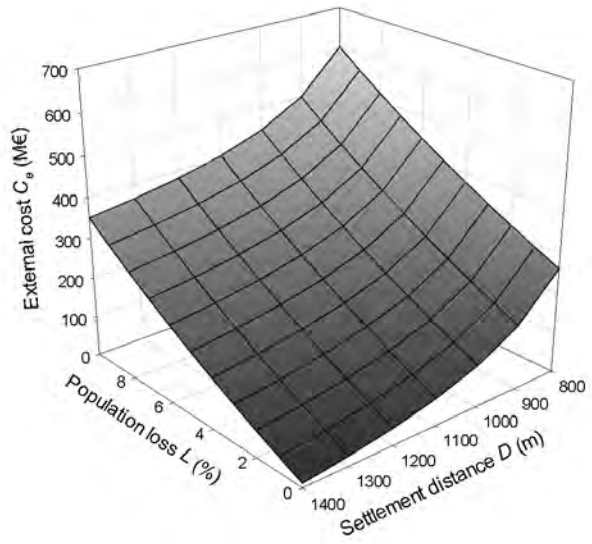

Fig. 1. External cost $C_e=C_L+C_D$ for the study region as a function of Red Kite loss rate L and settlement distance D, considering a time frame of 20 years with annual discount rate r=3%.

3.2. Evaluation of the attributes

Figure 2a shows the production cost C_p (over 20 years, discounted to the present year) for all potential WT sites i in the region. One can see that the production costs are lowest in the south, centre and east, and highest in the north east, which reflects relatively high wind speeds and large energy outputs E_{ik} in the south, centre and east and low wind speeds and energy outputs in the north east.

The external costs are determined by the settlement distance D and the Red Kite loss rate L which is the sum of the impacts l_i associated with each WT site i. The impacts for all potential WT sites are shown in Fig. 2b. We find that the l_i are relatively uncorrelated to the production costs, so there are both "low-conflict" WT sites that have low (high) production costs and low (high) impact on the Red Kite and "high-conflict" sites with low (high) production costs and high (low) impact on the Red Kite.

[1] The conditional logit reveals that only the attributes L and D have a significant influence on respondents' choices among the alternatives presented on the choice sets. Thus, only for these attributes MWTPs are calculated. See [9] for more details on the analysis of the choice experiments.

3.3. The welfare-optimal allocation of WT

The task is to allocate WT to the potential sites i=1,…,N so that the energy target E_{min}=690 GWh per year is achieved at minimal social cost where social cost is given by the sum of production costs (cf. Fig. 2a) and external costs (Fig. 1). The resulting optimal WT allocation scenario is characterized by the following welfare-optimal levels of the attributes: the optimal Red Kite population loss rate is L*=1.2 percent within 20 years, the optimal settlement distance is D*=1,025m and the optimal production cost amounts to C_p*=730 million Euros (sum over 20 years, present value, discounted at 3% per year). Altogether, a number of 122 large WT types but no small WT are installed.

To understand the trade-offs between production and external costs we determined the optimal allocation of WT under the assumption that the MWTP for avoiding externalities are reduced to one tenth of the observed values (cf. section 3.1). By assuming that society places little value to the externalities of the WT (L and D) this scenario considers mainly the production costs, and WT are allocated so that the total production cost (C_p) for reaching the energy target E_{min} are minimized. Consequently, the 690 GWh per year can be produced at a production cost of only C_p*=690 million Euros. While production costs are reduced, the optimal levels of the externalities are increased in this scenario: L* increases to 2.6 percent within 20 years and D* reduces to 800m. That means that the price for reducing the production cost is an increase in the external costs. According to Fig.1, increasing L from 1.2 to 2.6 and reducing D from 1025m to 800m increases the external cost by about 210 million Euros. So altogether, ignoring the externalities saves 40 million Euros of production costs but raises external costs by 210 million Euros and on net raises social cost by 170 million Euros.

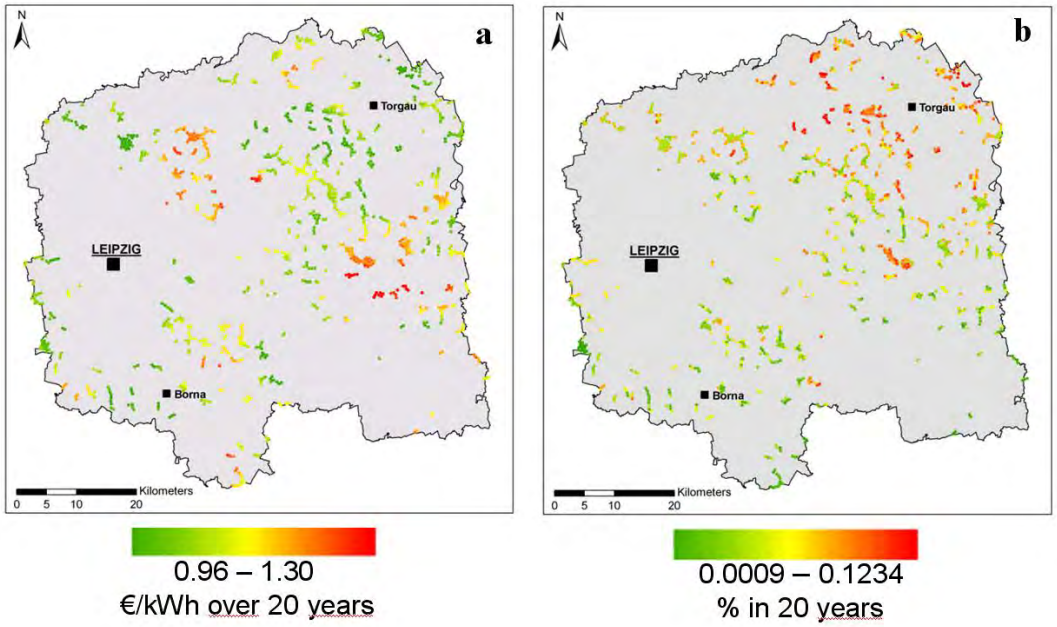

Fig. 2. a: Present value cost of producing 1 kWh over 20 years for each WT site, represented by color scale; b: contribution to Red Kite loss (l_i: see text) of each potential WT site i, represented by color scale. Small WT (k=1) are installed at sites between 750m and 1000m from settlements, large WT (k=2) at larger distances > 1000m.

4. Discussion and Conclusions

Wind power is one of the most promising options for producing energy in a climate-friendly manner. However, it causes negative externalities in terms of adverse impacts on humans and

biodiversity. To alleviate the conflict between the positive impact of wind power on climate policy and its negative externalities, wind turbines (WT) should be allocated so that social costs (i.e., the sum of wind power production costs plus external costs) are minimized with regard to the desired climate-friendly energy target. Determining such an allocation ex ante requires the combination of different methods, including economic modeling of the production costs, modeling of the non-monetary external effects, monetary valuation of these external effects, and numerical optimization.

The goal is to reach a certain energy target in a concrete region ($E_{\min}$) in a welfare-optimal manner, i.e. at lowest social costs. To do this, we explored trade-offs between production costs and externalities by combining choice experiments and spatially explicit modeling. It turned out that in the study region the distance of WT to settlements and the impact on a focal species, the Red Kite, represent significant externalities of wind power supply. On the other hand wind park size and height of the turbines are not. The welfare-optimal allocation balances production costs and externalities and minimizes the sum of production costs and external costs. When determining the welfare-optimal allocation of WT in our study region in Germany it turned out that ignoring the externalities and minimizing only the production costs would reduce the production costs by about five percent from 730 million Euros to 690 million Euros but increase the external cost by 210 million Euros each compared to the welfare optimum. Altogether, ignoring the externalities would increase social cost by 210-(730-690)=170 million Euros.

The magnitude of the chosen energy target reflects the importance of producing energy in a climate friendly manner. The optimal magnitude should be chosen such that the regional social costs of wind power production are outweighed by the benefits accruing from reduced CO2 emission. Determining the "globally" optimal level of the energy target, however, was beyond the scope of this study and is a matter of future research.

The numbers obtained in the analysis depend on several assumptions. In the assessment of the impacts of WT on the Red Kite, e.g., we ignored options of on-site management that make sites unattractive for the Red Kite and would thus reduce the modeled collision risk. Moreover, the search range of Red Kites is not circular. Information on the search behavior of Red Kites, however, is difficult to obtain and requires sophisticated field observations. If this information was at hand it could be easily fed into the model.

In the establishment of the external cost function (C_e, eq. (2)) we assumed that it is separable and can be written as the sum of partial costs. This ignores the possibility of interactions so that the marginal willingness to pay for the reduction of one externality depends on the level of another externality. In the choice experiments we searched for such interactions but did not find any significant ones. If they are significant, interactions can be considered by an appropriate adaptation of the shape of C_e.

With regard to the production costs we ignored the spatial variation of grid connection costs. These very much depend on the distance of a site to the next feed in station, and also on whether a solitary WT or a wind park is connected. Generally connection costs per WT decrease with increasing size of a wind park (economy of scale). Taking these factors into account would require detailed knowledge about the present power grid and even more, assumptions how allocation of WT and expansion of the power grid co-evolve. Since the evolution of power grids and the installation of new smart technologies to make existing

power grids effective for renewable energies are currently a hot topic it may be interesting to further explore this issue in future.

Opportunities for co-utilization of infrastructures for wind energy generation

Tarja Ketola[1]

Abstract: The co-utilization opportunities of different infrastructures for wind energy generation will be investigated in this paper. Information is derived from previous research and discussions with Finnish wind energy companies as well as with authorities, environmental organizations and local inhabitants in the Ostrobothnia region of Finland. Wind power can be built in areas where there are already other business activities. These co-utilization areas include harbours, industrial sites, roads, railways and existing masts and towers. Moreover, both natural and cultivated environments have vast co-utilization potentials for wind energy offshore, near shore and onshore like in fields, forests and swamps and on hills and islands. The environmental and socio-cultural considerations are of crucial importance when planning co-utilization in natural environments, and very important also in cultivated environments. Industrial areas are the least environmentally and socio-culturally vulnerable, but the potential partners there are businesses that demand substantial financial benefits from co-utilization cooperation, hence making the economic considerations decisive. Co-utilization projects can mitigate or prevent many undesirable environmental, socio-cultural and economic impacts of wind turbines, if they are holistically and carefully planned. Furthermore, wind turbines as structures can serve numerous environmentally, socio-culturally and economically beneficial purposes.

Keywords: *Wind energy, Co-utilization, Infrastructure, Life cycle assessment, Social acceptance*

1. Introduction

Wind turbines can be short, medium-sized and tall, are they can be located off shore, near shore and on shore. They have a variety of environmental, social, cultural and economic impacts, both positive and negative, which depend on the areas they are built in.

Wind turbines can be built in areas where there are already other business activities, and not only in locations where no other human activities take place. These co-utilization areas include e.g. harbours, industrial sites, roads, railways and existing masts and towers. Wind turbines and wind farms can also be built in cultivated environments, i.e. on fields and fallows. In addition, natural environments, such as forests, fields of flowers, arctic hills, swamps, islands and offshore sea areas, are increasingly used as wind farm building sites.

The environmental and socio-cultural considerations of wind turbines are of crucial importance when planning co-utilization in natural environments, and very important also in cultivated environments. Industrial areas are the least environmentally and socio-culturally vulnerable, but the potential partners there are businesses that demand substantial financial benefits from co-utilization cooperation, hence making the economic considerations decisive.

The starting point of this research is the compiling of a sustainability assessment, i.e. an environmental, social, cultural and economic life cycle assessment (LCA) of wind turbines from previous economic and environmental impact and social acceptance studies on wind power and discussions with Finnish wind energy companies and their interest groups. The opportunities for co-utilization will then be mapped in cooperation with Finnish wind energy companies and their interest groups. Wind turbines as structures can serve numerous environmentally, socio-culturally and economically beneficial purposes.

2. Methodology

This is an exploratory study, which derives its information from previous research[1,2,3,4,5,6,7,8] and discussions with wind energy companies, authorities, environmental groups and local inhabitants of Ostrobothnia at a wind energy seminar organized by the Regional Council of Ostrobothnia in Vaasa, Finland, on 30 September 2010, to discuss regional wind power planning. The author of this paper is a member of the CLEEN WIPO research group with 26 Finnish wind energy companies and seven Finnish research institutes. This research group is currently planning a major research project to enhance wind power (WIPO) building and exports. The CLEEN Ltd is the Finnish energy and environment strategic centre for science, technology and innovation with 44 shareholders (major Finland-based companies and national research institutes) established in 2008 to facilitate and coordinate research in the field of energy and environment. This paper analyses current knowledge of wind power impacts and co-utilization, and maps out some research cooperation possibilities for the WIPO project.

3. Results

Table 1 compiles environmental, social, cultural and economic impacts of wind turbines.

Table 1. Environmental, social, cultural and economic impacts of wind turbines.

Environmental impacts	**Social impacts**	**Cultural impacts**	**Economic impacts**
POSITIVE: +Renewable, natural energy production method +Rescue nature from harmful options +Hardly any CO_2 or other emissions +Hardly any hazards to humans or nature +Compensate within 3-6 months the energy used during their whole life-cycle +Nearly all parts of turbines are recyclable	POSITIVE: +Boost local employment: planning, construction & maintenance +Boost entrepreneurship +Boost research & development +Farmers: can lease land, generate small-scale power for their farms and become large-scale wind power producers	POSITIVE: +Traditional; long experience from windmills +Use and upkeep of local knowhow +Could be integrated into contemporary culture, like windmills were: parts of cultural heritage	POSITIVE: +Plenty of business opportunities +Innovation opportunities for many businesses +Major growth opportunities home & abroad +Low maintenance costs +Give nations a great chance to improve their energy self-sufficiency in the most renewable and least harmful way +Help meet CO_2 targets
NEGATIVE: -Wind turbine construction and infrastructure building on natural sites disturb flora and fauna, damage their habitats, and destroy forest, flower field and sea bottom ecosystems, diminishing biodiversity -Propellers and power lines are hazardous to birds, bats and insects -Radar impacts on bats disturb their orienteering - CO_2 & other emissions from parts production and transportation -Noise causes danger (cannot hear predators) and stress to animals	NEGATIVE: -Cause "not in my backyard" (NIMBY) syndrome -Cyclic noise causes stress & stress-related illnesses to humans -Hinder visibility -May spoil visual landscape -Cause light and shadow reflections -May cause accidents to people -May impact real estate values and prices	NEGATIVE: -May upset current cultural landscapes	NEGATIVE: -Local resistance inhibits or slows down investments -Require often many permits and environmental impact assessments (EIAs) with long, exhaustive application procedures -Winds change, challenging even energy supply -Possible radar impacts on military monitoring sensors and air & sea monitoring radars

Table 2 maps co-utilization opportunities of wind turbines in different areas and elaborates on the way they decrease malignant and increase benign environmental, social, cultural and/or economic impacts of wind power.

Table 2. Some co-utilization opportunities of wind turbines.

Co-utilization	**Benefits for environmental, social, cultural and/or economic impacts**
Industrial sites, warehouse areas, harbours	+Infrastructures are already in place; hence there is no need to cause ecological harm by building them. +Usually far away from natural sites and residential areas; hence propeller noise does not disturb nature or humans. +Visual disturbance is minimized by already spoilt scenery and long distance to natural and residential sites. +Require fewer permits & no environmental impact assessments (EIAs). +Wind power generation can be integrated into the site's business operations, thereby giving both energy & financial benefits to companies. +Easy to supply energy to cities and residential areas because of the established grid and power line connections. +Companies on the site can invent multiuse purposes for wind turbines. +The jungle of turbines of wind farms can breed novel business ideas. +Rebuilding power lines underground prevents birds, bats and insects from flying into them.
Roadsides and railway banks	+Propellers' noise is hidden by traffic. +Visual disturbance is lessened by already spoilt asphalt, metal and concrete constructions. +Turbines have tall towers that can be used for traffic control, other surveillance and storage. +Wind energy generation by roads and railways could allow recharging the batteries of electric cars and novel electric trains during the journey. +The jungle of turbine masts can inspire novel means of transportation (e.g. postmodern Tarzans). +Wind farms in public areas will attract extreme sports enthusiasts with their creative inventions. +Building power lines underground prevents birds, bats and insects from flying into them.
Masts and towers	+Radio masts, telecommunication masts and many different kinds of towers can act also as wind turbines. +Possible added negative environmental, social, cultural and economic impacts of attaching propellers to these masts and towers can be easily analyzed and minimized, taking the special characteristics of the location into account. +Both the infrastructure and the turbine trunks are ready-made. +These second-hand wind turbine masts and towers save plenty of steel, fibreglass and metal-plastic composites normally needed to build the turbine trunks. +The trunks could serve also as habitats and nesting places for animals, particularly if they are covered by moss, lichen and other plants. +Building power lines underground prevents birds, bats and insects from flying into them.

Farm fields and fallows	+Little ecological disturbance or damage, as farm fields are typically monocultures with diminished biodiversity. +Farming and wind power generation can be done simultaneously. +Farmers earn either from leasing land and doing turbine maintenance, from generating the energy they need through small-scale wind power, or from becoming large-scale wind power producers and sellers. +Social nuisance is minimized: farmers who benefit do not suffer from the NIMBY syndrome and tolerate the visual harm and noise stress caused by the turbines. +Distance to neighbours is often quite long. +Building power lines underground prevents birds, bats and insects from flying into them.
Swamps	+Swamps that are already in commercial peat energy production are suitable for wind power generation, as they have already been ruined ecologically, socially, culturally and visually, and are plagued by noise from heavy work machinery. +Building power lines underground prevents birds, bats and insects from flying into them. -However, swamps still in their natural state should not be disturbed or damaged by wind power developments, which would destroy their fragile ecosystems and biodiversity once and for all.
Islands	+Wind turbines could be built on the hilly centre of an island with fishermen and/or summer residency, so that they will not disturb the coastal fishermen's houses, summer cottage owners, tourists or nature. +The island's commercial activities (shops, bank, post-office, car battery recharge, etc.) could also be built in the centre. +Building power lines underground prevents birds, bats and insects from flying into them.
Offshore (and near-shore) areas	+The adverse ecological impacts of dredging, building infrastructure and setting up turbines in marine ecosystems can be mitigated by turning the concrete and steel foundations into artificial reefs by erosion protection. +The reefs would attract fish, plants and other marine life, and could develop into holistic ecosystems, thereby preserving biodiversity. +Blocks built from rocks of different sizes can muffle turbine noise that drives fish away. Strong fish populations enhance fishing as a natural livelihood of the area. +Near-shore and offshore wind farms can be built to accommodate research platforms for marine life, weather and tidal energy research. +Shark nets could possibly be attached to the below sea-level turbine constructions of near-shore wind farms. +Building power lines underwater prevents birds from flying into them.

4. Discussion and Conclusions

There are many co-utilization places for wind turbines in which they would not cause much environmental, social or cultural harm and could be made economically profitable.

Industrial sites, warehouse areas, harbours, roadsides and railway banks are environmentally, socially, culturally and economically best places for wind turbines. There they do not damage

nature or disturb humans; their building expenses are low because of the ready-made infrastructures, and profit opportunities are great due to the easy supply of energy to local businesses and residents.

Using existing, i.e. second-hand, masts and towers in these areas would cut down the turbine construction expenses to the minimum and save plenty of unrenewable building material.

Farm fields and fallows are also environmentally, socially, culturally and economically rather benign areas to build wind turbines since they are monocultures, lie often away from residential areas, and wind power generation provides several livelihood opportunities for farmers.

Swamps exploited for peat energy production, are already environmentally, socially and culturally ruined, and therefore, would not suffer much from wind turbines, which would add to the high profits derived from peat energy production. Untouched swamps should be left alone.

Islands are often ecologically valuable areas, but islands with a commercial centre in the middle would not be too much hurt by wind turbines, if they were also built in the centre, which would leave the ecologically fragile and socially important coastal areas untouched.

Offshore wind farm building has several environmentally damaging impacts, but they could be mitigated by turning the concrete and steel foundations into artificial reefs, which would attract fish and other marine life. This could lead also to a beneficial effect on the livelihoods of fishermen. Offshore wind farm platforms could be used by researchers. Near-shore wind farms are more malignant environmentally, socially and culturally, but could possibly be used e.g. for attaching shark nets to.

There are some areas where the malignant environmental, social, cultural and/or economic impacts outweigh the benign ones.

Arctic hills have plenty of space and plenty of wind. In wintertime the colour of wind turbines and snow is synchronized, making a visual match. However, infrastructure building and turbine construction rape virgin land. Moreover, reindeer herders oppose arctic wind farms because they endanger the winter pastures of reindeer. And ultimately, since climate change causes trees to migrate north, plenty of space must be left for the arrival of trees.

Forests of any kind are not suitable or economically profitable places as trees muffle wind. Furthermore, infrastructure building, turbine construction and propeller noise cause such massive disturbance and damage to flora, fauna, soil, rocks, and to the whole forest ecosystem that wind turbines should not be built in forests.

Wind power should not be built in nature protection areas or bird and other animal sanctuaries, on the migration routes of birds, fish and sea mammals, or on environmental or cultural heritage sites. An ample buffer zone between these areas and wind farms should be reserved to prevent any environmental, social or cultural disturbance against these most valuable assets of the humankind.

The findings of this research are based on previous studies of the impacts of wind turbines (which themselves have taken account of hundreds of studies) and on the partially conflicting views of wind energy companies, authorities, environmental organizations and local inhabitants of the Ostrobothnia region of Finland gathered together at a wind power seminar.

This study adds to the knowledge of previous wind turbine impact research through the empirical study. The most important value of this research comes from exploring and mapping out novel empirical findings for a new research area of co-utilization impacts of wind power.

This research has not critically evaluated any of the conflicting views of the seminar participants but listed them all as positive and negative impacts of wind turbines and their co-utilization. The number of participants at the wind power seminar was 63, which is not a representative sample of the population of the city of Vaasa (59,633 inhabitants on 31.10.2010) or the Ostrobothnia region (about 1 million inhabitants during the early 2000s). Those who attended the seminar were more interested in wind power than an average citizen of the city or region, but the participants (wind energy companies, authorities, environmental organizations and local inhabitants) represented the different views and perspectives to wind power development well enough to give a rather balanced account of the positive and negative impacts of wind turbines and their co-utilization.

Similar studies could be conducted at other wind power seminars and at wind farm planning meetings collecting together people with different backgrounds and interests. New issues to address and ideas to solve them would no doubt emerge in such gatherings as wind farms become more widespread and people gain more experience on their impacts.

5. Recommendations

Co-utilization is an effective way of enhancing the social acceptance of wind power. Participation at every stage of the planning process in close cooperation with the wind energy companies tends to make local people, farmers, environmental organizations, authorities and businesses adopt a very positive attitude towards wind power. They appreciate the wind energy companies' respect for their expertise and creativity in mapping out co-utilization possibilities and planning continuous cooperation.

The active involvement in the projects and the resulting structures in turbines that for example, protect nature or collect data, satisfy the needs of most local people, environmental organizations and authorities. Farmers and companies want also business opportunities from co-utilization. The others often shy away from the profit-maximizing limited liability type market economy in co-utilization, but show great interest in socio-culturally beneficial co-op type co-utilization. This poses both an opportunity and challenge for the limited liability type wind energy companies: can they set limits to their short-term profit greed in order to secure long-term survival and success?

These issues are worth contemplating, as wind power is one of the few energy businesses that are strongly supported by environmental organizations. One of the most radical environmental organizations, Greenpeace, estimates that 20 per cent of the world's energy could be produced by wind power by 2030.[6] Such encouragement should be taken advantage of by solving the negative environmental, social, cultural and economic impacts of wind power through co-utilization and other measures.

Optimal Layout for Wind Turbine Farms

Koby Attias[1,*], Shaul P. Ladany[1],

Abstract: A general discrete model was formulated for the expected Net Present Value (NPV) of the profit and for the expected yield of the investment (Internal Rate of Return - IRR) to be derived from rectangular grid shaped wind-turbine farms. The model considers the wind shade in the downwind direction and the effect of the wake behind the turbine, the joint wind-direction wind-velocity probability distribution, as well as the various relevant cost and revenue factors. It was assumed that the wind-turbines are identical and of equal heights, and are spaced equally along the axes of the rectangle, but not necessarily at the same equal distance at both axes. Using the model, the optimal layout that maximizes the expected NPV and/or IRR was derived numerically for a given data set, in stages, determining the optimal number of turbines in a row and the associated optimal distance in-between them, and also the optimal number of turbines in a column and the optimal distance in-between them. Sensitivity analysis has shown that minor changes in the parameters do not affect the selection of the optimal layout.

***Keywords**: wind energy, optimal layout, wind farms*

1. Introduction

The harvesting of wind energy is centuries old as manifested by the middle-age wind mills in Europe. Heier [1] describes how the use of wind energy to generate electricity started in 19th century, but only the oil crisis of October 1973 provided the strong impact. The understanding and use of wind energy has been investigated by Lindley et al.[2], and are summarized by Manwell et al. [3]and Burton et al. [4]. Plans for actions to increase the use of wind energy were introduced by Milborrow et al. [5] , and the success is evidenced by travelers in Denmark and North Western parts of Germany where thousands of wind-turbines have been installed in recent years. The performance of wind farms were evaluated by Haack [6], while the integration of wind power into general power systems is discussed by Ackermann [7]and Heier [1].

Obviously, the erection of multiple wind-turbines in windfarms necessitates the determination of their layout. Bossanyi et al.[8], has dealt with the issue of investigating the efficiency of different layouts and even for designing aerodynamically optimal layouts. However, they did not integrate the economic and financial optimization of windfarms with the aerodynamic aspects. Yet the methods of operational research and operations management determine such optimizations using the maximization of the expected profit as the objective function. For example, see Ladany [9] and [10] in which the optimal layout of urban gasoline-stations was determined.

Hence, the aim of this paper is to develop a model to determine economically optimal layouts for windfarms (i.e. the number of turbines and their setting), which include the aerodynamic interactions between the turbines, the various cost factors and the particular wind regime. Section 2 presents the model; Section 3 considers the aerodynamic interaction between the turbines; Section 4 describes the optimization procedure; Section 5 shows a numerical example; Section 6 offers the conclusions.

Searching through Tables 2 & 3, it is possible to detect solutions that provide the best combination of N_{PV}'s and I_r's, although each is less than its maximum value. For example, for

a layout of I=4, J=6 (24 turbines), with the turbines separated with x=100 m and y=300 m, provides an N_{PV}=$21.5 million, and an I_r=19.7%, which is the authors recommend "optimal solution."

1.1. Aim of this paper

The aim of this paper is to explore and searching a model. By Using the model, we got the optimal layout that maximizes the expected NPV and/or IRR was derived numerically for a given data set, in stages,

2. The model

Consider a rectangular grid layout (see Figure 1) of I x J wind-turbines of equal size and height, 2 adjacent turbines separated by the distance x in one direction and y in the other direction (obviously the minimum of x & y is more than the diameter of the turbine's rotor).

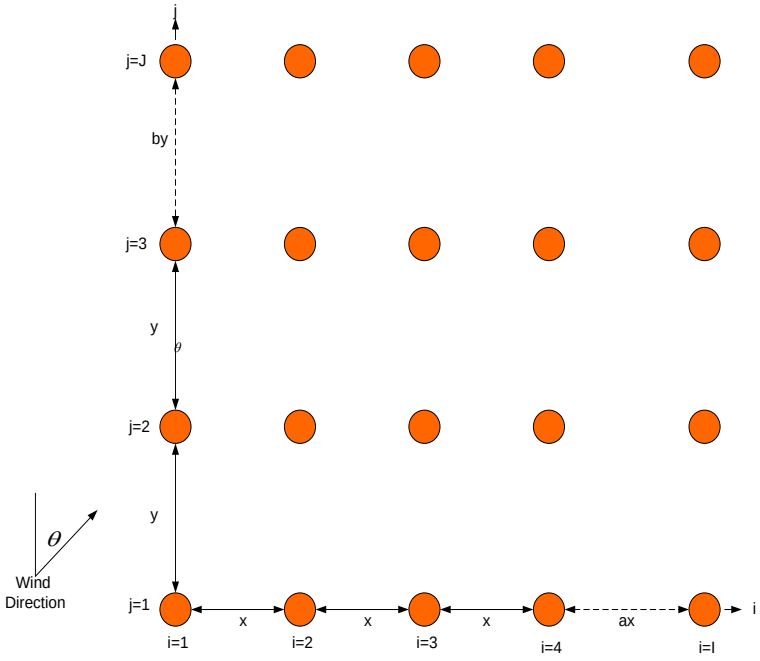

Figure 1: Location of turbine i, j in a rectangular grid layout of I x J turbines

When the wind blows in direction θ with a nominal velocity of V(θ), the effective wind velocity in front of the turbine at position i, j (which takes into account the aerodynamic interaction between the turbines, the wake affect – see the discussion in section 4) is Vij(θ, x, y).

Vij(θ, x, y) is obviously a function of V(θ), and it is developed in section 4. The effective wind velocity incident on 'turbine i, j' is Vij(θ, x, y), so the electrical power generated by the 'turbine i, j' is: eij(θ, x, y) [kwh]:

$$e_{ij}(\theta,x,y) = 0.5\rho V^3_{ij}(\theta,x,y)\cdot BC_pN_m \qquad (1)$$

where ρ is the air density [kg/m3], B is the swept rotor area [m2], Cp is the rotor efficiency coefficient (capacity factor) [%/100], Nm is the efficiency for converting the rotor mechanical power to electricity [%/100].

When the joint probability of the nominal wind velocity and its angle of incidence θ is defined as p (Vθ, θ), the expected annual energy to be generated by turbine i, j is

$$E(e \mid x, y)_{ij} = \sum_{v_\theta, \theta} e_{ij}(\theta, x, y) \cdot p(V_\theta, \theta) \tag{2}$$

while the total expected energy to be generated by the whole farm, T(x, y), is

$$T(x, y) = \sum_{i=1}^{I} \sum_{j=1}^{J} E(e \mid x, y)_{ij} \tag{3}$$

If the lifetime of a turbine is L, then K is the total investment in the windfarm (including the cost of turbines, installations and land cost), F is the net revenue from the selling electricity from the windfarm, r is the appropriate financial interest rate, H is the total operating time per period(for example operating time is: 24 h/d X 328.5 d/y =7884 h/y , and maintenance days are= 365-328.5=36.5d/y), P is the unit sale price of electricity , M is the cost of operation and maintenance of the windfarm per period, the Net Present Value, NPV, of the profit to be derived from the farm is

$$N_{pv}(x, y) = -K + \sum_{k=1}^{L} \frac{H \cdot T(x, y) \cdot P - M}{(1 + r)^{k-1}} = -K + \sum_{k=1}^{L} \frac{F}{(1 + r)^{k-1}} \tag{4}$$

Where $H \cdot T(x, y) \cdot P - M$ =F
The Internal Rate of Return (IRR) on the investment, Ir (x, y) is the value of the interest rate, r, that results in
NPV (x, y) =0.

3. The aerodynamic interaction between the turbines

Since a wind-turbine generates electricity from the energy in the wind, the wind leaving the turbine has less energy content than the wind arriving in front of the turbine. Therefore a wind-turbine will always cast a wind shadow in the downwind direction. This is described as the wake behind the turbine, which is quite turbulent and has an average down-wind speed slower than the wind arriving in front of the turbine.

With effective yawing, we assume the direction of the wind is always perpendicular to the front of the turbine. Hence, the diameter of the turbine is considered always perpendicular to the wind's direction. Nybore [11] has shown that behind the turbine the wind creates a cone-sloped wake which extends 4.5º to the sides, as shown in Figure 2, (i.e. creating a truncated cone with a 9º head-angle.)

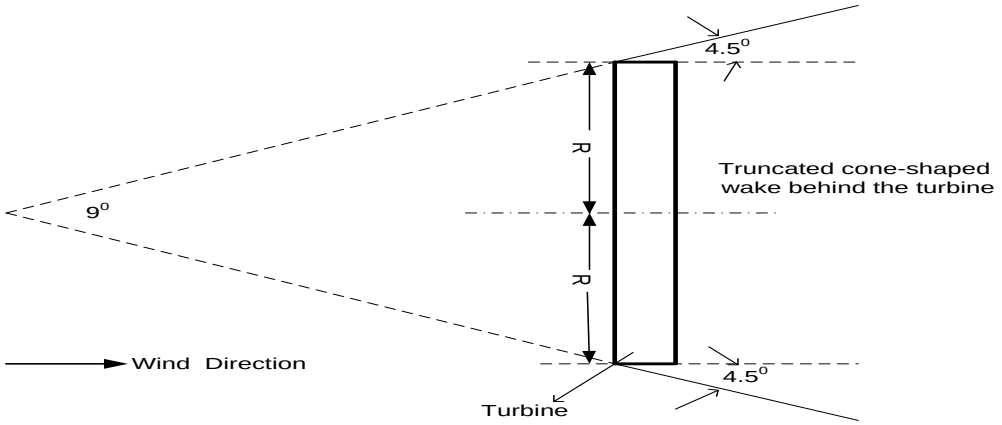

Figure 2: A 2-dimensional representation (top view) of the cone-shaped wake created by the wind behind the turbine

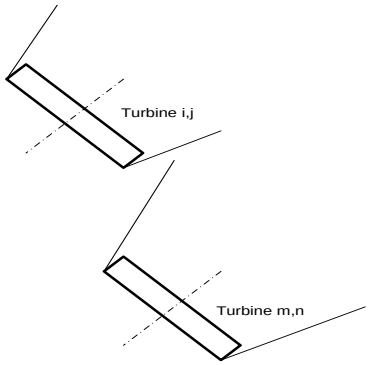
In a windfarm, 'turbine i, j' might or might not be affected by the wake created by another turbine positioned in front of it (in relation to the direction of the wind.) Moreover, the effect might be partial or complete. As a result, we distinguish 4 different states for the wind velocity hitting 'turbine i, j', as shown in Figure 3.

Adapting the findings of Nybore [11] to the notation required for dealing with a grid shaped farm, the wind velocity onto 'turbine i, j', when the general wind velocity in direction θ is V(θ), and the grids are separated by the distances x and y, is:

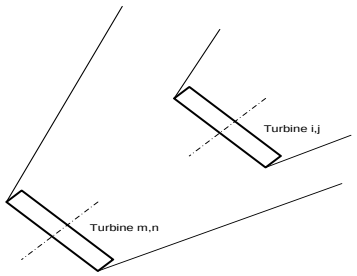
For state (a) when 'turbine i, j', is not affected by the wake of another turbine m, n ,

$$V_{ij}(\theta, x, y) = V(\theta) \quad (5)$$

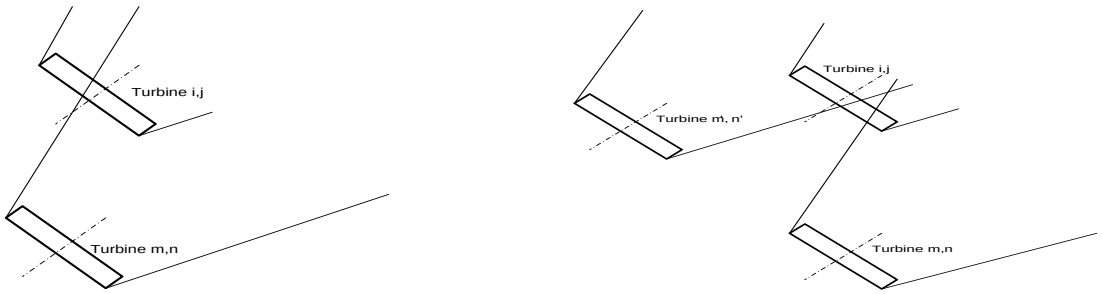
Where m, n are the coordinates on the grid of another turbine in front of 'turbine i, j'. m might be less, equal or more than i, and likewise n might be less, equal or more than j, but (m, n) ≠ (i, j).



(a) Turbine i, j not affected by the wake of another turbine m, n



(b) Turbine i, j fully affected by the wake of another turbine m, n



(c) Portion of turbine i, j is affected by the wake of another turbine m, n

(d) Portion of turbine i, j is affected simultaneously by the wake of turbine m, n and of turbine m', n'

Figure 3: Top view of the 4 states in which turbine i, j can be affected by the wake

For state (b) when turbine i, j is fully affected by the wake of turbine m, n,

$$V_{ij}(\theta,x,y) = V(\theta)\cdot\{1-[1-\frac{V_{mn}(\theta,x,y)}{3V(\theta)}]\cdot[\frac{R}{R+0.078d}]^2\} \quad (6)$$

where
R is the radius of the turbine's rotor, and
d is the distance between the centers of turbine i, j and turbine m, n (See fig. 4)
Note: This formula was developed by engineer Niels Otto Jensen from Risoe.

The wind in the wake $V_{ij}(\theta,x,y)$ is related to the surrounding free wind $V(\theta)$, the downwind distance (d meters), the rotor radius (R meters) and the spreading angle of the wind (about 4.5^0) . The factor 0.078 is called the constant of spreading, its corresponds to a spreading angle of about 4.5^0

For state (c) (when a portion (either a major or a minor portion) of turbine i, j is affected by the wake of another turbine m, n), Nybore's [11] equation is adjusted to the prevailing conditions:

$$V_{ij}(\theta,x,y) = V(\theta)\frac{A_{ij}}{\Pi R^2}\cdot\{1-[1-\frac{V_{mn}(\theta,x,y)}{3V(\theta)}]\cdot[\frac{R}{R+0.078d}]^2\} + V(\theta)[\frac{\Pi R^2 - A_{ij}}{\Pi R^2}], \quad (7)$$

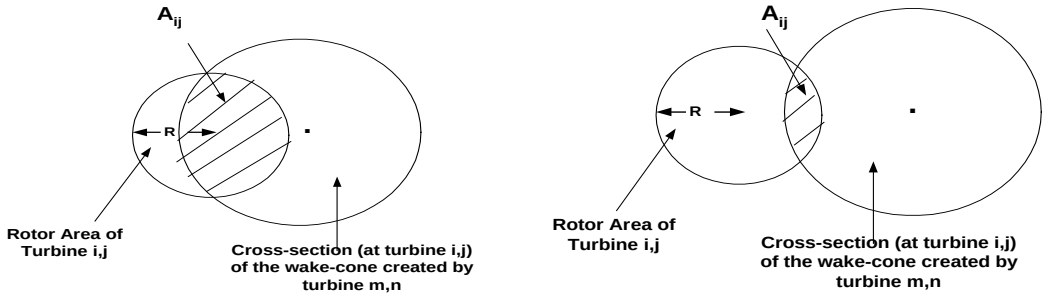
where
Aij is the area of intersection between the area of the rotor of turbine i, j and the cross-section (at turbine i, j) of the wake cone affected by turbine m, n.

For state (d) when a portion of turbine i, j is simultaneously affected by the wakes of turbine m, n and also of turbine m', n', Nybore's[11] equation is further adjusted:

$$\begin{aligned} V_{ij}(\theta,x,y) = {} & V(\theta)\frac{A_{ij}}{\Pi R^2}\cdot\{1-[1-\frac{V_{mn}(\theta,x,y)}{3V(\theta)}]\cdot[\frac{R}{R+0.078d}]^2\} \\ & + V(\theta)\frac{A_{i'j'}}{\Pi R^2}\cdot\{1-[1-\frac{V_{m'n'}(\theta,x,y)}{3V(\theta)}]\cdot[\frac{R}{R+0.078d'}]^2\} + V(\theta)[\frac{\Pi R^2 - A_{ij} - A_{i'j'}}{\Pi R^2}], \end{aligned} \quad (8)$$

where
$A_{i'j'}$ is the area of intersection between the area of the rotor of turbine i, j and the cross-section (at turbine i, j) of the wake cone affected by turbine m', n', and
d' is the distance between the centers of turbine i, j and turbine m', n'.
d is the distance between the centers of turbine i, j and turbine m, n.

For states (c) and (d), A_{ij} is depicted in Figure 4.



(a) Major portion of turbine i, j is affected (b) Minor part of turbine i, j is affected

Figure 4: Front view of the intersection (shaded) of the rotor area of turbine i, j, and of the cross-section (at turbine i, j) of the wake-cone affected by turbine m, n.

While the occurrence of state (d) in itself is very rare, theoretical situations exist in which in state (d) the cross-section (at turbine i, j) of the wake-cone created by turbine m, n and of turbine m', n' partially overlap while intersecting the rotor area of turbine i, j . Such other states can be dealt with by adjusting Nybore's [11] formula similarly to equation (8).

4. The optimization procedure

The optimization is performed in a sequential manner. An initial minimal sized layout with least possible number of turbines, (J=1, I=1) is selected and its NPV and Ir are calculated. At the second stage the number of turbines is increased, say to J=1, I=2, then numerically the value of x is searched that maximizes NPV, x1, and separately the value of x is searched that maximizes Ir, x2, retaining the resulting maximal NPV and Ir values. At the 3rd step, the number of turbines is further increased, say to J=2, I=2, the combination of values of x and y that maximize N_{PV}, (x_1, y_1), and that maximize IRR, (x_2, y_2), are evaluated, retaining the obtained maximal values of N_{PV} & I_r. The number of turbines is further increased, and the optimal outcomes of x & y for each layout are evaluated, and the corresponding maximal values of N_{PV} & I_r are retained.

5. Numerical example

To demonstrate the use of the model, a realistic set of data was assumed:
L= 20 y, R= 18 m, ρ = 1.225 kg/m^3, H= 7884 h/y (24 h/d X 328.5 d/y =7884 h/y),
P= 0.05 $/kWh, capacity of turbine=600kWh
C_p= 0.4, N_m= 0.95, and r=5% /y.
Total investment in the windfarm $K=I\cdot J\cdot\{C_T+C_I+C_L[(I-1)x\cdot(J-1)y]\}$, (9)
Where (cost in US dollar, $US)
C_T=cost per turbine=450,000$
C_I=cost per turbine installation=100,000$
C_L=cost of land per turbine=10$/m^2
Cost of operation&maintenance of the windfarm per turbine $M=0.015\cdot C_T\cdot I\cdot J$, $/y (10)

The results of the optimization procedure with the objective to maximize N_{pv} are presented in Table 2. The table provides for each combination of values of I x J the maximal achievable N_{pv}, and the values of x and y that generated this N_{pv}. In addition, the value of I_r generated by these values of x and y is also listed. Table 3 lists similar results, providing for each

combination of I x J the maximal achievable I_r, and the values of x and y that generated this I_r. In addition, the value of N_{pv} generated by these values of x and y is also presented .

Table 2: Optimal results of x and y (for any given I x J) for maximal N_{PV}, and I_r

Parameter	**J- Turbines in Column**	**I-Number of Turbines in Row**				
		2	**3**	**4**	**5**	**6**
x (m)	**2**	300	300	300	300	300
y (m)		100	100	100	100	100
N_{PV} (M$)		4.6	6.5	8.5	10.4	12.4
I_r (%)		27.7	25.3	24.4	23.9	23.5
x (m)	**5**	100	100	100	100	100
y (m)		300	300	500	500	500
N_{PV} (M$)		10.6	14.3	18.8	21.9	25.6
I_r (%)		24.1	21.3	17.9	17.2	16.8
x (m)	**6**	100	100	100	100	100
y (m)		300	300	300	500	500
N_{PV} (M$)		12.6	17.1	21.5	25.9	* **30.3**
I_r (%)		23.9	21.0	19.7	16.9	16.4

* Optimal results

Table 3: Optimal results of x and y (for any given I x J) for maximal I_r, and N_{PV}

Parameter	**J- Turbines in Column**	**I-Number of Turbines in Row**				
		2	**3**	**4**	**5**	**6**
x (m)	**2**	300	300	300	300	300
y (m)		100	100	100	100	100
N_{PV} (M$)		4.6	6.5	8.5	10.4	12.4
I_r (%)		* **27.7**	25.3	24.4	23.9	23.5
x (m)	**5**	100	100	100	100	300
y (m)		300	300	300	300	100
N_{PV} (M$)		10.6	14.3	18.0	21.4	24.3
I_r (%)		24.1	21.3	19.9	19.0	18.1
x (m)	**6**	100	100	100	100	100
y (m)		300	300	300	300	300
N_{PV} (M$)		12.6	17.1	21.5	25.6	28.9
I_r (%)		23.9	21.0	19.7	18.8	17.9

From Table 2, it is evident that maximal Net Present Value, N_{PV} of $ 30.3 million can be achieved for I=6 and J=6 (36 turbines), each one separated x=100 m on the x direction, and y=500 m on the y direction. However, this solution provides only an I_r=16.4%. On the other hand, Table 3 shows that a maximal rate of return, I_r of 27.7% is attainable with I=2 and J=2, the turbines being apart, in x=300 m on the x direction, and y=100 m on the y direction. The disadvantage of this high rate of return is that it generates only a Net Present Value of $4.6 million. If the decision would be done by an investment company, they should opt for the largest possible rate of return on their its investments in any given project. However, a power-generating company that is not diversifying its investments in many different types of projects with different level of risks, it would decide on a project that generates a large N_{PV} while satisfying at least a minimal level of I_r. Searching through Tables 2 & 3, it is possible to detect solutions that provide the best combination of N_{PV}'s and I_r's, although each is less than its maximum value. For example, for a layout of I=4, J=6 (24 turbines), with the turbines separated with x=100 m and y=300 m, provides an N_{PV}=$21.5 million, and an I_r=19.7%, which is the authors recommend "optimal solution."

6. Conclusions

The developed model optimizes windfarm layouts on flat ground or over water for both economic and aerodynamic criteria. Although there are other criteria (e.g. visual impact) to consider, the model performance is an advance for economic optimization. The model with its accompanying computer program, can handle different wind-regimes and all the different combinations of cost and technical parameters for rectangular layouts, of which single-line layouts are special cases. Even the seeming dependence of the solution on the initial selection of the directions of the perpendicular axes can be eliminated, by repeating the calculations for different directions of the axes, and by selecting the layout that has the axis given by the "recommended optimal solution" Furthermore, the computer program can be adjusted, for layouts that are not rectangles, but also parallelograms.

What do we really know? A meta-analysis of studies into public responses to wind energy

Ian D. Bishop[1,*]

[1] *University of Melbourne, Melbourne, Australia*
** Corresponding author. Tel: +61 383444180, Fax: +61 393472916, E-mail: i.bishop@unimelb.edu.au*

Abstract: There have now been many studies about the public response to wind energy infrastructure. This includes at least 31 papers already published in 2010. There remains however a large gap between the knowledge required for effective planning and the agreed understanding of visual and other impact levels, and the influence of planning and communication processes There is only limited agreement on some basic impact variables: numbers of turbines, amelioration with distance, role of design and so forth. There is no consensus on what methods should be used to assess acceptability or to design for acceptable outcomes. This means that, in many countries, there is no societal consensus about the acceptability of wide spread deployment of wind energy systems. This paper reviews recent studies in environmental, especially visual, impact and other aspects of the process that shape public response. These deal with issues and measures including both local and regional impacts, willingness-to-pay, validity of visual simulations and the use of virtual environments in design. The response of any individual and, cumulatively, of the community is a combination of affective and cognitive factors. Both are complex in character. Affective response involves primarily aesthetic appreciation but may be influenced by deep-seated philosophical attitudes to renewable energy in the context of global environmental issues. Cognitive responses overlay with the affective response in relation to global issues but also draw heavily on local factors of noise concerns, tourism effects and health issues. Cognitive responses are also dependent on personal circumstance and experiences and perceptions of the reasonableness of the planning process. These different aspects may be applied independently to infrastructure design, planning and evaluation but are often combined inappropriately in multi-factorial studies. A diversity of approaches in the literature are analyzed for their capacity to contribute to effective discrimination of the factors behind public responses to wind farm developments, to agreement on the key elements affecting local responses, and preferred approaches to planning and design. A combination of such meta-analysis and computational innovation in mapping and visualisation may provide the opportunity for integration of these advances in knowledge such that a systematic, objective, comprehensive and acceptable approach to wind energy infrastructure planning and design is feasible and achievable.

Keywords: *Wind energy, Visual impact, Affective response, Cognitive response*

1. Introduction

There has recently been a very rapid expansion of the literature on public responses to wind energy development and the visual landscape effects in particular. Between 2000 and 2006 there were 2-3 papers per year, in 2007 this jumped to 10, in 2009 to 15 and in 2010 over 30 papers were published on the topic. Some of these deal with aesthetic theory, some with impact mapping, some with experiments seeking to determine key impact variables and their relative importance, others deal with specific wind farm developments and the impact mapping, often linked to public consultation, which went with them. Given this surge of interest, provoked by the rapid expansion of the wind energy industry, it is time to ask what have we collectively learned from this research and how it makes for better planning.

While there is a high cross citation rate amongst these papers, there is also a wide diversity of approaches and research questions which means that there are as yet few definitive answers. The first stage of analysis of these contributions must therefore be to determine the research questions being asked and their relationship to each other. Key topics are:

- development of better tools or procedures for public engagement early in the planning process [1-5]

- understanding of relative significance of key design variables such as distance, contrast, colour, movement [6-8], number of turbines [9-11], size of turbines [10, 12] whether on-shore or off-shore [13] and the existing quality of the host landscape [14]
- understanding of non-design variables such as conservation value of location or the planning process [15, 16], broad social attitudes to wind energy [17, 18] or behaviour (e.g. recreation) when exposed to wind energy facilities [19, 20]
- more systematic analysis tools which respect multiple criteria in either site selection [21-25], impact assessment [8, 11, 26-28], historical changes in the landscape [29] or regional or national level impacts [30]
- responses to visual simulations [31]
- use of interactive virtual environments to facilitate interactive design [32]
- changing attitudes as a result of familiarity [16, 33]
- deep convictions about nature, landscapes and seascapes [34] and cultural ecosystem services [35]
- understanding the relationships between stakeholders in environmental conflicts [36]
- willingness-to-pay studies encompassing some of the other variables (such as distance) [13, 37-39]
- project evaluations including environmental externalities [40, 41]
- the NIMBY effect - or not? [18, 42-46]

This review will focus on just a small section of this wide range. That section is the attempt to establish some firm knowledge about how various design and planning variables contribute to expectations and responses to wind farm development. The analysis considers the variables in terms of the provoked affective and cognitive responses [47] since there are clear indications that both are at play in the public response. There is also a distinction to be made between responses to simulated wind energy developments, responses to proposed developments and responses to completed projects [16, 33]. It should also be noted that most studies consider several aspects of impact and response, in the list above and in the Tables below I have tended to focus on my perception of the main findings in each.

2. Findings from the literature

2.1. Affective Response to Wind Energy

As we experience the landscape we form impressions - such as beautiful or inspiring or unpleasant - without be conscious of any thinking behind those impressions. These responses have a high level of commonality within cultures and, in some respects, between cultures. They are largely unaffected by personal experiences, even familiarity with the landscape has been shown to have limited influence [48]. These apparently innate impressions are referred to as affective responses and have been attributed to evolutionary influences by some authors [49]. Because affective responses are relatively consistent across the population, we are in position to built a body of knowledge about typical responses and use these in spatially explicit landscape assessment and impact studies.

In the case of responses to wind energy infrastructure, we can consider our perceptions of the aesthetics of the developments as an affective response. Something we find intrudes on our enjoyment of landscape or something that adds elegance and interest to the view. Some people may have a positive response in certain landscape types and a negative response in a different landscape type, or the response may be influenced by the layout of the wind farm relative to the landscape, the number of turbines, their distance and so forth. However, we can expect similar sets of responses in different populations and similar dominant response types

allowing development of an empirical framework for impact estimation. As mentioned, the key variables have been analyzed in a number of papers [6-13]. Some of the key findings are summarised in Table 1. These are separated into effects of on-shore and offshore installations, as there is limited comparative work. A review of related work [13] concluded that there was less impact from off-shore installation (reflected in greater willingness-to-pay to adopt that option) but the relative impacts of off- and on-shore infrastructure are not yet well defined and the preference for offshore is disputed in at least one recent review [50].

Studies in affective response typically use scenic beauty, visual quality or a similar phrase as a key reported measure - with some examples of willingness-to-pay and choice experiments. Several of the papers studied multiple variables but disentangling these is sometimes difficult. In addition, there are some clear disagreements in findings in several places - including in relation to important considerations like distance and size. Some studies that considered the size of wind farms (numbers of turbines) did so in the context of fixed total power output. In this situation mixed results were reported [12] with some communities preferring more distributed production while other saw benefit in greater concentration. However, this is more of a reasoned factor than a purely aesthetic one and leads us into the next section.

Table 1. Some key finding relating to aesthetic responses to wind energy infrastructure

Variable Increasing	On-Shore Impact	Off-shore Impact
Distance	- linear decline to at least 12 km [6]	- linear decline to ~12 km [7]
	- limited distance effect [14]	- decline with distance [38]
Number of turbines	- increase with number, size and proximity until turbines occupy 15% of view, then constant [8]	no known studies
	- impact proportional to number of windmills [10]	
	- between 2 and 8 turbines best accepted [9]	
Colour/contrast	- increase with contrast [6, 7]	- increase with contrast [7]
	- increase to 1563 CIELAB points then constant [8]	
Size of turbines	-one 5MW turbine has more impact than same from smaller units [10]	no known studies
	- least important attribute [12]	
	- smaller turbines require less compensation [15]	
Movement	no known studies	- less when blades moving especially at low distances [7]
Visual complexity	- fractality introduced by [8], simpler structures preferred	no known studies
Continuity	- bumps in outline envelope not preferred [8]	no known studies
Host landscape	- effect is negative on landscapes of higher scenic quality but a positive on landscapes of lower quality [14]	- greater distance offshore preferred [38]

2.2. Cognitive Response to Wind Energy

It has been argued that the more visceral affective response ('the heart') is indeed conditioned by a rapid evolution driven cognitive response ('the head'). Whatever the truth of this, there are clearly a number of variables in human responses to wind turbines that require more sustained or deeper consideration than the aesthetic, or are dependent on knowledge or experience, and these are generally referred to as the cognitive factors. These may include specifically beliefs about nature, concerns about real estate values and trust in the planning process. Table 2 seeks to summarise findings on issues of this kind. Again, there are studies that were conducted in relation to on-shore installations and others where the focus was offshore, but these are not separated explicitly in this Table. Among the differences is the noise issue (which is in part aesthetic but of more sustained character and believed by some to induce specific negative health impacts hence applied with other cognitive factors here) that applies almost exclusively to on-shore facilities. The second is an argument, recently summarised [50], that off-shore turbines turn quintessentially natural [34] and often sublime sea or ocean views into industrial landscapes. On-shore facilities, on the other hand, are typically in locations long altered by human activities in the form of agricultural and transportation infrastructure.

Studies involving primarily cognitive variables use a range of measures that seem very similar but this similarity could be misleading. Acceptability is not the same as willingness-to-accept compensation, for example. General 'attitude' to wind infrastructure may be different again because of a range of factors reviewed in the environmental economics literature [51].

Table 2. Some key finding relating to cognitive responses to wind energy infrastructure. The variable of column 1 is measured by the measure in column 2. Column 3 indicates the way in which the response measure depends on the variable.

Variable	Response Measure	Findings
protected site [15]	willingness to accept compensation	avoid protected sites
planning with local representatives [15]	willingness to accept compensation	engage locally
prior experience with off-shore wind farms [16]	attitude to visual impacts	experience with more distance farm leads to more positive attitude
local electricity shortages [17]	acceptability	local needs on island suggested as positive contributor
small scale introduction [17]	acceptability	suggested as positive contributor
open-minded, international contacts [17]	acceptability	suggested as positive contributor
the developers, poor local communications [18, 44]	acceptability	suggested as negative contributor
occasional beach use [19]	stated attitude to offshore infrastructure	more positive attitude
regular year-round beach use [19]	stated attitude to offshore infrastructure	more negative attitude
living with wind farm [33]	range of beliefs on benefits, visual qualities, energy security	more awareness of benefits, greater acceptance

3. Discussion and Conclusion

The research methods used in trying to increase our understanding of the many variables introduced in the literature include attitude surveys, observational methods, willingness-to-pay (or be paid) studies, choice experiments and so forth. The entities on which people are asked to comment include real wind farms (post construction), hypothetical wind farms, visually simulated wind farms and abstract concepts in renewable energy. Nearly all the reported results are the outcome of research by professional people and have been peer reviewed.

Despite the breadth and depth of our investigations we do not yet know all the answers. We cannot yet predict what the response to a particular wind farm proposal will be (although many people would be willing to guess), if compensation is a possibility we do not know how to quantify it or spatially distribute it. We don't know what distribution of turbines across the landscape (to meet specific power needs) will have the least visual impact: should we have bigger but fewer turbines? Bigger but fewer farms?

Yet, some points are fairly clear:

- aesthetic impacts are less the further the viewer is from the turbines (although we have no clear idea of the shape of the distance-impact curve)
- contrast with the surroundings and background should be low
- farms should not be located in highly valued landscapes
- the distribution and design of the turbines should have regard for aesthetic factors such as complexity and continuity
- protected sites should be avoided
- less dissent arises through "involvement of the local population in the siting procedure, transparent planning processes, and a high information level" [18].
- familiarity with existing small scale projects is likely to increase later acceptance of further projects

A number of the studies mentioned were multi-factorial and sought to determine the relative significance of a range of contributing variables. If we accept the premise that responses to wind turbines are of two distinct kinds, one largely independent of culture, education, wealth and personal experience (the affective) and one heavily dependent on the circumstances of an affected community, then it is probably unwise to be mixing these together in our research studies. We need to know more about both, but putting both together into a single study can muddy the waters and fail to give a clear answer on either variable type. Once we have deeper knowledge about the aesthetics, for example, then we might combine this with other factors in a more comprehensive study.

In addition, and briefly mentioned above, there have been important attempts to create geographic information system based tools for prediction of visual, and other, impacts [52]. These have a significant potential role to play in relation to initial site selection and design and should complement systems based on wind potential mapping and other engineering factors. Finally, these can be supplemented but interactive collaborative design systems, such as [32], which can help to create the knowledge, participation and sense of involvement which are just as critical to the outcome as the planning and design itself.

Abstract: Wind energy has been the fastest growing and most promising renewable energy source in terms of profitability in recent years. However, one major drawback of wind energy is the variability in production due to the stochastic nature of wind. The article presents statistical simulation methods to incorporate risks from stochastic wind speeds into profitability calculations. We apply the Measure-Correlate-Predict Method (MCP) within the variance ratio method to generate long-term wind velocity estimates for a potential wind energy site in Austria. The bootstrapping method is applied to generate wind velocities for the economic life-time of a wind turbine. The internal rate of return is used as profitability indicator. We use the Conditional Value at Risk approach (CVaR) to derive probability levels for a certain internal rate of returns, as the CVaR is a reliable risk measure even if return distributions are not normal. In contrast to other scientific publications, our methodology can be generally applied, because we do not rely on estimated distributions for wind speed predictions, but on measured wind speed distributions, which are usually readily available. In addition, the CVaR has not been applied as a measure of risk for wind site evaluation before and it does not rely on any specific function regarding the profitability distribution.

Keywords: *Wind power, Bootstrapping, Measure-Correlate-Predict Method, Conditional Value at Risk, Internal Rate of Return*

1. Introduction

Wind energy was the fastest growing renewable energy resource in the European Union (EU) in the last decade. The annual installed capacity has risen from 814 MW in 1996 to 10,163 MW in 2009 [1]. In 2009, approx. € 13 billion, including € 1.5 billion offshore were invested in wind energy in the EU [1]. In this respect, the wind power capacity shall reach approx. 80 GW by 2010 becoming the renewable energy technology after hydro power with the highest installed capacity in the EU [1]. In 2009, approx. 5.4% of the electricity consumption was produced with wind energy in the EU. It is projected that the contribution of wind energy to total electricity consumption within the EU is increasing to approx. 15.5% in 2020 [2]. The stochastic nature of wind leads to fluctuations in wind energy production. The literature concerning wind speed uncertainty can be divided, for instance, into literature focusing on uncertainty in wind energy output and on economic profitability. With respect to uncertainty in wind energy output, Kwon [3] has elaborated a numerical procedure for evaluating the uncertainty caused by wind variability and power performance using probability models in order to assess the risk of power output deviations. He conducted a case study analysis to show that the standard deviation of the annual energy output normalized by the average value of power output is approx. 11%, which can cause investments to be unprofitable. Tindal et al. [4] have compared the predicted annual power production with the actual power production. Their dataset included 510 wind farms across Europe and the US. They showed that the actual wind power output is 93.3% of predicted wind power output. According to the authors, a major reason for this deviation is the rather poor quality of wind speed measurements which have been conducted before the installation of wind turbines.

A number of articles have statistically analysed wind speed data by assessing the wind energy potential in a certain region (e.g.[5], [6], [7], [8], [9], [10], [11]).The economic potential and profitability have been identified by applying traditional methods of financial analysis such as

the Net Present Value approach, the Internal Rate of Return approach, or the Life Cycle Cost Analysis approach.

Morthorst [12], for example, analysed whether there is a relationship between the expected profitability of a wind turbine and the annual increase in installed capacity in Denmark. He used the net internal rate of return approach (after tax) as a measure for profitability. Kaldellis et al. [13] conducted a sensitivity analysis in order to show the impact of different parameters on the economic viability and attractiveness of a wind energy plant. However, Montes and Martin [14] argue that statistical simulation methods should be used to account for and assess the economic risk resulting from the variability in wind speed.
Some authors analyze the wind energy potential of a specific site by using either Monte Carlo simulations for predicting wind speeds or by using the wind speed measurement data directly if sufficient measurement data are available [15], [3], [16], [9], [17]. However, Monte Carlo simulations require assumptions with respect to the distribution of the wind speeds. Consequently, Carta et al. [18] concluded that not every wind regime can be accurately described with known probability distributions.

The following article presents an approach that accounts for the uncertainty of wind speed in profitability assessments. The approach can easily be applied for any actual and potential wind energy site without specifying the distributions of wind speed. The article is structured as follows: Section 2 presents the methodology. Section 3 presents a case study analysis in which the methodology has been applied to and section 4 discusses the results and draws major conclusions from the methodology and analysis.

2. Methodology

Our approach consists of generating long-term wind speed data for a potential wind energy site (‘target site’) where only short time series of wind measurement data are available using the Measure-Correlate-Predict Algorithm (MCP) with wind speed data from a reference site. A bootstrapping procedure is applied to compute wind speed data for the economic life-time of the wind turbine. The internal rate of return approach is used as profitability index. The bootstrapping procedure allows more accurately reflecting the distribution of the wind regime in the predicted wind speeds than methods currently applied in the scientific literature on wind energy production. Furthermore, the bootstrapping procedure can be applied to any wind regime. As a measure of risk we use the Conditional Value at Risk approach (‘CVaR’). The CVaR can be uniformly applied and is not only appropriate if returns are normally distributed. The CVaR also provides information at which probability level a certain internal rate of return can be expected.

2.1. Assessment of the wind energy potential at a specific site

Wind speed measurement data are usually collected at a specific site (target site) through a period of one year or less. Wind speed frequency distributions are computed from the data in order to estimate a probability density function. Several probability density functions have been used in the literature, but the two-parametric Weibull and the one-parametric Rayleigh distribution, which is a special case of the Weibull distribution, are usually used to predict wind speeds [3], [13], [16], [15]. The two-paramteric Weibull probability density function is given by the following equation [9]:

$$f(V) = \frac{k}{c}\left(\frac{V}{c}\right)^{k-1} exp\left\{-\left(\frac{V}{c}\right)^{k}\right\},\ 0 < V < \infty \qquad (1)$$

where c and k are the scale and shape parameters and V the wind speed. The shape parameter k is usually between 1.5 and 3.0. If the value of the shape parameter is 2.0, the distribution is called Rayleigh distribution. The probability density function of the Rayleigh distribution is shown in Eq. 2 [9]:

$$f(V) = \frac{2V}{c^2} exp\left\{-\left(\frac{V}{c}\right)^k\right\} \quad (2)$$

A review carried out by Carta et al. [18] shows that the two-parametric Weibull distribution has several advantages compared to other probability density functions proposed in the scientific literature. However, not every wind speed regime can be described by a probability distribution. We applied the bootstrapping procedure as it does not require any assumptions on the distribution of the wind speed [18] [19]. However, long-term wind measurement data are needed for the target site. As already indicated, wind measurement data are usually collected through a period of one year or less. We apply the Measure-Correlate-Predict (MCP) algorithm to estimate long-term wind speed data for a target site using wind data from a reference site. We use long-term wind data from a closely located meteorological station at the reference site. According to [21], the MCP algorithm in the form of the Variance Ratio Method gives consistent and reliable estimates of wind speeds. The relationship between the wind speed data at the reference site and the wind speed at the target site can be expressed by the following equation [21]:

$$\widehat{V_t} = \left(\mu_t - \left(\frac{\sigma_t}{\sigma_r}\right)\mu_r\right) + \left(\frac{\sigma_t}{\sigma_r}\right)V_r \ , \quad (3)$$

where $\widehat{V_t}$ is the predicted long-term wind speed at the target site, V_r is the long-term wind speed at the reference site and μ_t, μ_r, σ_t and σ_r are the mean and the standard deviation of the target and the reference site, respectively. If wind measurements have not been conducted at hub height, the measured wind speeds have to be adjusted to hub height. We apply the following equation [10]

$$V_{hub} = V_m \frac{\ln\left(\frac{h_{hub}}{z}\right)}{\ln\left(\frac{h_m}{z}\right)} \quad (4)$$

where V_{hub} defines the wind speed at hub height, V_m the wind speed at measurement height, h_{hub} and h_m are the height of the hub and the measurement facility, and z is the roughness length [22]. The respective surface roughness at a specific site strongly depends on the terrain conditions.

The actual power output $P(V)$ of a wind turbine can be expressed by the following equation [9]:

$$P(V) = \int_{V_{in}}^{V_n} \frac{1}{2}\, cp \cdot \rho \cdot V^3 \cdot \pi \cdot \left(\frac{D}{2}\right)^2 + \int_{v_n}^{V_{out}} P_t \quad (5)$$

where V_n defines the rated wind speed, V_{in} the cut-in wind speed, cp the capacity factor, ρ the air mass density, V the wind speed, D the rotor diameter, V_{out} the cut-out wind speed and $P_t$the rated power output. A wind turbine starts generating power at the cut-in wind speed (V_{in}). From the cut-in wind speed to the rated wind speed (V_n), the power generated continuously increases up to the nominal power of the wind turbine. The turbine produces

constantly electricity at its rated power from the rated wind speed to the cut-out wind speed (V_{out}).

2.2. Profitability Calculations

The economic evaluation of investment projects is usually based on the Discounted Cash Flow (DCF) approach [23]. The approach provides information about the value of a project based on the present value of the cash flows that the project can be expected to generate in the future (cash in- and outflows). In the case of wind energy, cash inflows result from the electricity sold and cash outflows are investment and operating expenses. Operating expenses are mainly maintenance costs, personnel expenses, insurance costs, land lease, etc [24]. Cash in- and outflows are discounted to reflect the time and risk preferences of the decision maker associated with the cash flows. The DCF method comprises the following steps:
- estimating future cash flow for a certain discrete projection period, and
- discounting these cash flows to the present value at a rate of return that considers the relative risk of achieving the cash flows and the time value of money.

The financial attractiveness of wind energy investment projects is usually measured by the NPV and/ or the internal rate of return (IRR) [11], [12], [20], [25]. Investors are usually interested in the maximum NPV for a preferred discount rate of future cash flows. The IRR provides the discount rate at which NPV is equal to zero such that it can also be defined as the return that the project is going to generate considering cash out- and in- flows. A project can be stated to be economically viable, if the IRR is at least above the risk free rate or, if the NPV is equal or greater than zero. Equation 10 defines the IRR [23]:

$$NPV = 0 = CF_o + \frac{CF_1}{(1+IRR)^1} + \frac{CF_2}{(1+IRR)^2} + \cdots + \frac{CF_n}{(1+IRR)^n} = \sum_{t=0}^{n} \frac{CF_t}{(1+IRR)^t}, \quad (8)$$

where CF_t is the cash flow in the corresponding year.

2.3. The Conditional Value at Risk (CVaR)

We apply the CVaR as a measure of risk. Since the Value at Risk (VaR) as well as the variance as risk measures provide only reliable results if the underlying events are normally distributed [26], CVaR does not require a normal distribution of events and considers especially the tails of the underlying distribution [26]. The CVaR and the VaR are closely related, therefore we describe the VaR first. The VaR states that with probability β the expected value will not be lower than a certain threshold α. The CVaR focuses on the tails of the distribution and averages the values which fall short of threshold α depending on the probability level β. Therefore, the CVaR is a more conservative risk measure.

3. Case study analysis

The wind measurement data from a wind turbine site in Styria, which is in operation since 2005, have been used in our case study analysis. The data consist of hourly mean wind speeds as well as of hourly mean power output for the years 2006 to 2008. The hourly mean wind speeds of the year 2007 have been used as target site data. The data from a meteorological station (reference station) includes daily mean wind speeds for the years 1990 to 2009. Therefore, the calculations are based on daily mean wind speeds using the daily average of hourly wind speed measurement data of the target site. We use data from 2007 for the application of the MCP method. The different wind velocities are shown in Fig. 1, where Fig.

1a shows the daily mean wind velocities at the target site for the year 2007 and Fig. 1b shows the daily mean wind velocities at the reference site for the year 2007.

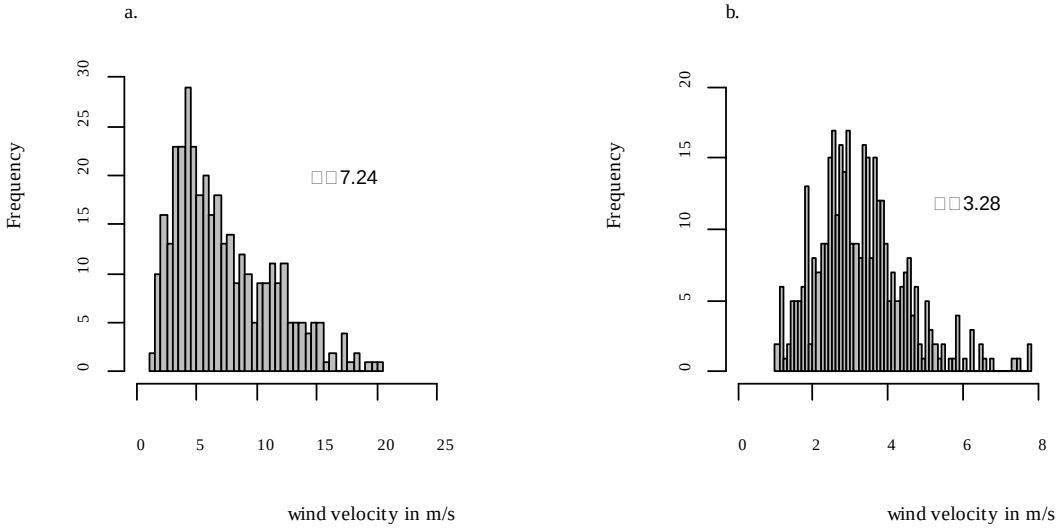

Fig. 1. Histogram of daily mean wind velocities: a. daily mean wind velocities at the target site for the year 2007; b. daily mean wind velocities at the reference site for the year 2007.

The correlation equation of the hourly mean wind velocity at the target site and the hourly mean wind velocity of the reference site derived from Eq. (3) is as follows:

$$\widehat{V_t} = -3.7507 + 3.3065\, V_r \qquad (9)$$

The long term wind velocities at the target site are estimated on the basis of the slope and the intercept of the Eq. (9). However, before applying the MCP method, the wind speed at the reference station has to be extrapolated from the anemometer to hub height using Eq. (4). As the target site is located in mountainous area, the correlation between the target and the reference site is low (0.2120). According to the utility manager (oral communication), the reference station has been used to evaluate the target station before deciding on the construction of the wind park. Therefore, we also use the same reference station in our case study analysis. The daily wind measurement data at the reference site record a period of 20 years such that long-term daily mean wind velocities are computed for this period with the MCP method.

Currently, the feed-in tariffs are guaranteed for a period of 13 years in Austria. Therefore, we assume that a potential investor requires a certain return of investment within the period in which he or she receives a guaranteed electricity price. Our calculations concerning the profitability assessment are based on a 13 year period of predicted daily mean wind velocities. Seasonal differences are reflected in the bootstrapping procedure, which has been repeated 1000 times. Consequently, several trajectories are obtained both for the wind speeds and the power outputs. The trajectories are also used in the statistical evaluations revealing information that are relevant for investment decisions.

The energy power output is derived for a 1.3 MW wind turbine with a turbine diameter (D) of 62 m, a cut-in wind speed (V_{in}) of 4 m/s, a cut-out wind speed (V_{out}) of 25 m/s, and a rated wind speed (V_n) of 13 m/s, respectively. The capacity factor (cp), which is defined as the ratio of the energy generated to nominal energy generation is 0.4. The air mass density (ρ) corresponds to 1.27 kg/m^3. The wind turbine starts producing power at a wind speed of 4

m/s and reaches its rated wind speed at 13 m/s. The daily generated electricity production can be computed by multiplying the computed power output with 24 (hours of a day). The daily generated electricity production is then added up to annual generated electricity production as profitability calculations are conducted on annual time steps.

The histogram of the daily and annual generated electricity in kWh is shown in Fig. 2a and Fig. 2b, which follows a normal distribution according to the central limit theorem. The theorem states that the probabilities of events generated with the sum of independent, identical distributed random variables X approximate to a normal distribution for a sufficiently large number of events. The central limit theorem indicates that the distribution of $\sum X_i$ for an increasing n approaches always the $N(n\mu; \sigma\sqrt{n})$ distribution.

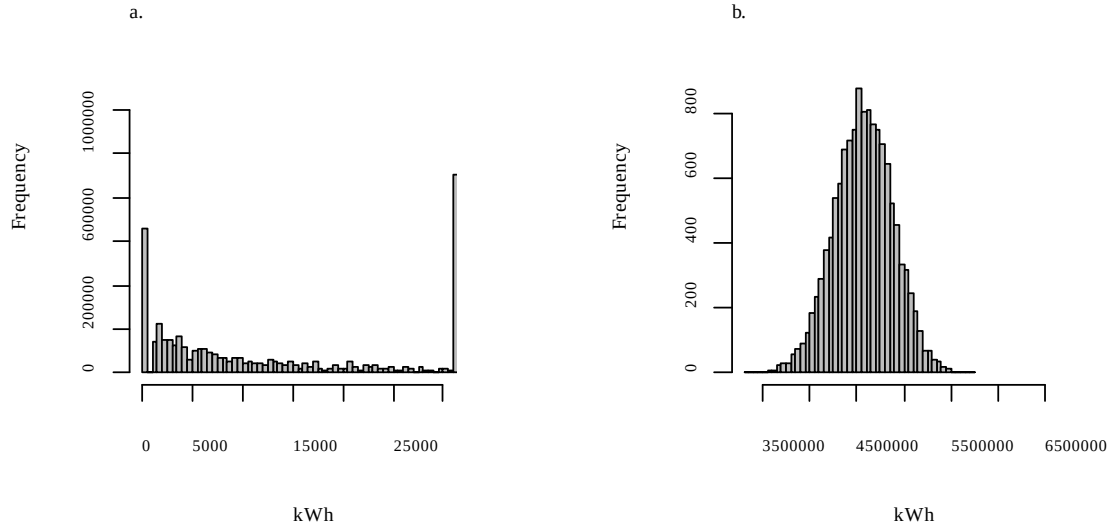

Fig. 2. a. Histogram of the daily generated electricity in kWh; b. Histogram of the annual generated electricity in kWh .

The annual Free Cash Flows (FCF) can be derived from the annual generated electricity. The cash inflows result from the generated electricity, which is sold at the guaranteed feed-in tariff that currently amounts to 0.0753 €/kWh in Austria. The cash outflows are the investment costs for the wind turbine, which are € 1.5 mil. per MW installed according to the provider of the wind measurement data. The operating costs are amounting to 0.020 €/kWh. Further corporate tax payments have to be considered when calculating the FCFs (current corporate tax rate is 25% in Austria). It is assumed that demolition costs at the end of the lifetime equal the revenue which can be generated out of selling the steel from the wind turbine. The internal rate of return has been calculated from the computed annual FCF. A standard criterion for investment decisions is the hurdle rate. It reflects a discounting rate at which the investments provide a positive cash flow. If a negative NPV results out of discounting the FCF with the hurdle rate, the underlying investment will most likely not be approved by the management. Consequently, an investment can be approved if the IRR exceeds the hurdle rate. The resulting probability density functions are shown for different risk aversion levels in Fig. 3. The IRR will be not lower than 7.94% at a probability level of β = 90% according to the probability density function of the IRR shown in Fig. 3 a. If the hurdle rate for an investor is above 7.94% then an investor shall not decide against the investment. However, the investor might realize an IRR above 9.19% with a 10% probability. Fig. 7b shows the resulting IRRs for a 95%- probability level.

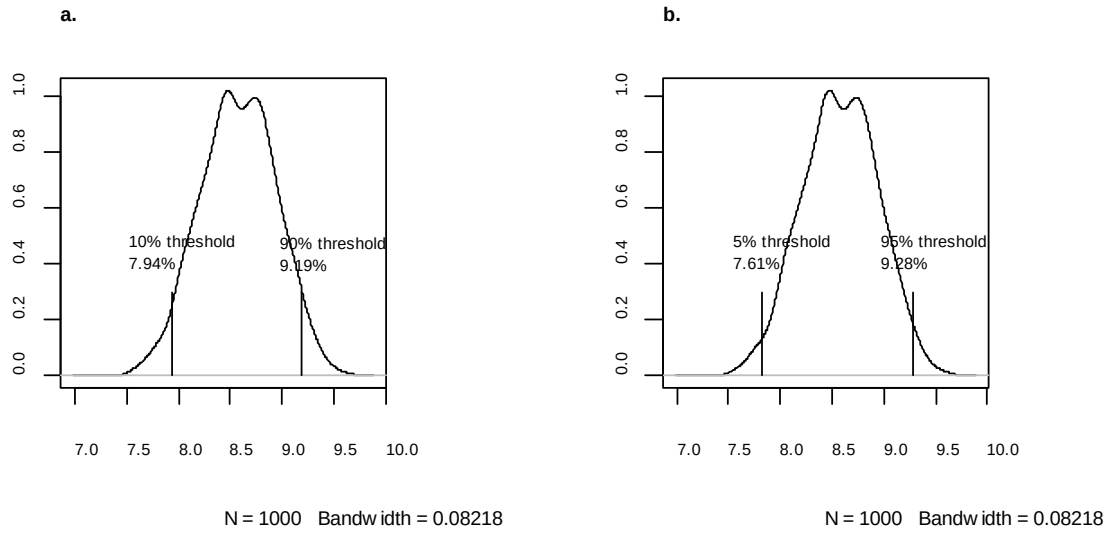

Fig. 3. Probability density functions of the IRR and the CVaR. a. Probability density function of the IRR with the threshold levels of 10% and 90%; b. Probability density function of the IRR with the threshold levels of 5% and 95%.

4. Concluding Remarks

We have developed a methodology to better assess the profitability of a wind energy site in the presence of wind speed uncertainty. Our approach can be applied to any wind regime. We apply statistical simulation methods to close the gap in the scientific literature on wind energy production [14]. Neither the bootstrapping method to predict wind speeds nor the conditional value at risk approach have been applied for investment assessments in combination with wind site evaluations. We have combined and applied these methods for a case study analysis. For a 1.5 MW wind turbine with investment costs of € 1.5 mil. per MW and operating expenses of 0.020 €/kWh, the IRR with a probability of 95% will not be lower than approx. 7.61% for the case study wind energy site. With a 5% probability, however, an investor can achieve an IRR of 9.28%.

Abstract: Using High Voltage Direct Current (HVDC) transmission lines to connect offshore wind parks to the onshore power grid has been proven technically advantageous to AC solutions and more cost-effective for relatively long transmission distances (>70km).The concept of applying DC technology can be expanded to the collection grid. DC collection grid offshore wind parks can be developed only if several key components currently nonexistent are available. The technical challenges involved can result in the unpredictability of their costs. This paper investigates the effect the uncertainty of the key components' cost can have on the overall economic performance of DC collection grid offshore wind parks. Results for a wide cost range are presented and corresponding cost boundaries which secure the economic viability of such parks were determined.

Keywords: *DC grid, Offshore Wind park, Techno-economics, DC/DC.*

1. Introduction

In the future the size of offshore wind farms and the distance to shore are expected to increase, thereby leading to higher losses in the AC collection grid and AC transmission. DC technologies can provide lower losses and use cheaper cables than their AC counterparts, thereby compensating for the increased cost of the necessary power electronic devices. HVDC transmission systems have already been proven technically advantageous and cost-effective over AC transmission for distances longer than 60-70 km according to [1], and applying DC technologies not only to the transmission system but also to the collection grid of offshore wind parks could prove additionally effective according to [2].

Key components refer to those components that are not at present available in the market but are needed to realize DC collection grids. According to [3], the following components are identified as key components: DC Circuit Breaker and DC/DC Converter which includes the Medium Frequency Transformer. DC breakers for high power applications have not been constructed and DC/DC converters are not currently available for high power rating beyond 1 or 2 MW [6]. Lundberg in [10] conducts a techno-economic analysis on DC wind parks but omits the cost of DC switchgear and underestimates the cost range of the DC/DC converters, neglecting their challenging nature.

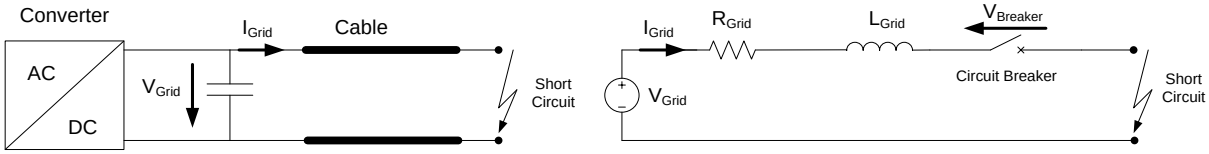
This paper investigates the effect of cost uncertainties of key components on the economic viability of offshore DC wind collection grid. Four different wind park layouts are considered. Initial assumptions on the key components' costs are made and using a cost-benefit programming tool, cost evaluation scenarios take place by altering the cost of the key components. Finally, cost boundaries are defined, beyond which any DC collection grid layout is not economically competitive.

2. Key components

2.1. DC Circuit breaker

Realising DC collection grid for offshore wind farms requires the existence of switching and protection devices specifically designed for DC grids. DC Circuit breakers are a characteristic example. Figure 1 (a) presents a typical DC grid. A capacitor is required to stabilize the

voltage and reduce the voltage ripple at the DC side of the converter. Due to this capacitor, the system can be described by an equivalent constant voltage source V_{Grid} and grid impedance L_{Grid} as in Figure 1 (b). When a short-circuit occurs, all of the grid voltage is applied across the equivalent resistance. As a result, there is a large and constant voltage across the inductance, leading to a constant and steep rate of rise of the current. Therefore, the fault current reaches dangerously high values quite quickly. Decreasing the rate of rise of the current implies the forced application of voltage across the circuit breaker so that the voltage drop across the inductance is decreased. Additionally in contrast to an AC system, a DC system by definition does not have current zero crossings, which could aid for the safe interruption of the fault current.



(a) (b)

Figure 1. a) Representation of DC grid under short circuit condition b) Equivalent circuit of a DC grid under short circuit conditions

Therefore a high-power DC breaker must a) be able to act very rapidly to avoid extremely high currents and b) Allow active turn-off.

2.2. DC/DC Converter

The requirement for transforming voltages in a high-power DC grid is one of the major challenges towards the realization of DC power networks including DC collection grid. Different topologies for DC/DC converters have been developed using medium or high-frequency AC link as discussed in [4], based on the general model of Figure 2. A galvanic isolated DC/DC converter consists of an inverter at the input side, an AC link consisting of a transformer and an inverter at the output side to transform back to DC. The voltage at the endpoints of the transformer does not need to be sinusoidal or at 50-60Hz. Hence the frequency of the alternating voltage can be equal to the switching frequency and a rectangular waveform of such frequency can be applied to the transformer. The AC link is based on a medium/high frequency transformer, resulting in galvanic isolation which is important for security reasons in high power applications.

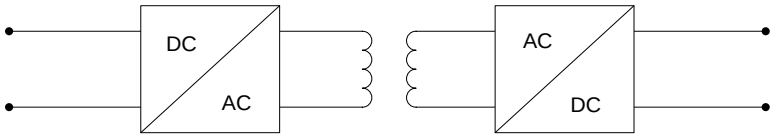


Figure 2. General topology of a galvanic isolated DC/DC converter

The overall dimensions of such a transformer are significantly reduced due to the higher operating frequency, resulting in a compact DC/DC converter. The transformer can be single or three phase. The transformer can be single or three phase with the latter being more advantageous for high-power applications [5].

2.3. Medium Frequency Transformer

As mentioned in section 2.2, the fundamental component of a high power DC/DC converter is the medium frequency transformer, which is also the most challenging to construct for high power applications. The non-sinusoidal excitation of the core and the use of high-frequency components require sophisticated approach methods. The material and the design of the core of the transformer are of utmost importance. Traditional low frequency-high voltage-high power transformers use laminated cores. However, this concept cannot be applied to medium frequency transformers. Increasing the frequency leads to excessive losses and the insulation between the core sheets will lead to a reduced thermal conductivity of the core [3].

3. Methodology

3.1. Layouts

For the scope of this paper, four different offshore wind park layouts where investigated: "Small DC", "Large DC", "Series DC" and "AC/DC". These designs are thoroughly presented in [10] and [7]. All of them have a DC transmission link and DC collection grid with the notable exception of the AC/DC which has an AC collection grid. AC is currently the only technology used in the collection grid of wind parks and therefore, AC/DC layout is used as a benchmark for the rest fully DC wind park designs. It is important to mention that the turbines in all DC collection grids, the turbines consist of a Permanent magnet generator coupled to a rectifier and then to a DC/DC converter while the turbines of the AC/DC park consist of a Doubly Fed Induction Generator (DFIG) connected to a transformer.

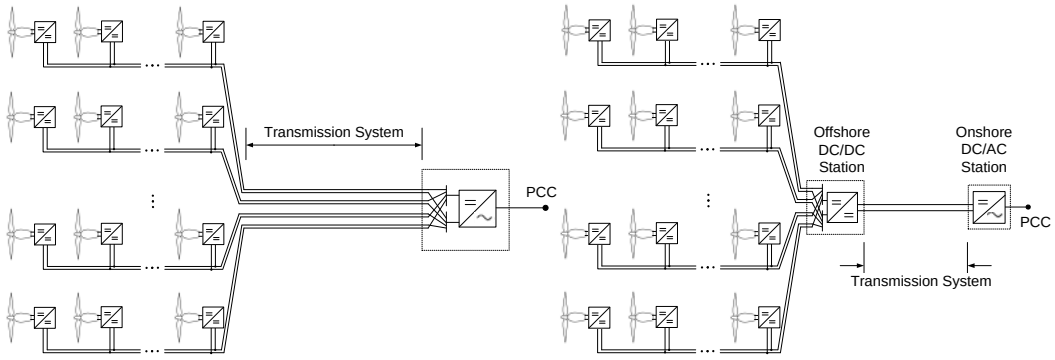

Figure 3. a) Small DC offshore wind park b) Large DC offshore wind park

The small DC layout presented in Figure 3 (a) has DC feeders of Medium Voltage (MV) which are extended to the onshore inverter, located just before the Point of Common Coupling (PCC) to the main grid. Figure 3 (b) presents the Large DC layout which resembles the Small DC but uses a large offshore DC/DC converter on a platform, to achieve High Voltage DC (HVDC) on the transmission system, resulting in decreased transmission losses. The Series DC layout is featured in Figure 4 (a). The turbines have a MV DC output and are connected in series, resulting in HVDC along each feeder and also on the transmission line, without the need of an additional offshore DC/DC converter. The AC/DC layout is depicted in Figure 4 (b), having a conventional AC collection grid and an HVDC transmission system.

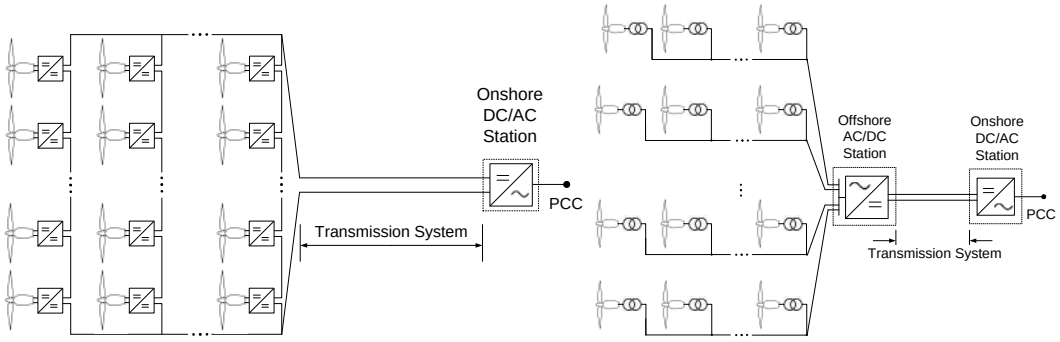

Figure 4. a) Series DC offshore wind park b) AC/DC offshore wind park

3.2. Energy Cost

The minimum cost of energy production for any desired wind farm project is described by the Energy Cost and is given in currency units per kWh delivered to the PCC. Its calculation is given by equation (1):

$$\text{Energy Cost} = \frac{\text{Total capital cost} \cdot \dfrac{\mathrm{r}(1+\mathrm{r})^{N}}{(1+\mathrm{r})^{N}-1} + \text{O\&M}}{\text{Average power production} \cdot \mathrm{T}} \qquad (1)$$

where O&M is the total annual Operation and Maintenance costs, r is the interest rate, N is the lifetime of the wind farm in years and T is the average operational hours per year in the form of T=24·365 hours·0.95, where the last term expresses a park availability of 95% annually. Ideally, a project should have the lowest energy cost possible.

3.3. Cost-Benefit Tool

A Cost-Benefit programming tool was developed in order to calculate the Energy Cost. It consists of sets of function/script in Matlab environment while the management of input and output information is provided by dedicated Microsoft Office Excel files. Every desired offshore wind park is represented by a dedicated Excel file, containing all the important technical and economical parameters that precisely describe its unique configuration. The tool imports this information and after performing a sequence of calculations, determines the Energy Cost according to equation (1).

3.3.1. Energy yield Calculation

The determination of the Energy Cost requires the calculation of the average power production of the wind parks. This is done by considering every wind park as a complex model consisting of interconnected elements. The components which have been modeled are the wind turbines, transformer, DC/DC converter, HVDC station and cables (AC and DC). The modeling details are available in [7]. The power at PCC is calculated for a given instantaneous wind speed and to describe the variations in the wind speed over time, a density function is used and in particular the Weibull distribution $f(w)$ described in [8], were w is the wind speed in m/s, as the ideal representation of real measured wind data. Using the probability density function, the average power can be generally calculated as:

$$P_{average} = \int_0^{\infty} P(w) \cdot f(w) \cdot dw \qquad (2)$$

where P(w) is the power at PCC for wind speed of w m/s.

3.3.2. Capital and maintenance costs

Wind park related cost data was obtained from published sources. A lot of information was available in [9] and [10]. The gathered data is referred in [7] regarded the following: Wind turbine (different for AC and DC grid), foundations, transformer, HVDC stations, cables (AC and DC), cable installation, offshore platform, DC/DC converters (according to type of usage) and switchgear (for AC). No resource was found on DC switchgear and due to the challenging construction, we assumed that setting its cost as double the AC switchgear. Additionally, Lundberg in [10] claims that since a DC/DC converter contains approximately the same amount of semiconductors as an AC/DC converter of the same rating, it is reasonable to have the same cost as the latter, namely 1 SEK/VA. However, regarding the complexities involved in the construction of DC/DC converters, such a cost was not considered adequate. A more careful and trustworthy approach was adopted. The converters on the turbines of the Series DC layout were considered at 3 SEK/VA owing to the high insulation requirements. The high power converters used in the offshore platform of the Large DC were considered at 2 SEK/VA because of the complex construction and the DC/DC converters on the turbines of the Small and Large DC schemes cost 1.5 SEK/VA due to the complexities involved.

In order to calculate the O&M costs, the components which require maintenance were gathered in three sets of related components: "Turbine", "Collection grid" and "Transmission system". According to literature sources, O&M can be taken as a certain percentage of the capital cost. Therefore the corresponding “Turbine O&M”, “Collection grid O&M” and “Transmission system O&M” were defined as 4%, 2% and 0.5% percentages respectively, of the total capital costs of the three initial sets.

3.4. Simulation considerations and assumptions

For each of the four suggested layouts, three different power capacities were considered: a) 160 MW, b) 500 MW and c) 1200 MW. Regarding the design considerations, the collection grid voltage was set at 30kV DC for DC grids and 30kV AC for the AC grids. Additionally the HVDC transmission links were rated at ±150kV for the 160 and 500 MW cases and ±320kV for the 1200 MW. Finally each feeder of the collection grid consisted of 10 turbines in all cases. The design peculiarity of the 1200 MW Series DC requested the need for 32kV DC at the exit of the turbines’ DC/DC converters and 20 turbines per feeder. Finally, every wind park was simulated for transmission distances in the range of 0-200km. Additionally, several assumptions were made as in Table 1.

Table 1. Simulation assumption

Parameter	Assumption
Wake effect	Neglected
Cable inventory	Maximum 4 different cables per model
Turbine's power rating	2MW
Turbine power curve	Same for DFIG (before transformer) and FPCG (before DC/DC converter)
Weibull shape factor	k=2
Converter loss curve	Same for HVDC and DC/DC
Interest rate	7% per annum
Life cycle	25 years
Average wind speed	10 m/s for all cases and all transmission distances

4. Results

4.1. Cost of DC/DC converters

In order to determine how sensitive the economic viability of the DC collection grid is with respect to the DC/DC converter cost, all costs were kept unchanged and the DC/DC converter cost was altered. Assuming that the cost proportion between the 3 different kinds of DC/DC converters as described in 3.3.1 remains always fixed, the following concept is followed: all of these values are multiplied by a common percentage representing the cost fluctuation i.e. a 50% percentage means that the new costs are half the original ones.

Figure 5 presents the results in Energy Cost terms for all layouts of the 160 MW power rating, for percentages of 50%, 100% and 300%. For a specific power capacity, the energy cost curves of the Large DC, Series DC and AC/DC seem to be parallel. This happens because these three layouts share the same transmission lines and increasing the distance will only increase the length of the cables. As a result, all three layouts will experience the same amount of capital and O&M cost increase and therefore energy cost increase. The order of the energy cost curves is defined by the costs with no transmission line involved. This is the energy cost at 0 km of distance. The Small DC differs in a great degree because it features multiple transmission cables and for increasing distance, the huge capital and O&M cost as well as excessive transmission system losses, force the energy cost to increase at a steep rate. As expected, the energy cost curve of the AC/DC layout remains the same in all three scenarios as it contains no DC/DC converters. On the contrary, the energy cost of the Small DC, Large DC and Series DC increase for increasing percentage (more expensive converters). As observed in the figure and also confirmed in [7], the Small DC rarely has the smallest energy cost and when this happens, it is only for distances less than 2-3 km. Additionally, its energy cost increases almost exponentially due to the large number of costly transmission lines and increased losses. Therefore, Small DC is of no interest for offshore development where distances are expected to be in the order of 10s to 100s of km and as a result, it will not be depicted again in the following figures.

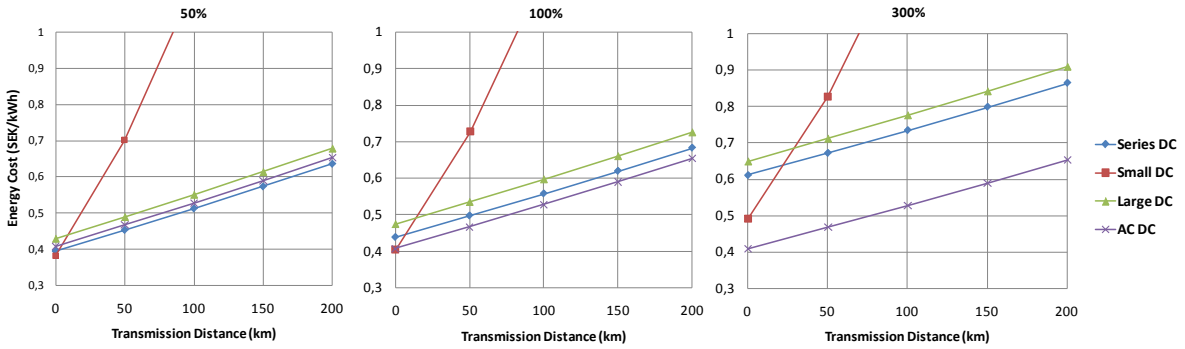

Figure 5. Energy cost curves of 160MW layouts for DC/DC cost percentages of 50%, 100% and 300%

For very small percentages, the Series DC has the smallest energy cost in all distances with the AC/DC following. For increasing percentage, AC/DC remains constant with the Series DC moving upwards until they coincide for a certain percentage. After this, the AC/DC maintains the smallest energy cost for all distances, and effectively all DC collection grid layouts have been ruled out of the competition. In every case, the Large DC has always higher energy cost than both the Series DC and the AC/DC. Therefore, only AC/DC and Series DC are considered as competitive layouts. This break-even percentage is different for each of the three power ratings and the findings are presented in Table 1.

Table 2. Break-even DC/DC cost percentages for each power rating

Wind park Power rating	Break-even percentage
160 MW	67%
500 MW	94%
1200MW	145%

If the results from all layouts and capacities are presented in the same graph as in Figure 6, it can be seen that for the basic scenario of 100% percentage, the AC/DC technology has the lowest energy cost up to a distance of ~100km, with the Series DC having the lowest energy cost for any greater distance. It was observed that by decreasing the DC/DC converter cost, the AC/DC technology was the most cost-benefit solution for smaller distances until it was eventually not competitive at all, with the Series DC being the cheapest for all distances. Reversely, for increasing converter cost the dominance of the Series DC is shifted to higher distances until a certain point when AC/DC has the lowest energy cost for all distances within the range of 0-200km.

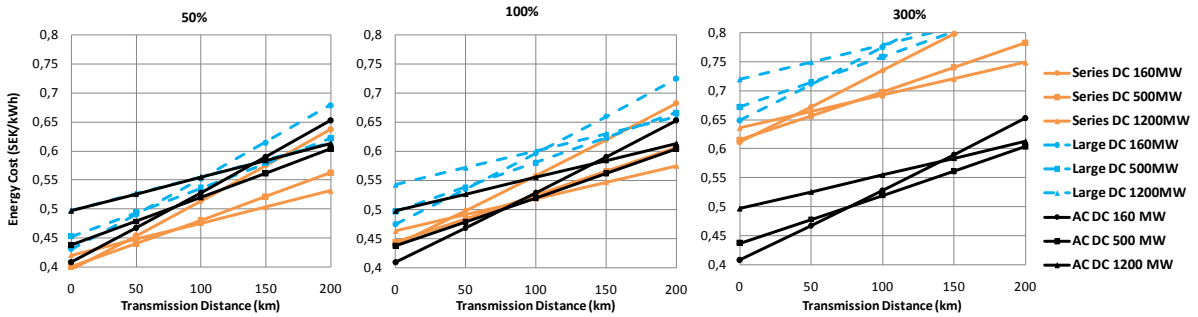

Figure 6. Energy Cost curves of Series DC, Large DC and AC/DC for DC/DC cost percentages of 50%, 100% and 300%.

It was determined that these two percentages are the break-even values for the 160MW and 1200MW as in Table 2. Therefore, for a percentage lower than 67%, the Series DC is the technology with the lowest energy cost for all distances, then AC/DC begins to be the cheapest up to certain distances, and when the percentage exceeds 145%, the AC/DC is the cheapest overall with no DC collection grid layout being competitive any more. The general conclusion is that if DC collection grid is to be regarded as a future solution for offshore wind parks for distances up to 200km, Series DC is the most cost-benefit wise interesting approach and the cost of the DC/DC converters must not exceed 145% of the originally assumed costs described in Table 1. When the cost percentage is less than 67%, Series DC (therefore DC collection grid) is the best solution in all distances.

4.2. DC switchgear cost

The same concept as before was followed in the case of the DC switchgear cost were the uncertainties in the DC breaker cost are involved. The original cost was multiplied by a percentage and break-even costs were determined as in Table 3. It is interesting to notice that no break-even percentage was evaluated for the 160MW case, meaning that AC/DC has always the lowest energy cost for all distances, no matter how cheap the DC switchgear gets.

When all the results are compared, the Series DC remains competitive until the percentage regarding the cost of the DC switchgear exceeds 378% and the AC/DC technology features the lowest energy cost for all 200km. This margin is high due to the smaller contribution of

Table 3. Break-even DC switchgear cost percentages for each power rating

Wind park Power rating	Break-even percentage
160 MW	Nonexistent
500 MW	54%
1200MW	378%

the DC switchgear to the overall capital costs, compared to the DC/DC converters. Even if the percentage drops to 0%, AC/DC will still be the most competitive for distances up to 60km.

5. Conclusions

Under the circumstances where offshore wind farms are growing in the capacity and distance from shore, DC wind collection grid along with DC transmission can be the most cost effective solution. However, any development of such designs depends on the presence of currently unavailable components, namely DC/DC converters and DC circuit breakers, and also on their expected costs. Specifically, the cost of DC/DC converters must be quite close to the suggested values of this paper while there is a lot more margin for the DC circuit breaker's cost. Any future research aiming to materialise the needed key components must be done with respect to the indicated cost boundaries and general findings of this paper.

Abstract: Distributed generators systems and Microgrid are becoming more important to increase the renewable energy penetration in the public utility. This paper presents a mathematical model for connected inverters in Microgrid systems with large range variations in operating conditions. No-lineal tools and computer simulations, phase-plane trajectory analysis, method of Lyapunov and bifurcations analysis for evaluate the limits of the small signal models are used, and conclusion suggested utilizing models that can permit to analysis of the system when subjected to a severe transient disturbance such as loss a large load or loss of generation. The study of transient stability for Microgrid systems in stand-alone of the utility grid is useful to improve the design of Microgrid's architecture.

Keywords: *Microgrid model, Transient Stability, Parallel Inverters, Method of Lyapunov.*

1. Introduction

Distributed generators systems and Microgrid are becoming more important to increase the renewable energy penetration in the public utility [1-2]. Thus, the use of intelligent power interfaces between the electrical photovoltaic generation source and the grid is required. These interfaces have a final stage consisting of dc/ac inverters, which can be classified in current source inverters (CSI) and voltage-source inverters (VSI). In order to inject current to the grid, CSI are commonly used, while in island or autonomous operation, VSI are needed to maintain the voltage stability [3-5].

A Microgrid can be operated either in grid connected mode or in stand-alone mode. In grid connected mode, most of the system level dynamics are established by the public utility, this is due to the relatively small size of local generators. In stand-alone mode, the system dynamics are established by micro generators themselves [6]. This paper presents an analysis of transient stability of power systems for parallel connected inverter in a Microgrid under autonomous operation.

The power inverters do not present the natural relations between frequency and active output power, neither between output voltage and reactive output power. Therefore, in order to reach stable operation, when the inverters are connected in parallel, these inherent operating conditions must be established by the inverter's control system [7].

Previous analysis of stability of stand-alone systems have been done by means of small signal models [5, 8], either assuming an ideal inverter or considering power inverter with a high switching frequency and their closed-loop inner controllers. Simulation and experimental result show that the systems work well when there is a small perturbation, but when the perturbation is bigger, the system could be in unstable operation.

The small signal analysis works with root locus plots Bode diagrams, Nyquist plots, etc., researching the desired dynamic behaviour of the systems. On the contrary, this paper works with no-lineal tools for large signal analysis supported by computer simulations. It is used

phase-plane trajectory analysis and method of Lyapunov to evaluate the limits of the small signal models. It is suggested the utilization of models that allow to analyze the system when it is subjected to a s evere transient disturbance such as loss of large loads or loss of generation.

2. A Microgrid Study

Fig 1 shows the circuit diagram of the Microgrid systems in stand-alone considered in this paper. This system configuration was studied by Duminda, in [8]. It was considered small signal modeling. For simplicity, the system has two inverter connected, but it can be extended for n-number of inverters.

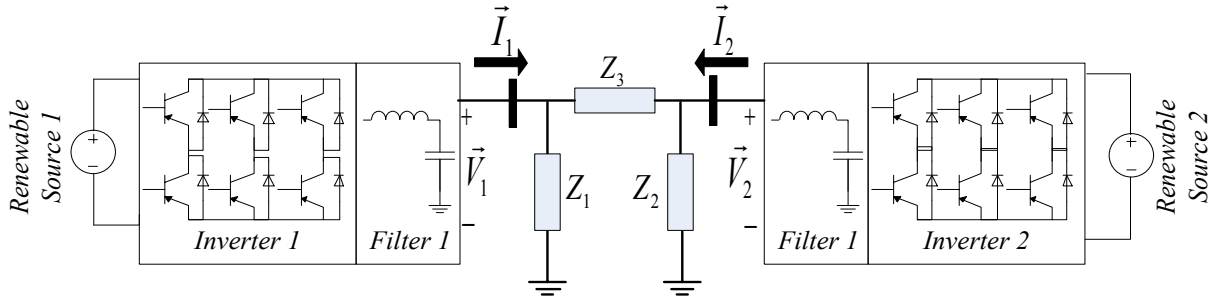

Fig. 1. Parallel connected inverters in Microgrid system works in stand-alone.

The Distributed Generator (DG) considered consists of a power DC renewable source, a three-leg inverter and an output LC filter. By assuming the renewable energy source as an ideal source form, the DC bus dynamics can be neglected. Each DG presents a PWM controller with a current and voltage loop and a PQ controller. The PQ controller must autonomously respond effectively to system changes without communication, only with local variables. Commonly, the PQ controller uses the droop curves (*f vs P* and *V vs Q*) and a filter with a cut-off frequency of approximately a decade smaller than a grid frequency. The task of the PQ controller is to imitate the governor of a synchronous generator. This artificial droop control scheme can be expressed as follows

$$\omega = \omega_0 - k_p P \qquad V = V_0 - k_v Q \tag{1}$$

Where P and Q are filtered with a low pass filter with cut-off frequency ω_f, the equations of these filters in the Laplace domain can be expressed as:

$$P(s) = \frac{\omega_f}{s+\omega_f} P_i(s) \qquad Q(s) = \frac{\omega_f}{s+\omega_f} Q_i(s) \tag{2}$$

P_i and Q_i are instantaneous power and are calculated from the measured output voltage and output current as in

$$P_i(s) = V_d I_d + V_q I_q \qquad Q_i(s) = V_d I_q - V_q I_d \tag{3}$$

2.1. A mathematical model of the each voltage source inverter

Considering (1), (2) and working in the time domain,

$$\dot{\omega} = -\omega_f \omega - k_p \omega_f + P_i \tag{4}$$

$$\dot{V} = -\omega_f V - k_v \omega_f + Q_i \tag{5}$$

The inverters are modeled in a common reference frame (d-q), fig. 2. Each voltage vector has an angle δ_i with respect to the d-axes.

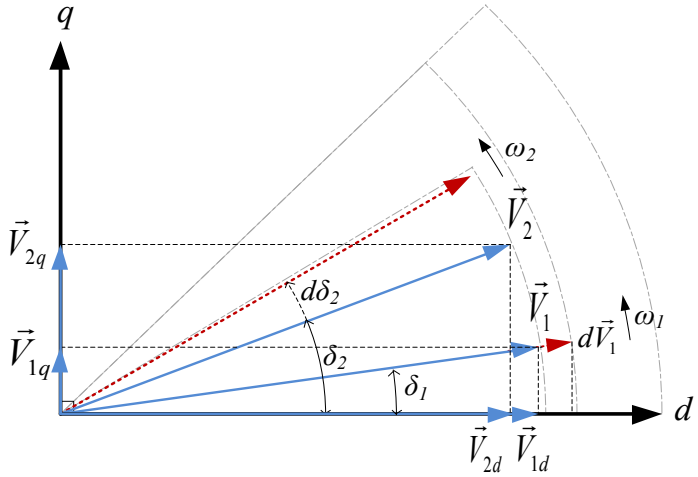

Fig. 2. Voltage vectors in reference d-q frame.

The vector V can be represented as $\vec{V} = V_d + jV_q$ Where

$$V_d = V\cos(\delta) \qquad V_q = V\sin(\delta) \qquad \delta = \arctan\left(\frac{V_q}{V_d}\right) \tag{6}$$

From (4) and fig. 2 it is shown that ω_i changes in response to the real power flow and modifies the angle δ_i. Thus, from (6) it can be expressed

$\omega = \dot{\delta} = \frac{\dot{V}_q V_d - \dot{V}_d V_q}{V_d^{\,2} + V_q^{\,2}}$ Considering $|V| = \sqrt{V_d^{\,2} + V_q^{\,2}}$ and the expressions (4), (5) and (6) it can be obtained the state equation (7) which describe the behavior of each inverter.

$$\begin{cases} \dot{\omega} = \omega_f \omega - k_p \omega_f P \\ \dot{V}_d = -\omega_f V_d - \omega V_q - \dfrac{k_p \omega_f V_d}{|V|} Q \\ \dot{V}_q = \omega V_d - \omega_f V_q - - \dfrac{k_v \omega_f V_q}{|V|} Q \end{cases} \tag{7}$$

2.2. Combined model of all the inverters and network model

In previous section the mathematical model of an individual inverter on a common reference d-q frame was discussed. Let us consider a system with two inverters connected to a network, as shown in fig. 1. The state equation for two inverters is

$$\begin{cases} \dot{\omega}_1 = \omega_{f1}\omega_1 - k_{p1}\omega_{f1}P_1 \\ \dot{V}_{d1} = -\omega_{f1}V_{d1} - \omega_1 V_{q1} - \dfrac{k_{p1}\omega_{f1}V_{d1}}{|V_1|}Q_1 \\ \dot{V}_{q1} = \omega_1 V_{d1} - \omega_{f1}V_{q1} - -\dfrac{k_{v1}\omega_{f1}V_{q1}}{|V_1|}Q_1 \\ \dot{\omega}_2 = \omega_{f2}\omega_2 - k_{p2}\omega_{f2}P_2 \\ \dot{V}_{d2} = -\omega_{f2}V_{d2} - \omega_2 V_{q2} - \dfrac{k_{p2}\omega_{f2}V_{d2}}{|V_2|}Q_2 \\ \dot{V}_{q2} = \omega_2 V_{d2} - \omega_{f2}V_{q2} - -\dfrac{k_{v2}\omega_{f2}V_{q2}}{|V_2|}Q_2 \end{cases} \tag{8}$$

The network in the fig. 1 is described by the nodal admittance matrix equation

$$\begin{bmatrix} \vec{I}_1 \\ \vec{I}_2 \end{bmatrix} = \begin{bmatrix} Y_1 + Y_3 & -Y_3 \\ -Y_3 & Y_2 + Y_3 \end{bmatrix} \begin{bmatrix} \vec{E}_1 \\ \vec{E}_2 \end{bmatrix} \rightarrow \begin{bmatrix} I_{1d} \\ I_{1q} \\ I_{2d} \\ I_{2q} \end{bmatrix} = \begin{bmatrix} G_{11} & -B_{11} & -G_{12} & B_{12} \\ B_{11} & G_{11} & -B_{12} & -G_{12} \\ G_{12} & B_{12} & G_{22} & -B_{22} \\ -B_{12} & -G_{12} & B_{22} & G_{22} \end{bmatrix} \begin{bmatrix} V_{d1} \\ V_{q1} \\ V_{d2} \\ V_{q2} \end{bmatrix} \tag{9}$$

Considering the active and reactive power equations (3) and (9),

$$\begin{bmatrix} P_1 \\ Q_1 \\ P_2 \\ Q_2 \end{bmatrix} = \begin{bmatrix} V_{d1} & V_{q1} & 0 & 0 \\ -V_{q1} & V_{d1} & 0 & 0 \\ 0 & 0 & V_{d2} & V_{q2} \\ 0 & 0 & -V_{q2} & V_{d2} \end{bmatrix} \begin{bmatrix} G_{11} & -B_{11} & -G_{12} & B_{12} \\ B_{11} & G_{11} & -B_{12} & -G_{12} \\ G_{12} & B_{12} & G_{22} & -B_{22} \\ -B_{12} & -G_{12} & B_{22} & G_{22} \end{bmatrix} \begin{bmatrix} V_{d1} \\ V_{q1} \\ V_{d2} \\ V_{q2} \end{bmatrix} \tag{10}$$

Which the above equation, combined with (8), gives the whole system equations

$$\begin{cases} \dot{X}_1 = \alpha_1 X_1 - \alpha_2\sqrt{X_2^2 + X_3^2} - \alpha_3 \dfrac{(X_2X_5 + X_3X_6)}{\sqrt{X_2^2 + X_3^2}} + \alpha_4 \dfrac{(X_3X_5 - X_2X_6)}{\sqrt{X_2^2 + X_3^2}} \\ \dot{X}_2 = \alpha_1 X_2 - X_1X_3 - \alpha_5 X_2\sqrt{X_2^2 + X_3^2} - \alpha_6 X_2 \dfrac{(X_2X_5 + X_3X_6)}{\sqrt{X_2^2 + X_3^2}} + \alpha_7 X_2 \dfrac{(X_3X_5 - X_2X_6)}{\sqrt{X_2^2 + X_3^2}} \\ \dot{X}_3 = \alpha_1 X_3 - X_1X_2 - \alpha_5 X_3\sqrt{X_2^2 + X_3^2} - \alpha_6 X_3 \dfrac{(X_2X_5 + X_3X_6)}{\sqrt{X_2^2 + X_3^2}} + \alpha_7 X_3 \dfrac{(X_3X_5 - X_2X_6)}{\sqrt{X_2^2 + X_3^2}} \\ \dot{X}_4 = \beta_1 X_4 - \beta_2\sqrt{X_5^2 + X_6^2} - \beta_3 \dfrac{(X_2X_5 + X_3X_6)}{\sqrt{X_5^2 + X_6^2}} + \beta_4 \dfrac{(X_3X_5 - X_2X_6)}{\sqrt{X_5^2 + X_6^2}} \\ \dot{X}_5 = \beta_1 X_5 - X_4X_6 - \beta_5 X_5\sqrt{X_5^2 + X_6^2} - \beta_6 X_5 \dfrac{(X_2X_5 + X_3X_6)}{\sqrt{X_5^2 + X_6^2}} + \beta_7 X_5 \dfrac{(X_3X_5 - X_2X_6)}{\sqrt{X_5^2 + X_6^2}} \\ \dot{X}_6 = \beta_1 X_6 - X_4X_5 - \beta_5 X_6\sqrt{X_5^2 + X_6^2} - \beta_6 X_6 \dfrac{(X_2X_5 + X_3X_6)}{\sqrt{X_5^2 + X_6^2}} + \beta_7 X_6 \dfrac{(X_3X_5 - X_2X_6)}{\sqrt{X_5^2 + X_6^2}} \end{cases} \tag{11}$$

Where

$\alpha_1 = -\omega_{f1};\ \alpha_2 = k_{p1}G_{11}\omega_{f1};\ \alpha_3 = k_{p1}G_{12}\omega_{f1};\ \alpha_4 = k_{p1}B_{12}\omega_{f1};\ \alpha_5 = k_{v1}B_{11}\omega_{f1};\ \alpha_6 = k_{v1}B_{12}\omega_{f1};\ \alpha_7 = k_{v1}G_{12}\omega_{f1}$

$\beta_1 = -\omega_{f2};\ \beta_2 = k_{p2}G_{22}\omega_{f2};\ \beta_3 = k_{p2}G_{12}\omega_{f2};\ \beta_4 = k_{p2}B_{12}\omega_{f2};\ \beta_5 = k_{v2}B_{22}\omega_{f2};\ \beta_6 = k_{v2}B_{12}\omega_{f2};\ \beta_7 = k_{v2}G_{12}\omega_{f2}$

3. Study of Stability for the Microgrid

In this section it is constructed a Lyapunov function for the Microgrid system and obtained the respective eigenvalues for the A matrix of lineal system.

3.1. Lyapunov's method

One of the main impediments for the application of Lyapunov's method to physical systems is the lack of formal procedures to construct the Lyapunov function for the differential equations describing the given physical system [10]. A function *V(X)* is called a Lyapunov function of the system *f(X)* where *f(0)=0* if it fulfills the following properties [11]:

i. $V(0) = 0$

ii. $V(X) > 0$ for all X

iii. $\frac{d}{dt}V(X) \le 0$ along all trajectories of the system

Then the point *X=0* is locally stable.

It is proposed to construct the Lyapunov function by using the set of representative variables for each generator. By following this principle, firstly it is chosen the square frequency variables (X1 and X4) divided into the working frequency to obtain "per unit" values and secondly it is used the dq voltage of each generator divided by the module of voltage; this method is repeated for every generator of the Microgrid. Finally, every term of the obtained Lyapunov function are multiplied by a different constant. These constants must be chosen to fulfill the iii property.

$$V(X) = \frac{AX_1^2}{\omega_k} + B\frac{X_2^2 + X_3^2}{\sqrt{X_2^2 + X_3^2}} + \frac{CX_4^2}{\omega_k} + D\frac{X_5^2 + X_6^2}{\sqrt{X_5^2 + X_6^2}} \tag{12}$$

The above equation fulfills (i) and (ii) properties as can be seen by inspection. Condition (iii) can be shown as

$$\frac{\partial V(X)}{\partial X_1}\dot{X}_1 + \frac{\partial V(X)}{\partial X_2}\dot{X}_2 + \frac{\partial V(X)}{\partial X_3}\dot{X}_3 + \frac{\partial V(X)}{\partial X_4}\dot{X}_4 + \frac{\partial V(X)}{\partial X_5} + \dot{X}_5 + \frac{\partial V(X)}{\partial X_6}\dot{X}_6 \le 0 \tag{13}$$

Hence,

$$\begin{aligned} AX_1\dot{X}_1 + B\left(X_2^2 + X_3^2\right)^{1/2} X_2\dot{X}_2 + C\left(X_2^2 + X_3^2\right)^{1/2} + DX_3\dot{X}_3 + CX_4\dot{X}_4 + \\ + E\left(X_5^2 + X_6^2\right)^{1/2} X_5\dot{X}_5 + F\left(X_5^2 + X_6^2\right)^{1/2} X_6\dot{X}_6 \le 0 \end{aligned} \tag{14}$$

Then the Lyapunov function (12) and the mathematical model (11) are simulated in MATLAB/Simulink for reaching the best values of every constant and the region where the Lyapunov function is valid and the system is stable. A first study it is used A=C; B=E and C=F.

3.2. Eigenvalues of lineal system

Considering the system of the figure 1 and the nonlineal model in (11) and applying Taylor's series around the operating point at this model, it can be obtained the state-space equations of the small-signal model. This is acceptable if variations around the operating point are assumed to be small; therefore, the small signal lineal model is $\left[\dot{\tilde{X}}\right]=[A]\left[\tilde{X}\right]$.

Finally the systems with parameters presented on Table I, the initial active and reactive output powers zero, and initial vectors V1 y V2 in phase, the A matrix values are

$$A=\begin{bmatrix} -37.7 & -0.466 & -0.936 & 0 & 0.157 & 0.944 \\ 0 & -36.57 & -0.217 & 0 & -0.94 & 0.157 \\ 154.5 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0.097 & -0.956 & -37.7 & -0.34 & -0.97 \\ 0 & -0.954 & 0.097 & -9.86 & -36.5 & -2.42 \\ 0 & -0.061 & 0.006 & 154.9 & -2.32 & -0.15 \end{bmatrix}$$

And the respective eigenvalues are $\lambda_1=0;\ \lambda_2=-10.8;\ \lambda_3=-26.9;\ \lambda_4=-35.7\ \lambda_5=-37.7;\ \lambda_6=-37.5;$
According to [8] only the nonzero eigenvalues are important for the stability studies. The system has five negative real eigenvalues, and then it is a stable point.

Table I. System parameters.

Variable	Value	unit
Line transmission (Z_3)	0.5+3i	Ω
Local load (Z_1)	13+6i	Ω
Local load (Z_2)	25+13i	Ω
Cut-off freq. of measuring filter (ω_f)	37.7	rd/s
Frequency droop coefficient (k_p)	0.0005	rd/s/W
Frequency droop coefficient (k_v)	0.0005	V/VAR
Nominal frequency	377	rd/s

4. Simulation Results

The methodology used is as follows; firstly of all the Microgrid system is implemented be means of the power electronics toolbox of Matlab/SIMULINK, the system parameters for simulation are shown in table I. Secondly, the simulated values of every state variable in the operating point are used to find the A matrix values and its eigenvalues. This eigenvalues are used to determinate the stability of the system. After that, it is utilized the set of equation (11) to verified the model and then the values of the state variables and its derivatives are used to evaluate the Lyapunov function. Finally it is studied the Lyapunov function and it is determined the region of stability of the system.

The fig 3 shows the PQ power simulation by means of the Power electronic toolbox. This was repeated with a different line inductor values (from 8mH to 0.5mH with step of 0.5mH). For each simulation the values of state variables at the operating point were saved and these were used to study the small signal stability.

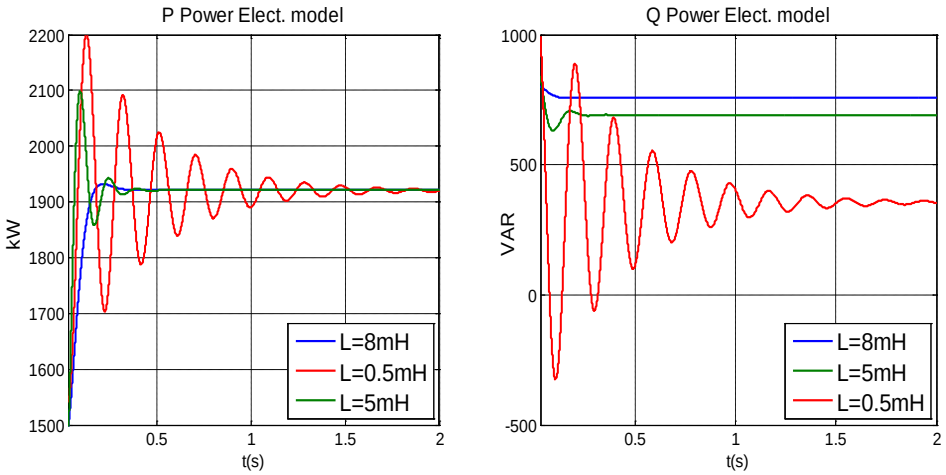

Fig. 3. Simulation results of a DG Microgrid system by means of Power Electronics tools

The fig 4 shows the PQ power simulation by means of nonlineal model of the Microgrid systems obtained in 2.2. It can be seen the same behavior in both transient and steady state values. As explained previously, the line inductance was varied for the nonlineal model. The values of state variables were used to validate the Lyapunov function.

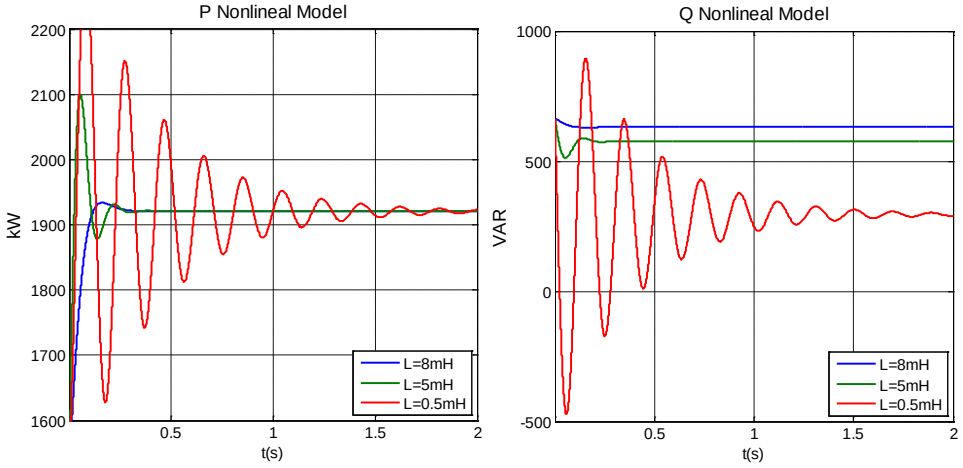

Fig. 4. Simulation results of a DG Microgrid system by means of Nonlineal model.

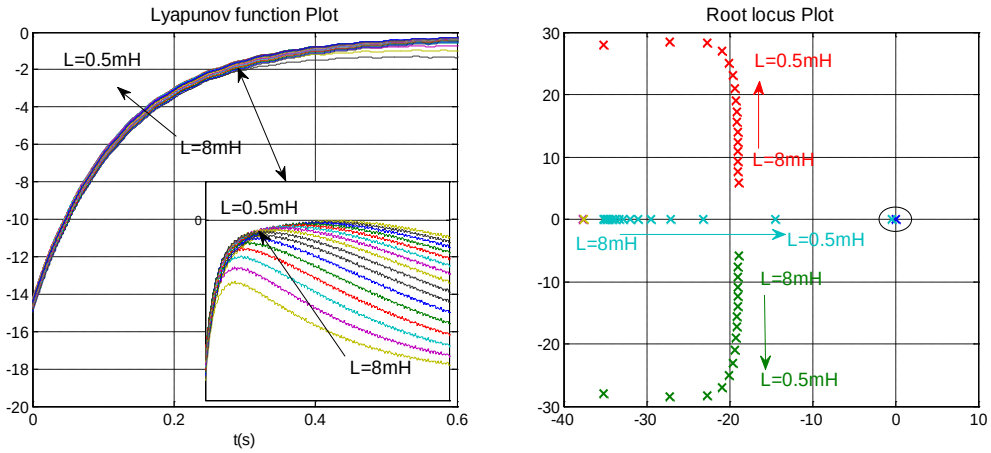

Fig. 5. Study of stability by means of Lyapunov function and root locus plot.

Fig 5 shows the study of stability by using the Lyapunov function and the root locus plot. They can be seen how the stability is affected when the line inductance decrease. The transient stability analysis by a Lyapunov method evaluate all variations starting in around a stable point that converge to it, therefore it can determine the lowest value of V(X) on the surface $\dot{V}(X) = 0$ and by this way the region of asymptotic stability is determined. The small signal stability analysis by a root locus plot shows how the roots are moved when the line inductor decreases, but cannot give an "a priori" region of asymptotic stability.

5. Conclusions

In this paper, a nonlinear state-space model of a Microgrid is presented. The model includes the most important dynamics. This modeling method is able to be extended to n-generators. The model has been analyzed by means of both stability studies Lyapunov function and root locus plot. A general methodology to find a valid Lyapunov function for non linear stability analysis has been presented. Using that Lyapunov function the region of asymptotic stability can be determined. These tools will allow the design of Microgrid systems with loads, generators and storage systems assuring the global stability of the system.

Abstract: This paper presents an optimal design procedure for a small permanent magnet wind generator which supplies a full-bridge diode rectified load. The aim is to improve the output voltage waveform of the generator. An electromagnetic-thermal design algorithm is proposed based on an analytical model of a surface-mounted permanent magnet generator. A comprehensive combined model, consisting of design program and simulation of the designed generator under rectified load, is utilized. Design variables are optimized over their appropriate limits using a genetic algorithm. The results indicate the improvement of the output voltage waveform.

1. Introduction

Permanent magnet generator (PMG) is a self-excited system and it can be a proper choice to coupling it to wind turbine. The output of the generator can charge the batteries or supply inverter or both [1]. There are different techniques to connect a DC bus (with power electronics devices) to the PMG [2]. Utilization of rectified loads distorts the output voltage waveform of the PMG leading to a low quality power delivered to the load. A proper operation of the generator under such conditions requires a precise design optimization of the PMG. Such design needs an appropriate modeling and comprehensive design algorithm.

Details of PMG design for direct coupling to a wind turbine has been given in [3] in which four configurations including radial-flux, axial-flux, cross-field-flux and claw-pole generators have been compared based on the air gap flux density, copper losses, PM weakening and the system cost. This comparison indicates that a radial-flux, internal-PM is a proper choice for designing a 400 kW generator. Application of different configurations of PMG for wind turbine has been proposed in [4] and 60 configurations has been compared based on the torque density and also cost per developed torque function. It shows a radial-flux PMG using surface-mounted Ferrite PMs has a better performance compared with the internal PM

version. In [5], the axial-flux and radial-flux PMGs, for direct driven wind turbine, have been optimized based on the cost per developed torque objective function. The results indicate that the radial-flux machines have lower cost and torque density. In [6], two types of radial-flux PMG (internal- and surface-mounted PM) with inner rotor structures for direct coupling to wind turbine are analyzed and compared. The electromagnetic behavior of generators and optimal shape of the PMs have been estimated by finite element method (FEM). The results indicate lower torque ripples in the surface-mounted PMG. Design and performance analysis of an ironless axial-flux PMG have been proposed in [7] and [8]. The particular ironless machine configuration leads to a longer effective air gap of the machine. Also a multi-variable optimization algorithm based on the design parameters for improvement of the PMG performance of the machine has been introduced. Finally, a prototype 3.5 kW machine has been built and tested in which noise, cogging torque and copper losses have been reduced in expense of heavier machine. In [9], a small radial- and axial-flux wind generators have been optimally designed using an optimization algorithm based on population growth which tries to maximize annual energy gaining from variable speed wind turbine-generator. However, thermal analysis of the PMG has been neglected.

In recent years application of power electronics components in variable speed drives and controlling output of generators has been increased. Therefore, a reliable, economical design and satisfactory operation of these machines are crucial. This paper considers the electromechanical conversion of wind energy. Electromagnetic design procedure of a surface-mounted radial-flux PMG and its thermal model are proposed. A comprehensive combined model consisting of the generator design routine and simultaneous simulation of the typical design in the presence of a rectified load is introduced and impact of this type of load upon the distortion of the output voltage waveform of the generator is studied. Finally, the design optimization procedure is proposed to achieve a near sinusoidal output voltage waveform.

2. Electromechanical Conversion of Wind Energy

Wind speed is modeled as a continuous stochastic variable. The probability of the occurrence of a define wind velocity can be expressed by a probability density function. Comparisons of the measured wind speeds show that if the time interval is long enough, the Weibull distribution function is suitable to describe the wind velocity [10, 11]:

$$f(U) = \frac{k}{c}\left(\frac{U}{c}\right)^{k-1} e^{-\left(\frac{U}{c}\right)^{k}} \tag{1}$$

where k=2 and c is the magnification parameter ($2U_{mean}/\sqrt{\pi}$). *A portion of the wind energy transmitted* to the shaft is converted into mechanical energy by blades of the turbine and its efficiency depends on the blades profile, and air density. Wind energy converted into mechanical energy (P_{shaft}) is:

$$P_{shaft} = 0.5\rho_{air}\pi R^2 U^3 \left(0.51\left(\frac{116}{\lambda_1} - 0.4\beta - 5\right)e^{-\frac{21}{\lambda_1}} + 0.006\lambda\right) \tag{2}$$

Nowadays most horizontal three-blade turbines are designed as such that their operating point are placed in the range of 5 to 7 m/s. In this case, turbine operates with maximum $C_p(\lambda,\beta)$ between 0.35 and 0.45 [9]. R and ω_r can be determined as follows:

$$R = \sqrt{\frac{P_{gen}}{\frac{1}{2}\rho_{air}\pi U^3 C_P \eta_{gen}}}$$

$$\omega_r = \sqrt{\frac{\frac{1}{2}\rho_{air}\pi\lambda^2 U^5 C_P \eta_{gen}}{P_{gen}}} \tag{3}$$

(4)

Eqns. (3) and (4) can be used as a guide for estimation of *R* and *U* in the design process of the small wind generator.

3. Design of PMG

Low-Carbon soft-steel is used in the rotor and silicon-steel laminations in the stator of PMG. The slot has semi-closed shape. The PM (NdFeB) pieces are mounted on the external surface of the rotor. The apparent power of the air gap of a radial-flux generator (S_g) versus the main dimensions of the machine is as follows [12]:

$$S_g = \frac{1}{2}\pi^2 . K_{w1} . D^2 L . n_s . SML_{pk} . SEL_{pk} \tag{5}$$

Product D^2L determines the capability of the energy absorbed by the turbine:

$$D^2 L = \frac{\varepsilon P_{gen}}{0.5\pi^2 . K_{W1} . n_s . SML_{pk} . SEL_{pk} . \cos\varphi} \tag{6}$$

where $\varepsilon = E_f / V_a$. Ratio $K_L = L/D$ is chosen in the range of 0.14 and 0.50 based on the main design and available backgrounds [12-14]. Therefore, diameter and stack length are evaluated using this ratio. In choosing *D* a particular attention must be paid to the required *P* and a proper pole pitch. On the other hand, in order to reduce the overhang copper losses and its additional expense, *D* must be limited as possible.

3.1. Magnetic Design

The generator pole numbers, PM dimensions, stator and rotor dimensions are determined in this stage.

Air gap Flux Density: The air gap flux density is limited by saturation level of the stator teeth. An appropriate value for SML_{pk} is 0.9 T. This can hold a relative balance between the magnetic circuit saturation and power absorption capability of PMG [15, 16].
Generator Poles Number: Frequency range of small PMGs is between 10 and 70 Hz or 30 and 80 Hz [9]. Therefore, the rated frequency of the generator can be chosen in the range of 45-65 Hz and P is then calculated. Conventional PM machines have normally low P and the pole pitch is considerably larger than the PM pitch; therefore, the pole arc to PM arc ratio (α) is not so crucial. However, in wind PMG, P is high and pole pitch and PM pitch are comparable and suggested range is between 0.67 and 0.77 [14].
PM Dimensions: Operating point of the magnetic circuit can be determined by intersection of the PM demagnetization curve and load line of the magnetic circuit. The slope of the load line shows the resistance of the PM against demagnetizing. A security margin in a surface-mounted PMG is guaranteed by choosing PC≥6. The PM length is estimated as follows [13]:

$$l_m = (PC - p_{rl}\mu_r) . C_\phi K_c l_g \tag{7}$$

p_{rl} is typically between 0.05 and 0.2 [15]. As seen, the required length of PM for providing the excitation flux depends on the air gap length. The air gap length in this design is taken to be about 0.01*D*.
Dimensions of Stator and Rotor: To prevent the saturation of the PMG yoke, a special attention must be paid to the dimensions and cross-section of the yoke. Assume a define stack length for PMG; the height of the yoke is evaluated as follows [17]:

$$h_{sy} > \frac{\alpha \pi D}{4pK_s} \cdot \frac{B_g}{B_{sat-s}} \tag{8}$$

$$h_{ry} > \frac{\alpha \pi (D - 2l_{m)}}{4p} \cdot \frac{B_g}{B_{sat-r}} \tag{9}$$

In order to be ensuring about non-saturated teeth of the stator, the following constraint must be held [17]:

$$w_t > \frac{\tau_s}{K_s} \cdot \frac{B_g}{B_{sat-s}} \tag{10}$$

In most electrical machines w_s is taken to be almost equal to the tooth width as such that $0.5<w_s/\tau_s<0.6$ [18]. However, if $w_s=w_t=0.5\tau_s$, the product of the electric and magnet loading approaches its peak value, and this maximizes the power absorption capability of PMG. Therefore, in a PMG with equal slot and tooth width, the non-saturation condition is as follows:

$$B_g < \frac{1}{2} . K_s . B_{sat-s} \tag{11}$$

3.2. Electrical Design

SEL_{pk} of a PMG is limited by the slot filling factor, slot height and stator conductors current density. The typical range of SEL_{pk} for a PMG is 1000 to 4000 A/m [9]. For low-voltage PMGs, the slot filling factor is in the range of 0.3 and 0.5 and current density of the stator conductors is between 3 and 8 A/mm^2. Of course, for higher current density up to 10 A/mm^2, class F insulation for windings and a proper cooling system are suggested [16]. For given SEL_{pk}, filling factor and conductor current density in a radial PMG with elliptic slots, the slot height is as follows [9]:

$$h_s = \frac{SEL_{pk}}{\sqrt{2} . J . K_{sf} . (1 - w_t / \tau_s)} \tag{12}$$

3.3. Thermal Modeling of PMG

Thermal analysis of any electrical machine is a crucial stage of the design process. Different models, depending on the required precision and complexity, have been so far proposed for thermal analysis of the PM machines. Here, an equivalent thermal-resistance network is used [18] to estimate the temperature distribution over 8 different points of PMG. To use the model, the corresponding losses of any node are calculated and by applying the losses to the resistance network, the temperature rise of the above-mentioned points are evaluated. A particular attention must be paid to the temperature rise of the PM and winding in PMG. Conducting resistance between any two-node is used to complete the 8 points in the equivalent thermal model of the motor as seen in Fig. 1. Computation procedure for the resistances is complicated and it is necessary to take into account the precise heat flow, heat convection, internal heat generation sources, different materials and dimensions of the PMG. To simplify the model, heat transfer between the PMG and cooling environment is considered assuming a mean temperature for the cooling material (15 degrees).

Two nodes have been assigned to the stator, one node to the yoke and one node to the tooth. In the full-load PMG, windings are the main source of the generated heat. Two nodes are considered in the model, one for the conductors in the slots and one for the end windings. Prediction of the PMs temperature rise is important in the thermal modeling of the PMG,

therefore one node is assigned to the PMs. Estimation of the temperature rise of PMG by n+1 thermal networks need to solve n related equations. These equations are extracted from $\theta = G^{-1}P_d$ [18], where P_d is the dissipated losses vector corresponding to any node and θ is the temperature rise vector. Thermal resistances model for forming the thermal conduction matrix G is as follows:

$$G = \begin{bmatrix} \sum_{i=1}^{n} \frac{1}{R_{1,i}} & -\frac{1}{R_{1,2}} & \cdots & -\frac{1}{R_{1,n}} \\ -\frac{1}{R_{2,1}} & \sum_{i=1}^{n} \frac{1}{R_{2,i}} & & -\frac{1}{R_{2,n}} \\ \vdots & \vdots & \ddots & \vdots \\ -\frac{1}{R_{n,1}} & -\frac{1}{R_{n,2}} & \cdots & \sum_{i=1}^{n} \frac{1}{R_{n,i}} \end{bmatrix} \quad (13)$$

This model is used in the final stage of the electromagnetic design of PMG temperature constraints are maximum permissible temperature of winding=120°C, and PM=100°C. If these constraints are satisfied, the design will be completed; otherwise the design process returns to the initial stage of the design routine and necessary modifications for the current density and magnetic flux density are made in order to decrease the heat and thus losses.

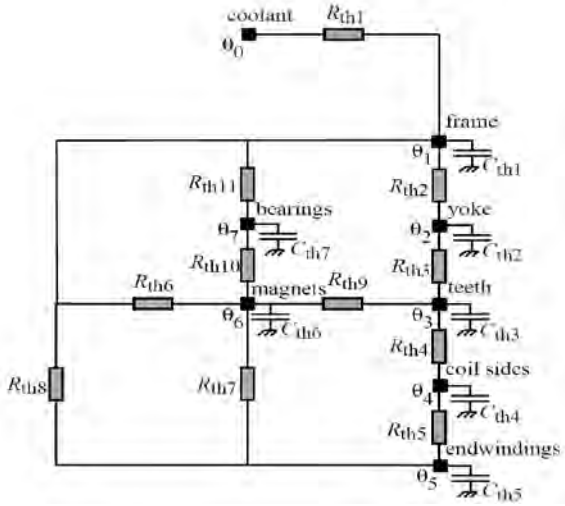

Fig. 1. Equivalent circuit of thermal model of PMG [18]

3.4. Cost Estimation for PMG Manufacturing

The cost of manufacturing a machine in an industrial plant is under influence of many factors such as identical built machines every year, technology and automation level used, organizing the product process, expense of the skilled labor, and quality of materials used. Since, here it is not possible to take into account all the above-mentioned factors in a mathematical model for cost estimation, a logical procedure is followed and the active materials of the machine are considered to evaluate the cost index and express it as a function of the dimensions of the PMG. The active materials of a PMG consist of PM, copper and iron used in the rotor and stator. Therefore, the cost index of a PMG is approximated as follows:

$$C_{total} = C_{PM}.\rho_{PM}.V_{PM} + C_{cu}.\rho_{cu}.V_{cu} + C_{fe}.\rho_{fe}.V_{fe} \quad (14)$$

where ρ is the density, V is the volume and C is the unit weight cost of the materials. The cost of each material includes: Iron 1.65 €, PM 50 € and Copper 3.1 €.

3.5. Synthetic Simulation Model

To study the impact of a rectified load upon the PMG operation, a synthetic comprehensive system consisting of simultaneous generator design routine and simulation has been proposed and applied. In this system, first the design routine calculates characteristics of the generator based on the proposed voltage, power, power factor and frequency; then turbine-generator-rectifier set included in Simulink receives the required data such as flux-linkage under each pole, resistance, inductance and poles number. At the end of simulation process, voltage waveform and performance characteristics of generator are determined. In this system, generator design algorithm is programmed. At the end of design routine, system model consisting of turbine, generator and rectifier system are implemented.

A 3 kW, 220 V, 50 Hz optimally designed PMG based on efficiency [9] is re-designed here in the presence of a nominal rectified load. The generator voltage waveform has been presented in Fig. 2. The results show that the harmonic distortion index of the voltage waveform is 15.5% which indicates the low quality output power of the PMG.

3.6. Optimization

As shown in Fig. 2, rectified load distorts the output voltage waveform and a genetic algorithm is implemented to improve the output voltage waveform. For this a fitness function based on the THD_v reduction is defined as follows:

$$Fitness\ Function = \frac{1}{THD_v} \tag{15}$$

Test designs on the wind PMG are obtained and the corresponding fitness functions are evaluated, then new design is generated by combining the best previous results. The PM residual flux density, ratio between the stack length and air gap diameter, PM arc, number of slot per pole per phase, magnetic permeance coefficient, specific electrical loading and current density are taken as design variables.

Also the range of variables values has been restricted to reasonable limits as shown in Table 1. Fig. 3 shows the obtained voltage waveforms based on the objective function of (15). Table 2 summarizes the design details of two generators. Referring to the obtained results in the design with optimal voltage, THD of voltage improves 9%. The induced voltage is Ldi/dt, and THD can be reduced by decreasing the number of winding turns.

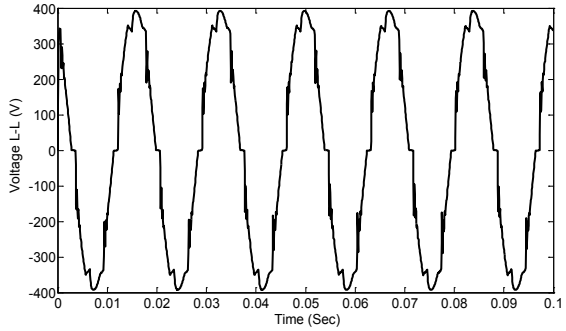

Fig. 2. Non-optimal induced line voltage of a generator under rectified load

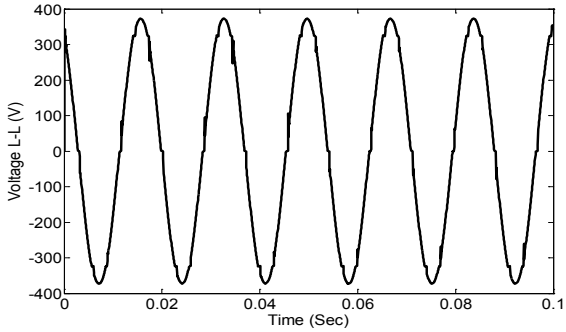

Fig. 3. Optimal induced line voltage of generator under rectified load

Also contribution of the PM arc in the pole of PMG rises in order to compensate the back-emf. Following these improvements, voltage distortion is reduced, but considering the increase *SEL* and *SML*, the magnetic loading is decreased to provide the required power. Consequents of these changes are: rising the iron losses due to the increase of the air gap flux

density, increasing the cost due to increase of PM volume, decreasing copper losses due to lower number of winding turns and resistance. Since the losses distribution in the optimal design of the PMG is subject to the change of the temperature rise of the six above-mentioned points, the PMG are in the permissible ranges

Table 1. Constraints of variables in optimization routine.

Parameter	Symbol	Value
PM residual density (T)	B_r	1-1.4
PM arc (ºElec)	A	90-170
Current density (A/mm^2)	J	3-8
Specific electrical loading (kA/m)	SEL	10-40
Air gap width to diameter ratio	k_L	0.2-1
Slot No./pole/phase	Q	1-2
Magnetic permeance coefficient	PC	5-16

Table 2. Comparison of design and performance of a 3 kW, 220 V and 60 Hz PMG with optimal efficiency and voltage in presence of rectified load (U=12 m/s).

Parameter	Symbol	Optimal Efficiency	Optimal Voltage
Shaft speed (rpm)	N_m	440/66	440/66
Generator stack length (m)	L	0.1437	0.164
Air gap diameter (m)	D	0.1437	0.232
PM arc (elec. Deg.)	A	144	157.5
PM height (m)	l_m	0.01	0.0183
PM residual flux density (T)	B_s	1.2	1.25
Phase winding no. of turns	N_{ph}	N_{ph}	176
No. of slots/phase/pole	q	1	2
Air gap length (m)	l_g	0.0011	0.0012
Winding diameter (m)	D_{cond}	0.0011	0.0013
Copper losses/Iron losses (W)	P_{cu}/P_{fe}	95.9/80.8	56.5/136.6
Power factor	Pf	91	93
Efficiency (%)	η	94.18	93.1
Air gap flux density (T)	B_g	0.72	0.79
Specific electric loading (kA/m)	SEL	30	10
Winding current density (A/mm^2)	J	5	3.64
THDv (%)	-----	15.5	5.7
Materials cost (€)	Cost	249.9	776.4
Stator winding resistance (Ω)	R_s	2.55	1.27
Stator winding leakage inductance (H)	L_l	0.003	0.00064
Stator winding mutual inductance (H)	L_m	0.005	0.0011

4. Conclusion

In this paper a comprehensive electromagnetic-thermal design algorithm for a wind PMG was presented. A combined model consisting of simultaneous generator design program and simulation in the presence of a rectified load was used to study the impact of this type of load upon the induced voltage distortion. Base on the presented model and genetic algorithm optimization routine, specifications of an optimal generator for improvement of the induced output voltage waveform of the PMG were obtained which leads to 9% decrease of the harmonic distortion index.

Abstract: With more than 20 GW of installed wind power capacity installed in Northern Germany and more to come when offshore wind power expands, there are periods when the available wind power exceeds the grid capacity or even the electricity demand in reach. This excess wind power could be utilised for the electrolytic production of hydrogen, which can be stored and used as a transportation fuel, feedstock for the chemical industry, for re-electrification or for natural gas (NG) pipeline injection.
Based on the potential availability of excess wind power for hydrogen production and in view of the expected build-out, the paper drafts and discusses the economic framework and modalities of hydrogen production. Potential usages are discussed in general and specially for Northern Germany, where a hydrogen demand of 320 mill. Nm^3 was identified by 2020 for industry and transportation.
With some initial incentives, electrolytic hydrogen production can be made competitive by 2020. It is concluded that Northern Germany is an ideal region for the production of hydrogen from renewables due to the its high wind power density, its geologic conditions allowing for cavern storage, its industrial demand for hydrogen and also its pioneering role in hydrogen fuelled road transportation.

Keywords: *Hydrogen, Storage, Electrolysis.*

1. Introduction

With the increasing renewable power capacity, especially wind power, installed in many countries, there will be periods when the available power exceeds the capacity of the grid or even the demand in reach. This excess electricity may be eliminated by cutting down renewable power feed-in or, more advantageously, by adding additional temporal demand through electricity storage devices. In countries without excessive potential for pumped hydro storage, the storage technology with the highest energetic potential is offered by hydrogen. Hydrogen can be produced from electricity by water electrolysis and stored inexpensively in underground salt caverns where geologic conditions are suitable, or at higher costs in aboveground pressure vessels or liquid dewars. The hydrogen can be used for power generation when renewable generation is low, but also as a transportation fuel, as a feedstock for the chemical industry or other purposes. Therewith, hydrogen not only makes renewable electricity storable over long periods but also creates cross-links to other energy-intensive sectors.

This paper presents the main results of a recent study on the potentials of hydrogen production from wind power in Northern Germany [1], where more than 20 GW of wind power capacity are installed today and there will be tremendous increases in the coming years due to the expansion of offshore wind power. It will first review the current framework of the German electricity generation. Then, based on the expected electricity generation and demand, the amount of excess power available for hydrogen production will be estimated. This will be followed by a discussion of operation models for hydrogen electrolysis, rounded off by a discussion of required storage demand and possible uses and costs of the hydrogen.

2. General framework of the German electricity generation

Since 1990, electricity production in Germany has only increased by about 0.8% p.a. on average, and almost the entire surplus has been covered by renewable electricity [2].

Due to the age structure of the power plant park and in view of the previously planned nuclear phase-out, currently a large number of new fossil power plant projects (especially hard coal) are in the planning phase; yet, it needs to be mentioned that the realization of many projects is becoming ever more uncertain, partly due to the postponement of the nuclear phase-out but also due to decreasing public acceptance for infrastructure projects [3].

The share of renewables for electricity production in Germany has increased from 10 to 15% in only three years (2005-2008), and for 2011 the Transmission System Operators (TSOs) expect a total of 112 TWh renewable electricity, representing almost 20% of overall production [4]. Highest shares are being achieved in the North (e.g., in Schleswig-Holstein, renewable energy generation, mainly wind power, exceeds 40% of the electricity demand). Specifically in regions with high intermittent renewable capacities installed, already today grid capacity issues occur and wind turbine power need to be cut off temporarily in order not to cause grid breakdown (regulated in the renewable energy law as "feed-in management") [5]. Further extensive renewable potentials lie within repowering of onshore wind farms and the build-out of offshore wind energy use in the North and Baltic Sea.

By 2020, according to the "Lead scenario 2009" [6], 33 GW from onshore and 9 GW from offshore wind power are expected to be fed into the German grid. The offshore feed-in is expected to grow to 24 GW by 2030. Since all offshore capacity is landed in Northern Germany (mainly in Schleswig-Holstein and Lower Saxony) where also the density of onshore generation is high, this will at times cause massive excess power production. This implies grid reinforcement and extension to transmit the power to neighboring regions; however, even Germany-wide power production may exceed the demand and export capacities at times of low load and high wind.

Possible remedies are the temporal shift of loads by demand-side management and battery electric vehicles; however, potentials are limited both with respect to quantities and time periods over which the loads can be bridged [7]. Therefore, large-scale electricity storage will be urgently required in order to more easily integrate the further increase in intermittent renewable electricity generation into the grid.

3. Availability of excess power for hydrogen production

In order to analyse the potentials of hydrogen production from excess renewable electricity, the quantities of power surplus have to be estimated. In this sense "excess power/electricity" will be defined as the portion of power/electricity which cannot be utilised in times of high generation (renewable+fossil+nuclear) and low demand as well as export capacities of a region. In such cases the renewable generation will have to be cut off in order to assure grid stability. The quantity of excess power production depends mainly on the following four factors:

- Installed capacity of intermittent renewables, especially wind power. The feed-in of photovoltaics is less relevant in this context as it provides electricity during daytime where demand is comparatively high.
- Installed capacity of conventional power plants, especially base load plants. In particular, lignite and nuclear power plants are operated at high load also in times of high winds increasing the excess power. For example, during the night of October 4th, 2009, high wind volume and low electricity demand resulted in the negative spot market price of 0.50 €/kWh. Since at this time German nuclear power plants still operated at an average load of 77%, lignite at 65%, hard coal at 12% and natural gas at

9% [8] we assume this capacity utilization as the minimum practical part load of conventional plants during situations with excess electricity.

- Electricity demand and demand profile of the region. In general, the excess electricity can be reduced either by demand-side management or by an increased demand for a given level of power supply.
- Export capacity to neighbour regions. This is not only limited by the available transfer capacities, but also by the fact that adjacent regions are meteorologically linked. In this sense, excess wind power generation may occur not only in Northern Germany but also in other regions with own wind parks. In consequence, extension of grid capacity alone is not always effective to reduce excess power.

For the calculation of the excess power, specific assumptions regarding the capacity of energy generation per type and demand curves had to be made. The minimum generation of dispatchable power plants was derived from the estimated available capacity and the minimum part load numbers mentioned above. Onshore wind power curves were based on scaled Germany-wide production curves of the reference year 2008. Wind speed data from FINO platforms in the North and Baltic Sea were used in order to calculate the offshore power curves based on the characteristics of a 5 MW turbine. To estimate the electricity demand, hourly data from 2008 provided by UCTE / ENTSOE [9] were scaled to the respective future demand. Due to metrological linkages between adjacent regions, electricity export to neighbour countries was not considered as a way to use excess electricity. From the comparison of resulting generation and demand, the excess power generation could be estimated as shown in Figure 1.

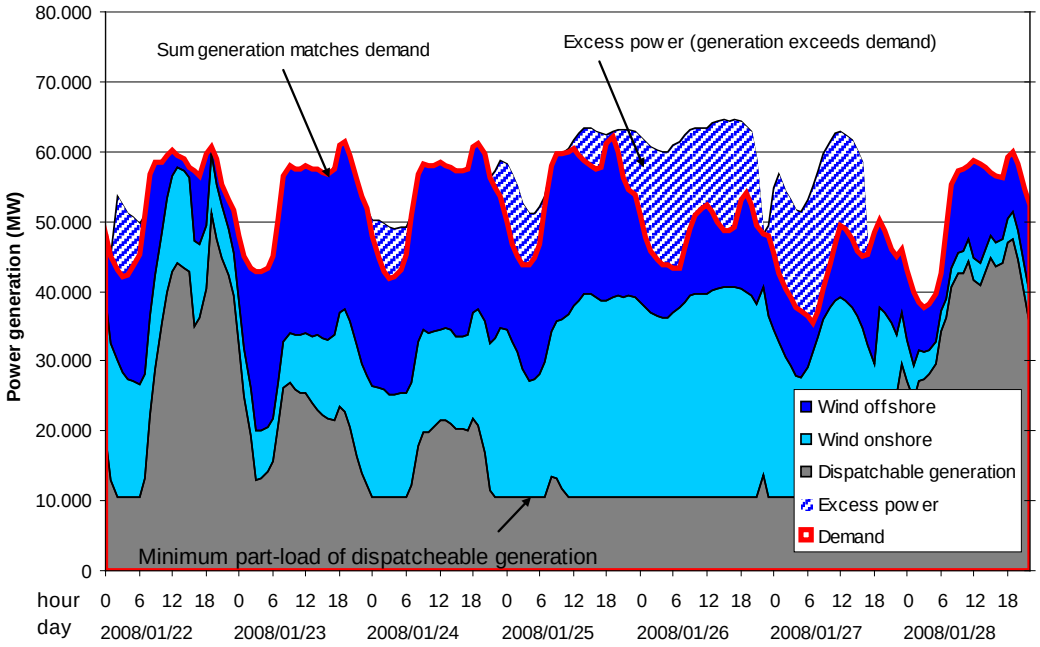

Fig. 1. Methodology to determine excess power (1 week displayed)

With this methodology, the excess electricity was estimated for different scenarios based on the generation and demand projections of the "Lead scenario 2009" [6]. Two variations from the lead scenario were considered: a scenario where 15 GW nuclear generation capacity would remain online (compensated by lower capacities of hard coal and natural gas), and an extreme scenario where the 2008 values for fossil and nuclear generation capacity and demand were frozen and the onshore and offshore generation capacity ramped up as in the

Lead scenario (33 GW onshore + 9 GW offshore by 2020, and 36 GW onshore + 24 GW offshore by 2030). Figure 2 shows the resulting excess power generation per year in Germany until 2030. In the lead scenario, only up to 9 TWh of excess electricity accrue until 2030 due to the consequent phase-out of fossil power plants. Retaining nuclear capacities will strongly increase excess electricity, and assuming that the power plant park of 2008 is retained while ramping up renewables, huge amounts of excess electricity will accrue until 2030. According to this estimation, by 2020 between 1.1 and 13 TWh of electricity (corresponding to 1.1-13% of overall wind power generation) cannot be used when they accrue and will therefore be available for energy storage in the form of hydrogen. For comparison, other authors with similar approaches have concluded that for whole Europe, 16 to 260 TWh excess power would accrue by 2020 [10]. Wietschel et al. [11] found that for Germany, 9 TWh excess power would accrue with 38.3 GW wind power installed, increasing to 28 TWh with 48.3 GW wind power installed.

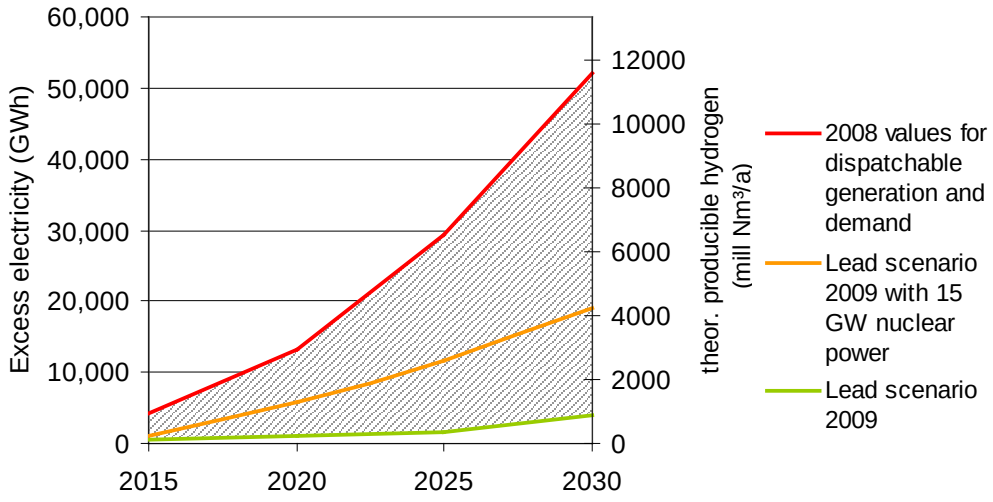

Fig. 2. Resulting excess power generation in Germany through 2030

4. Operation model for hydrogen production

Northern Germany is generally an ideal location for hydrogen production from renewables and large-scale storage due to the high concentration of wind power capacity and the geologic conditions facilitating the construction of underground salt caverns suitable for hydrogen storage. With the aim to develop a sound operation strategy for hydrogen production based on the use of excess electricity while at the same time unstraining the grid in the most economic way, the location of electrolysers as well as the economics of purchasing electricity (i.e. the connection to the electricity market) are the main criteria to be addressed.

In general there are three major options for the allocation of electrolysers: directly at the larger on- and offshore wind farms, at the end user location (e.g., an industrial sites or a hydrogen refuelling station) or at grid hubs of the high or ultra-high voltage grid in the areas with the highest wind loads and the heaviest loads on the grid (e.g., along the west coast of Schleswig-Holstein). Placement directly at the wind farms helps to unstrain the electric grid regionally and super-regionally, but hydrogen production is dispersed and the distribution to the consumers is comparatively complex, especially from offshore locations. Placement directly at the consumer site omits the transportation of hydrogen, but does not unstrain the electric grid between the wind farm and the consumer. Furthermore, access to large-scale storage caverns for longer-term storage of hydrogen cannot be provided easily in either of the distributed placement strategies. Therefore we assume that placing larger electrolysis plants at

grid hubs in areas with high wind power capacity is most beneficial, since this concept effectively unstrains the electric grid and allows for access to large-scale storage and efficient distribution of the produced hydrogen. The maximum electrolysis capacity installed at the grid hubs should be limited to a certain share of the upstream wind power. Figure 3 shows the scheme of a large-scale hydrogen storage plant (re-electrification by either CCGT or fuel cell is optional).

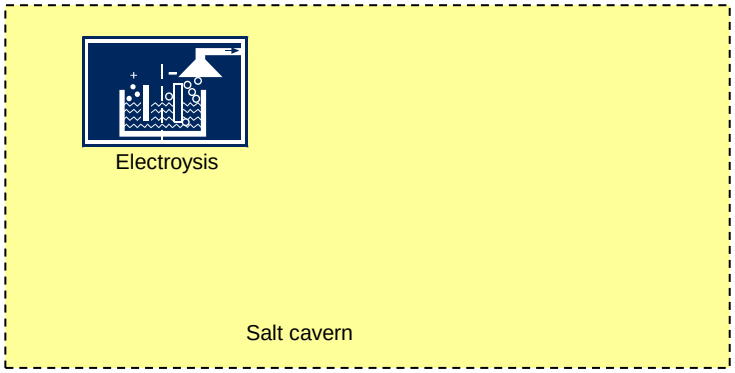

Fig. 3. Scheme of a hydrogen storage plant with optional re-electrification

As a price basis for the required electricity, either the feed-in tariffs for renewable electricity, or the day-ahead spot market hourly price curve of the European Energy Exchange (EEX) are reasonable. The latter can be interpreted either as purchasing the power at the EEX or directly from the wind farm operators, who otherwise would trade at EEX. Today, most wind power is fed in according to the fixed feed-in tariffs regulated by the German Renewable Energy Law. However, it can be expected that by 2020 the fixed feed-in tariffs will have been changed into market premiums, and most wind power will be directly traded at the spot market. Moreover, the spot market price represents the balance between electricity demand and supply: in times of low demand and high renewable energy generation the spot market price will be low, and vice versa. Hence, taking the spot market price as a base for electricity purchases ensures the operation of electrolysers in a way which indirectly unstrains the grid by using the excess electricity at low costs. As a simple operation strategy, electrolysers may be operated at full load during hours when the price is below a certain threshold, and may be kept in warm stand-by mode when the price is above the threshold. The number of operation hours per year and the average electricity price paid then depend on the price threshold set.

Further revenues for hydrogen producers can result from control reserve, since electrolysers represent a controllable load within the power grid. An electrolyser can be turned off or switched on upon request in order to provide positive or negative control reserve. The provision of the so-called “minute reserve” is tendered jointly by the transmission system operators (TSO) in Germany in 4-hour blocks for the following day. It is important to mention that the pure provision of control power (without actually being called) is already compensated by a per-MW rate. While tendering for control reserve brings additional revenues to the hydrogen production, it also increases the administration effort; since the control reserve is awarded at 10:00 AM for the next day, and the day-ahead spot market auction is at noon, the operator has to rely on a forecast of the spot market price in order to

decide whether the electrolyser should be operated during every 4 hour block (i.e. tender positive control reserve), or not (i.e. tender negative control reserve). Once control reserve has been awarded, the electrolyser must be operated according to the plan, even if electricity prices differ from the forecast. Therefore and due to the implication to operate in 4-hour blocks, the average electricity price levels will be somewhat higher if control reserve is to be provided.

A further benefit for the hydrogen producers can be achieved by directly utilising stranded wind power from turbines which otherwise would need to be temporarily cut down due to local grid restrictions (so-called "feed-in management"), provided that there are no grid restrictions between the wind turbines and the electrolysers. However, the TSOs are obliged to reinforce the power grid in order to avoid such events; hence, the potential benefits from this strategy are limited and uncertain.

5. Required storage demand, options for usage of the hydrogen, and costs

A strategy as described above will lead to a variable electrolyser utilisation with a tendency to higher production in the winter time with high wind power feed-in. In order to optimally level out the seasonal variations in production and facilitate a constant delivery of hydrogen to the end customers we found that a hydrogen storage capacity of approximately 700 full load hours is needed. If the hydrogen consumption can be adapted to the availability (higher consumption in winter than in summer), the storage capacity can be lower; on the other hand, if the hydrogen consumption is inflexible and peaks in summer, the storage capacity will need to be higher. Generally, the economic optimum of design storage capacity will be a trade-off between storage costs and timely flexibility of electrolysis operation (leading to savings in electricity costs). In the case of large-scale storage in salt caverns, the storage only contributes a minor part to the overall costs; however, if storage in e.g. aboveground pressure vessels or liquid hydrogen dewars is chosen, then the costs will be a multiple of the electrolysis costs.

A viable use of the renewable hydrogen is the partial or complete substitution of hydrogen generated from natural gas for uses in chemical and process industry. Besides saving fossil primary energy for hydrogen production by reforming, this has the potential to reduce the greenhouse gas emissions of the industries, improving their carbon footprint and avoiding costs of CO_2 certificates. Furthermore, hydrogen-powered road transportation will be an emerging market in the mid term. Offering renewable hydrogen at the refuelling stations to be erected is an interesting option, especially when considering the fact that the consumers might prefer "green hydrogen" and could also be forced by legislation (California has already implemented a law that 33% of all hydrogen for transportation will need to be renewable).

By screening the hydrogen consuming industry and using estimates on the hydrogen demand for road transportation, we have identified a demand potential of about 320 mill. Nm^3 hydrogen from wind power in the federal states Hamburg and Schleswig-Holstein by 2020 [1]. Based on lower heating value, this represents an energy of 960 GWh, which equals about 4.5% of the overall industrial final energy use in this region today. For the production and distribution of the hydrogen, about 1.55 TWh of electricity would be needed per year that could be predominantly supplied from excess electricity. The use of the this amount of renewable hydrogen in industry and transportation in Hamburg and Schleswig-Holstein instead of fossil hydrogen would save about 320.000 tons of CO_2-equivalent emissions. Beyond this, there might be potential to export renewable hydrogen, e.g. as a transportation fuel to other regions in Europe.

Based on current technology, the specific costs of hydrogen production from wind energy in Schleswig-Holstein including distribution will, depending on quantity and location of the consumption, amount to 0.42-0.75 €/Nm³ by 2020 (0.14-0.25 €/kWh of lower heating value). This is about 0.12-0.32 €/Nm³ more than the cheapest supply from fossil energy sources today. However, in the case of an incentive-supported early implementation of electrolytic hydrogen production, hydrogen from wind energy can become competitive by 2020, mainly through the rise of fossil energy prices and the cost reduction potentials of electrolysis.

A further use of the hydrogen could be used for power generation (so-called re-electrification) in combined cycle gas turbines or fuel cells. Re-electrification is a way to stabilise the electric grid by not only taking away power in times of excess renewable electricity but also providing backup power to compensate lack of renewable generation, e.g. in times of low wind. Co-firing gas turbines with natural gas at flexible shares is technically feasible. Also, the injection of hydrogen into the natural gas grid to substitute a certain part of the natural gas is possible. Almost all NG end users can tolerate hydrogen fractions up to 5% by volume (representing 1.6% by energy) without modifications. From the NG grid perspective, mainly the process gas chromatographs will have to be modified in order to detect hydrogen. In a future scenario, also up to 20% by volume hydrogen could be admixed to natural gas [12].

6. Conclusion

The paper showed that due to the ongoing build-out of intermittent renewable generation capacity and limited part-load ability of dispatchable power plants, significant amounts of excess electricity will accrue in the German electricity system in the future. This excess energy may be used to generate hydrogen, which can then be economically stored in large-scale salt caverns and utilized in industry and transportation sector or for electricity generation at times of low feed-in of renewables. An operation model based on central electrolysis plants at grid hubs, the spot market as a price basis for electricity purchases and a threshold-price strategy can yield minimum overall hydrogen production costs and at the same time facilitate effective unstraining of the grid.

Northern Germany is an ideal region for the production of hydrogen from renewables due to the its high wind power density, its geologic conditions allowing for cavern storage, its industrial demand for hydrogen and also its pioneering role in hydrogen fuelled road transportation (Berlin, Hamburg). Hydrogen storage is the only technology that can provide sufficient storage potential (multi-TWh) in Germany for a fully renewable electricity system. With some initial incentives, electrolytic hydrogen production can be made competitive within some years after the start of its deployment.

Abstract: The growing interest in diversifying the energy sources used, the major environmental objectives established, and the need to reduce the current European energy dependence, have been causing a growing and significant increase in betting on renewable energy sources. Thus recent years have witnessed a continuous increase of installed power from sources like solar, biomass, photovoltaic, wind, Biofuels, biogas among other.
The integration of renewable energy is mainly in the production of electrical power, in which has already a significant contribution. In the group of renewable energy sources used for the production of electrical power wind is the source that has registered further progress, and is also expected, that represents in the future, large part of the electric energy produced by renewable energy sources.

Although the wind helps to meet many of the problems, it's also presents some disadvantages, or constraints. Among the best-known disadvantages associated with wind, as noise and visual impact, stands out as the major technical problems the flashing of its production. The inability to predict the production of wind, leads to problems in securing demand, as well as in network integrity.

In this scenario the Combined Cycle Gas Turbine (CCGT) stands out as a great complement to wind power. Their ability to quickly put into operation, as well as the advantages that technology and fuel used presents, makes it the optimal solution to integrate with the wind energy.

Keywords: *Combined cycle plants, wind power,*

1. Introduction

In the last decade it has been attended an increasing interest on renewable energy sources. This trend is mainly in response to the increased consumption of fossil fuels, to the problem of security of supply and still to tackle the environmental problems caused by such consumption. Alternative power plants, as the solar, biomass and wind energy are the great trends. However in the majority of the cases the alternative energies are incapable to support, alone, the existing demand, forcing then, a combination with other fossil fuels like natural gas, oil, etc.

Natural gas emerged as the best fuel to be used in partnership with renewable. Its combustion gives low emission levels of pollutants, ash free, the content of carbon monoxide (the most responsible for acid rain) is practically zero and the levels of NO_x formed are well below the values of any other fossil fuel. Additional in its combustion, CO_2 emissions (responsible for the greenhouse effect) are much lower than other fuels, may even make the comparison between the products of combustion and respiration of the human (CO_2 and H_2O). For this reasons natural gas is the best option to use in support to renewable energy.

Since 1990 gross electricity generation from renewable energy sources (RES) in Europe grew significantly. Among new renewable (excluding large hydropower), wind power has the largest addition to renewable energy capacity. One of the main disadvantages of wind power is that wind is very unpredictable. Strength can vary from none to storm force. Therefore, wind turbines are unable to produce a continuous amount of electricity during the time, creating problems with network stability, and uncertainty regarding the availability of energy.

The combination of natural gas combined cycle plants and wind power is a good answer to grid stability problems and makes the whole system more secure. Gas is used as a back-up to overcome the intermittency of wind power.

2. Renewable energy policies in Europe

In the last decade, the number of countries that exploit renewable energy production has increased exponentially, and wind energy has been highlighted as a promising and attractive option among the other renewable energy sources.

Renewable have a long history of European policies and associated measures. Since 1986 the European Commission has listed among its objectives the promotion of community renewable energy [1]. In 1997 set the goal of achieving a target of 12% renewable energy by 2010. Most recent measurements, as the document "AN ENERGY POLICY FOR EUROPE" [2], published in 2007, amends the targets for 20% integration of renewable energy by 2020 and 10% integration of renewable energy in the transport.

2.1. European policies for wind power

The 20% target means that more than one-third of the EU's electricity will come from renewable sources in 2020 – up from 16% in 2006. By 2020, wind energy is expected to have overtaken hydropower as the EU's largest source of renewable electricity (Table 1).

Table 1. Renewable contribute to EU electricity consumption in 2020 [3].

Type of energy	2005	2020 - Targets	
	TWh	TWh	%
Wind	70,5	477	34,8
Hydro	346,9	384	28
Photovoltaic	1,5	180	13,1
Biomass	80	250	18,3
Geothermal	5,4	31	2,3
Solar thermal elect.	---	43	3,1
Ocean	---	5	0,4

To achieve this objective, the EU adopted a new Renewable Directive in April 2009, which set individual targets for each member state. In response to the Directive 2009/28/EC [4] member countries in 2010 presented its National Action Plan for Renewable Energy [5]. This plan sets national targets for 2020 relating to the share of energy from renewable sources consumed in transport, power generation and heating and cooling (Figure 1).

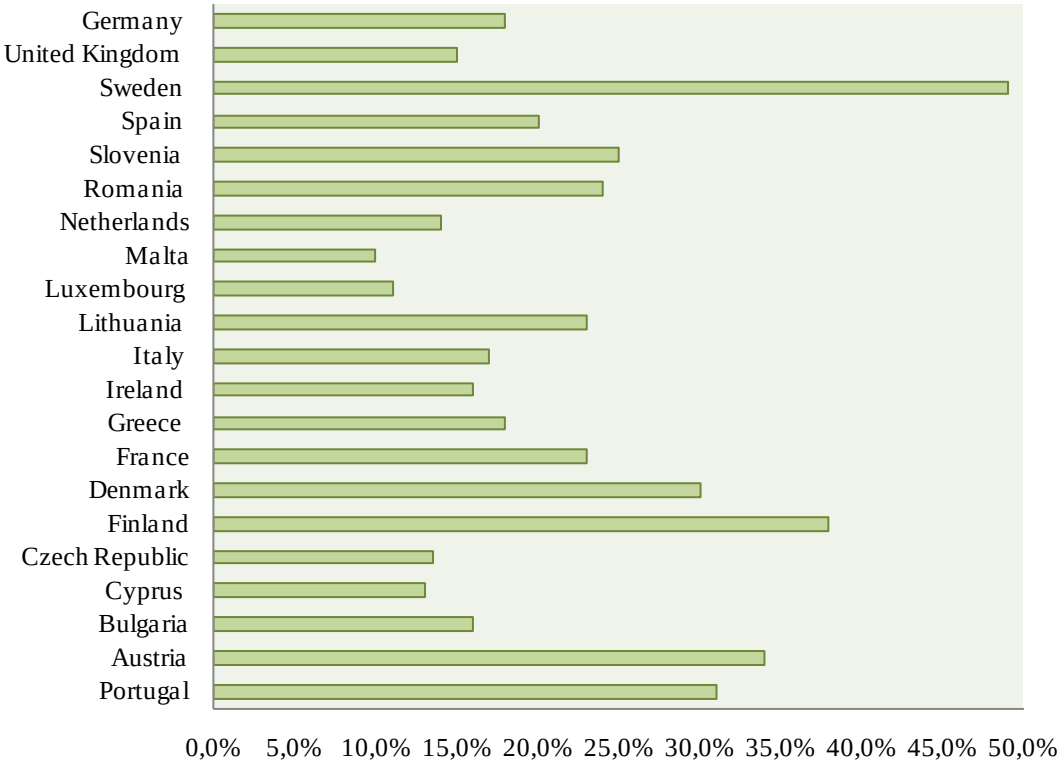

Fig. 1. Targets for Renewable Energy inclusion in final energy consumption in 2020.

With few exceptions, the field of electric energy production is the sector which foresees a greater share of energy produced by renewable energy sources. Wind energy stands out as a renewable energy source with greater participation (figure 2), and on average, excluding countries like the Czech Republic and Finland that does not estimates wind power production, the average of European countries to integrate wind power in 2020, as estimated targets, is approximately 42.3%.

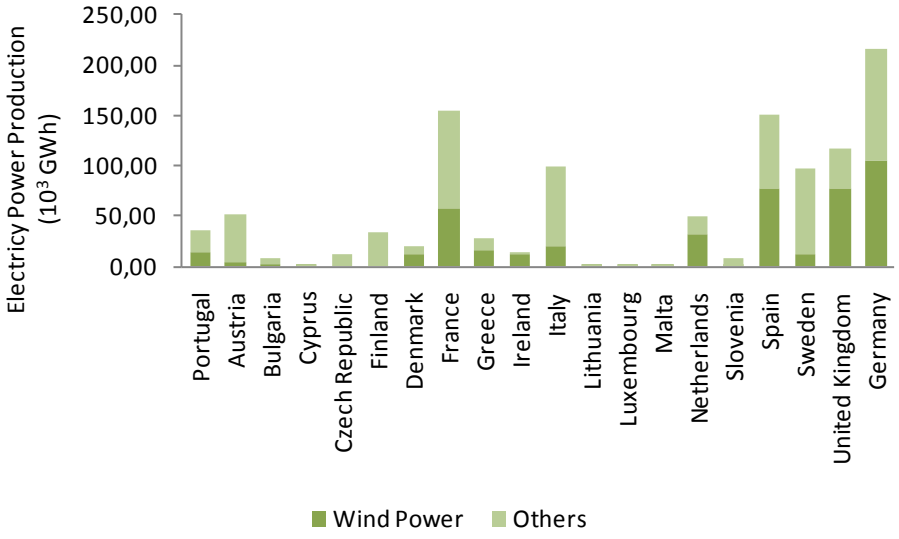

Fig. 2. Targets for Wind Power and others in electricity power production.

2.2. European wind energy tariffs

In most EU member states electricity utilities now buy electricity generated from renewable sources produced by individuals and companies. Prices paid for 'self-produced' electricity is called a feed-in tariff.

Table 2. Fee-in tariffs on member state in 2010 (€/kWh) [6].

Member state	Windpower 'On-shore'	Wind power 'Off-shore'	Solar PV	Biomass	Hydro
Austria	0.073	0.073	0.29 - 0.46	0.06 -0.16	n/a
Belgium	n/a	n/a	n/a	n/a	n/a

Czech Republic	0.108	0.108	0.455	0.077 - 0.103	0.081
Denmark	0.078	0.078	n/a	0.039	n/a
Estonia	0.051	0.051	0.051	0.051	0.051
Finland	n/a	n/a	n/a	n/a	n/a
France	0.082	0.31 - 0.58	n/a	0.125	0.06
Germany	0.05 - 0.09	0.13 - 0.15	0.29 - 0.55	0.08 - 0.12	0.04 - 0.13
Greece	0.073	0.073	0.29 - 0.46	0.06 -0.16	n/a
Hungary	n/a	n/a	n/a	n/a	n/a
Ireland	0.07 - 0.09	0.07 - 0.09	0.34 - 0.38	0.08 - 0.10	0.045
Italy	0.166	0.166	0.34	0.135	n/a
Latvia	0.108	0.108	0.455	0.077 - 0.103	0.081
Lithuania	0.078	0.078	n/a	0.039	n/a
Luxembourg	0.051	0.051	0.051	0.051	0.051
Malta	n/a	n/a	n/a	n/a	n/a

The rates of remuneration for wind energy are generally among the lowest rates of pay for electric energy produced by renewable sources in EU countries. The exceptions are Estonia, Latvia and Lithuania who practice the same tariffs for electricity produced by renewable energy sources, and Denmark, where the remuneration of the energy produced by wind is greater than the produced from biomass.

3. Development of installed capacity and production of wind and combined cycle plants power

During 2009, 10,526 MW of wind power was installed across Europe, of which 10,163 MW in EU countries. This represents growth in the EU of approximately 15, 5% compared with the values of installed power in 2008 (figure 3).

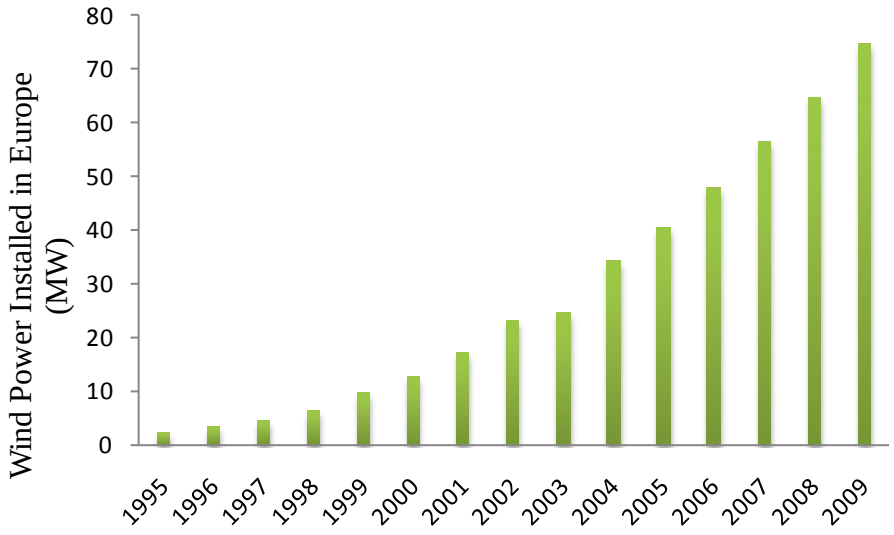

Fig. 3. Wind Power Installed in Europe [7].

The facilities in Europe are characterized by a continuous development in mature markets like Spain and Germany, along with countries like Italy, France and the UK. In 2007, production of electrical power through the wind reached a value of 104.3 GWh in the European Union [8].

Spain is the second EU country with the highest installed capacity of wind power. In 2009 it had an installed capacity of 18 GW, double the number counted in 2005 (figure 4).

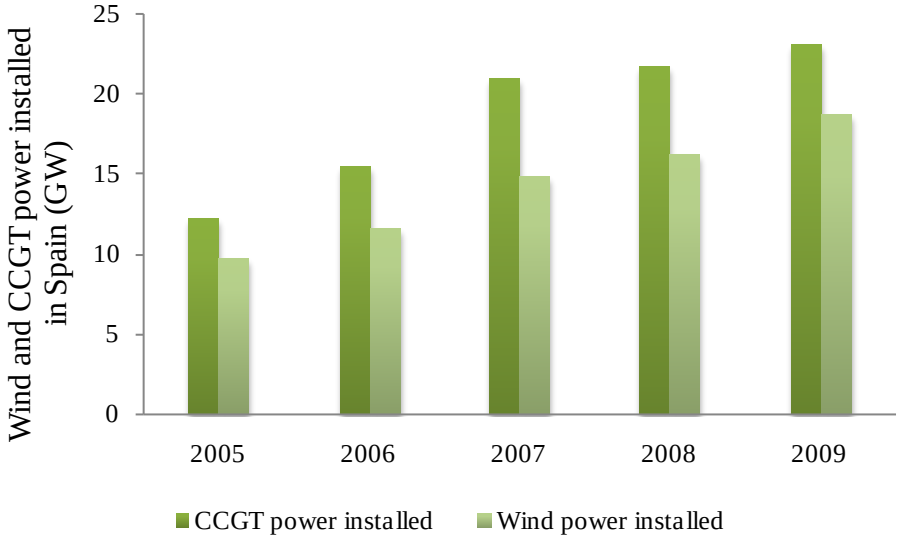

Fig. 4. CCGT and Wind Power Installed in Spain [10].

Many of the world`s electric utilities and independent power producers are turning to gas turbine combined-cycle power technology for new capacity. The major reasons for the predominance of this technology are high efficiency, moderate capital cost, low environmental impact, favorable natural gas prices and short construction schedules. Recent advances in gas turbine technology allow for a combined-cycle efficiency of almost 60 percent. The turbines used in Combined Cycle Plants are commonly fuelled with natural gas, which is found in abundant reserves in several countries. Natural gas is becoming the fuel of

choice for private investors and consumers because it is more versatile than coal or oil and can be used in 90% of energy applications.

In the last decade, most countries concentrated their power generation investments in gas-fired power plants, especially combined-cycle gas turbines (CCGT). The document "European Energy and Transport - Trends to 2030" [9], indicates that the CCGT plants accounted for about 51% of total investment in power plants combined, between 2005 and 2010. Also according to the estimates presented in this document, in 2030 the CCGT plants will reach a total installed capacity of 145 GW in Europe.

A country that reflects the growing interest and increasing investment in CCGT plants is Spain. In 2005 Spain had a total installed capacity of 12 GW of CCGT, in 2009 reached 23 GW, which represents an increase of 88% (figure 4).

4. Correlation Analysis

Although wind energy has many advantages, like being a renewable source of energy, not emissions of greenhouse gases, among other well-known advantages, also has considerable disadvantages. The disadvantages more marked are the related to visual and noise pollution caused by the same; however to technical level the biggest disadvantage of wind power is the intermittency of production. That is, wind does not present a continues production, as it is not possible to predict in advance with will be its real production.

For this reason, it is necessary to resort to so-called support system. The support system is a complementary system to the wind power, than is able to put into operation that is, to produce electrical power, in case of failure of electric power generation by wind energy, ensuring availability to demand.

The most common support systems used to support wind power plants are Combined Cycle Gas Turbine. This choice is justified by the use of a fuel that although is a fossil fuel, has great advantages when compared to the other, as well as the highly effective technology applied.

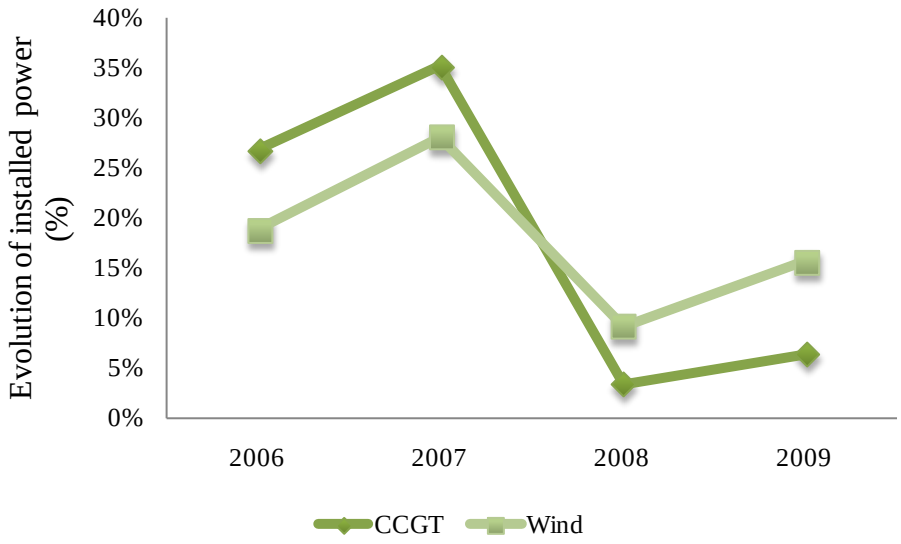

Fig. 5. CCGT and Wind evolution of installed power in Spain [10].

As we can see by the analysis of figure 5, the evolution of installed power to CCGT and wind power is very similar. Both forms of energy have a significant increase of installed power to the scheduled between 2006/07 and 2008/09, and both show a decrease in the growth of installed capacity in 2008.

In the year 2007, which corresponded to the years where there was a greater increase of installed power, CCGT reached a total installed capacity of 20 GW, corresponding to an increase of 5.5 GW compared to the previous period, and the energy wind power grew by 3.2 GW, reaching a total of 14.8 GW.

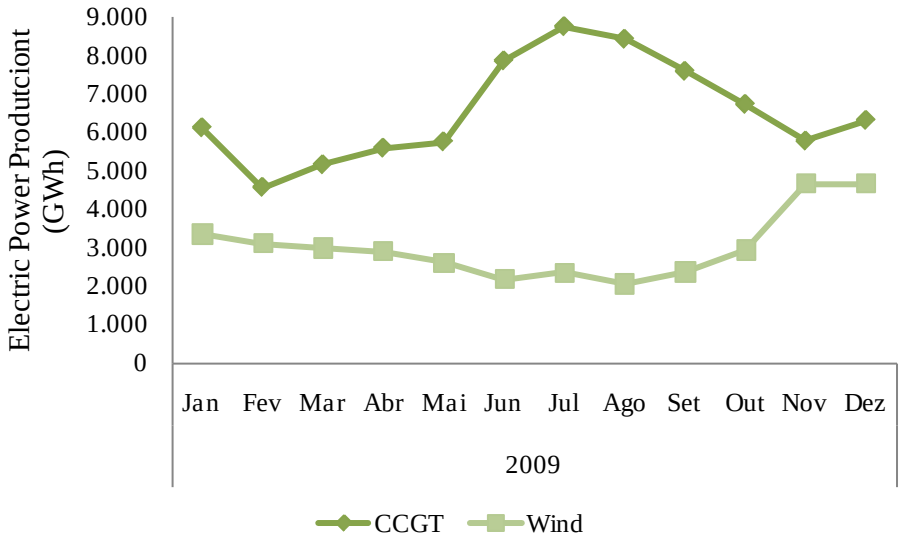

Fig. 6. CCGT and Wind electric power production in Spain [11].

As we can see by the analysis of the previous figure (Fig. 6) the electricity produce by CCGT follows the production of electric power by wind. That is, whenever there is a decrease in wind generation, the CCGT start working to remedy this breach. With the increase of electricity generation by wind, CCGT production decreases.

Thus the intermittency of electricity generation by wind does not because failures in the availability of energy and do not create problems in the network integrity.

5. Development Perspectives

According to estimates the installed capacity of wind power will tend to continue to increase. The figures for Europe are that the production of electricity by wind power to reach 477 TWH in 2020.

Assuming that the trends are maintained, the increase in installed capacity of CCGT will also maintain its growth trend, and is also expected that due to the development of technology associated with CCGT this increase will be even higher than expected. With current technology, the CCGT are already the best option to serve to support the production of other renewable energy sources, specifically through the production of wind energy.

Abstract: Improving the performance of prediction algorithms is one of the priorities in the wind energy research agenda of the scientific community. In a very simplistic approach, short-term predictions of wind power production at a given site could be generated by passing forecasts of meteorological variables (namely wind speed) through the so-called wind farm power curve, which links the wind speed to the power that is produced by the whole wind farm. However, the estimation of this conversion function is indeed a challenging task, because it is nonlinear and bounded, in addition to being non-stationary due for example to changes in the site environment and seasonality. Even for a single wind turbine the measured power at different wind speeds is generally different to the rated power, since the operating conditions on site are generally different to the conditions under which the turbine was calibrated (the wind speed on site is not uniform horizontally across the face of the turbine; the vertical wind profile and the air density are different than during the calibration; the wind data available on site are not always measured at the height of the turbine's hub).

The recent developments in data mining and evolutionary computation (EC) offer promising approaches to modelling the power curves of turbines. In this paper we use a self-supervised neural network called GMR (Generalized Mapping Regressor) to learn the relationship between the wind speed and the generated power in a whole wind farm. GMR is an incremental self-supervised neural network which can approximate every multidimensional function or relation presenting any kind of discontinuity. The approach used is a data driven one, in the sense that the relationship is learned directly from the data, without using any explicit physical or mathematical relationship between input and output space. The model is potentially applicable to any site, provided that a statistically consistent amount of wind and power data is available. The methodology allows the creation of a non-parametric model of the power curve that can be used as a reference profile for on-line monitoring of the power generation process, as well as for power forecasts.

The results obtained with the proposed approach are compared with another state-of-the-art data mining algorithm (namely, a feedforward Multi Layer Perceptron) showing that the algorithm provides fair performances if a suitable pre-processing of the input data is accomplished.

Keywords: *Wind farm, Power curve, Data-driven, Neural network, Machine learning*

1. Introduction

An interesting aspect of current research on wind power generation is the definition and implementation of accurate models to predict the energy output of a whole wind farm, rather than single wind turbines. In power systems a traditional generator is usually described as 'dispatchable', whereas wind generation is often referred to as 'non dispatchable'. Even though wind power generation has reached maturity in power systems, it is often still considered as a negative load because it is less predictable than thermal generation [1; 2].
Accurate wind power forecasting and prediction reduces the risk of uncertainty and allows for better grid planning and integration of wind into power systems.

There has been much debate and discussion in relation to the costs associated with wind power integration. A common conclusion is that as the levels of wind power penetration increase additional system balancing is required. Wind power forecasting and prediction tools are therefore invaluable because they enable better dispatch, scheduling and unit commitment of thermal generators, hydro plant and energy storage plant and more competitive market trading as wind power ramps up and down. Overall they reduce the financial and technical risk of uncertainty of wind power production for all electricity market participants.

Researchers have applied different methodologies in studying wind farms. In [3] the author built a model to predict the power produced by a wind farm using the data from the weather prediction model (HIRLAM) and the local weather model (WASP). In [4] a regression and a neural network (NN) model are compared in order to estimate a turbine's power curve. A novel approach for the analysis and modelling of wind vector fields was introduced by Goh et al. [5] and developed by Mandic et al. [6]. In these papers the wind vector is represented as a complex-valued quantity and wind speed and direction are modelled simultaneously. In [7] a new algorithm based on fuzzy logic was applied to estimate wind turbine power curve. In [8] a variety of different approaches have been used to build prediction models and characterize power curves of a wind farm by a nonlinear parametric model. In [9] parametric and non-parametric models have been applied for the same task and results have been compared. An extensive review of the existing wind speed and related generated power forecasting approaches can be found in [10].

The key issue addressed in this paper is the estimation of the relationship between the wind speed and a wind farm power output. This relationship is expressed as a power curve, which has a logistic function shape. However, as discussed in [8], the experimental power curve of a wind turbine (and of an entire wind farm as well) is not an ideal logistic function. All regions outside of the logistic curve represent either power losses or power gains. The presence of outliers and abnormal values might be due to several reasons: the presence of values of wind speed close to the cut-in or the cut-out speed of the installed wind turbines; environmental issues (blades affected by dirt, bugs and ice); shut-down due to maintenance or energy curtailment; control system issues; sensors malfunctions; pitch control malfunctions; unsuitable blade pitch angle setting; blade damage [8; 11]. Finally, the measured powers at different wind speeds are generally different than the rated power also because the operating conditions on site are generally different than the conditions under which the turbine was calibrated (the wind speed on site is not uniform horizontally across the face of the turbine; the vertical wind profile and the air density are different during the operation phase than during the calibration; the wind data on site are not always measured at the height of the turbine's hub). Moreover, due to the nonlinearity of the wind farm power curve, the uncertainty in its estimation dramatically amplifies the uncertainty contained in the wind speed forecasts. If the model of a power curve reflecting a normal status was available, the abnormal status of a turbine could be monitored and detected by this model.

The main motivation of this paper lies in the detection of the abnormalities of the wind turbines (and as a consequence also wind farms as a whole) power curve. The recent developments in data mining and evolutionary computation (EC) offer promising approaches to modelling turbines power curves. In this paper we use a self-supervised neural network called GMR (Generalized Mapping Regressor) [12; 13] to learn the relationship between the wind speed and the power generated in a wind farm. GMR is an incremental self-supervised neural network which can approximate every multidimensional function or relation presenting any kind of discontinuity. The approach used is a data driven approach, in the sense that the relationship is learned directly from the data, without using any explicit physical or mathematical relationship between input and output space. The methodology allows the creation of a non-parametric model of the power curve that can be used as a reference profile for on-line monitoring of the power generation process, as well as for power forecasts.

2. Methodology

GMR is an incremental self-organizing neural network with chains (second layer weights) among neurons. The basic idea of GMR is to transform the function approximation problem

into a pattern recognition problem under an unsupervised framework. Hence, a coarse-to-fine covering strategy of the mapping is used. Suppose we want to model the mapping relationship between a set of inputs **x** and a set of outputs **y**. GMR algorithm works transforming the data mapping problem *f*: $\mathbf{x} \rightarrow \mathbf{y}$ into a pattern recognition problem in the augmented space *Z* represented by vectors $\mathbf{z} = [\mathbf{x}^T \ \mathbf{y}^T]^T$, which are the inputs of GMR. In this space, the branches of the mapping become clusters which have to be identified.
The algorithm comprises four phases (training, linking, merging, and recalling) which are schematized in Fig. 1.

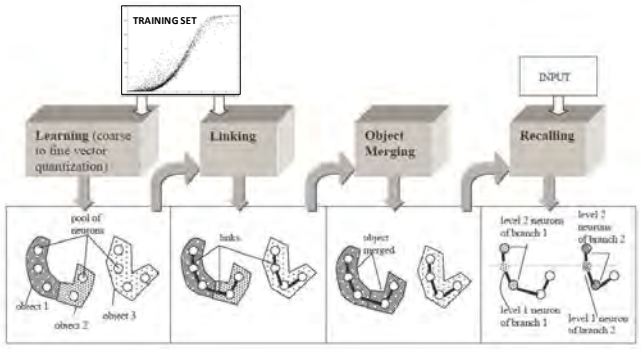

Fig. 1. The four phases of the GMR algorithm.

The ***training phase*** concerns the *vector quantization* of the *Z* space. The aim of vector quantization is, in practice, the reduction of the original data set to a small representative set of prototype vectors that are easier to manage [14]. During training, the augmented space is recovered by either creating neurons or adapting their weights according to the novelty of the input data. At the presentation of each input belonging to the training data set (TS), there are two possibilities: either creation of a new neuron (whose weight vector is equal to the input vector) or adaptation of the weight vector of the closest neuron (in input/weight space). Given a threshold ρ (*vigilance threshold*), a new neuron is created if the hyperspheres of radius ρ, centered in the already created weight vectors, do not contain the input. The parameter ρ is very important: it determines the resolution of training. Learning can be divided into two sub-phases: *coarse quantization* and *fine quantization*. The vigilance threshold used in the coarse quantization phase (ρ_1) is higher than the one used in the fine quantization, ρ_2. In general, the first epoch (i.e. presentation of the entire TS) defines the number of neurons needed for mapping and the others adapt their weights for a better approximation. The neurons thus obtained identify the *objects*, which are compact sets of data in *Z*. The resulting neurons are called *object neurons*. In the second sub-phase, at first a pre-processing is required for labelling each neuron with the list of the input data which had the neuron as winner (i.e. whose weight vector is the closest to the input vector); it can be accomplished by presenting all data (*production phase*) to GMR and recording the corresponding winning neurons. At the end, for each neuron a list of the inputs for which it won is stored. This list represents the *domain* of the object neuron. Every list is considered as the TS for a subsequent training which takes place separately (and in parallel) for each object domain. At the end, the neural network is made up of the neurons generated by the secondary learning phases (*final neurons*), labelled as belonging to an object by the corresponding object neuron.

The next phase is the ***linking phase***. Neurons' linking is accomplished by computing the second layer weights, which are discrete and equal to zero in the absence of a link. A link is computed at the presentation of each piece of data from the TS. The technique used in this paper to perform the linking phase exploits the direction of the principal component of the domain data (i.e. the direction corresponding to the highest eigenvalue of the autocorrelation matrix of the domain data) [12]. This direction is here referred to as domain *principal*

direction (PD). For each data point, the weights are sorted according to the Euclidean distance from it, and the winning neuron is determined. It is then linked to another neuron chosen in a subset of neurons (*candidate neurons*). The subset was here determined by defining in advance a number *k* of nearest neighbours of the input. Then, for each candidate, the absolute value of the scalar product between its PD and the winner's PD is evaluated. The winner is linked to the candidate yielding the maximum scalar product (i.e., the candidate whose PD is closest in direction to the winner's PD). This approach is justified by the fact that clusters with similar shapes have to be connected.

In the ***merging phase***, GMR checks whether different objects are linked. If they are, the objects are merged. The ***recalling phase*** replaces the neurons in the reduced manifold with Gaussians representing the domain. Their parameters are estimated by the maximum likelihood (ML) technique. This phase is essentially a process of Gaussian labelling followed, if required, by an interpolation step. A more detailed description of GMR is contained in [12].

3. Results

The data used for the case study refer to a wind farm (whose location is not disclosed for confidentiality reasons) and the available data set comprises a wind speed time series (one whole year) measured by an anemometer located at 50 m above the ground level (a.g.l.), as well as the power produced by each of the wind turbines, collected by a SCADA (Supervisory Control and Data Acquisition) systems at the wind farm. Since the aim of the study was modelling the power curve of the wind farm as a whole, the sum of the power produced by all the turbines was used for the application of the proposed algorithm. A training and a test set containing respectively 90% and 10% of the entire time series available (randomly selected across the whole data set) were created. In order to speed up the training, a sampling of one datum out of three was then made on the training set (TS), so to select a smaller subset (that was used as the actual TS). Before starting the training phase, the data which had been clearly recorded erroneously, due to a malfunctioning of the SCADA system, were filtered out (namely, data with an abscissa greater than the cut-in speed of the wind turbines and with a null ordinate). The remaining data were normalized in the interval [–1; +1] and denoised using the Kernel Principal Component Analysis (KPCA) technique with a bandwidth of the Gaussian kernel $\sigma = 0.4$. KPCA is a *generically nonlinear* signal processing technique; it is often used for denoising in image applications [15]. The denoised TS used to train GMR contains 2828 observations. A test data set containing 876 observations has been used in the recalling phase. Figure 2 shows the data before (a) and after (b) the normalization and denoising procedure. The data showed in Fig. 2(a) have been previously rescaled, only for visualization purposes, in order to protect data confidentiality.

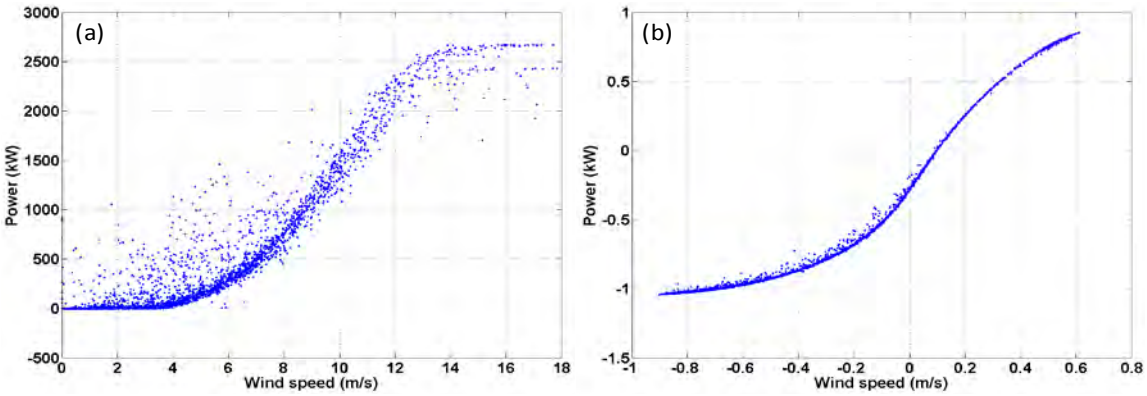

Fig. 2. Training set data before (a) and after (b) normalization and denoising.

A number of nearest neighbours k=4 was used during the linking phase. In the rough phase the vigilance threshold was set to $\rho_1 = 0.5$ and in the fine tuning phase $\rho_2 = 0.025$ was used. The number of final neurons is 101 and the number of object neurons is 26. During the recalling phase, GMR was used both without interpolation and with Gaussian interpolation. Figure 3 shows the results of the linking and merging phases of GMR. A zoom of the part of the curve contained in the dashed box is showed in the upper left and lower right corners of Fig. 3(b). In the lower right corner different objects are represented with different symbols to improve readability.

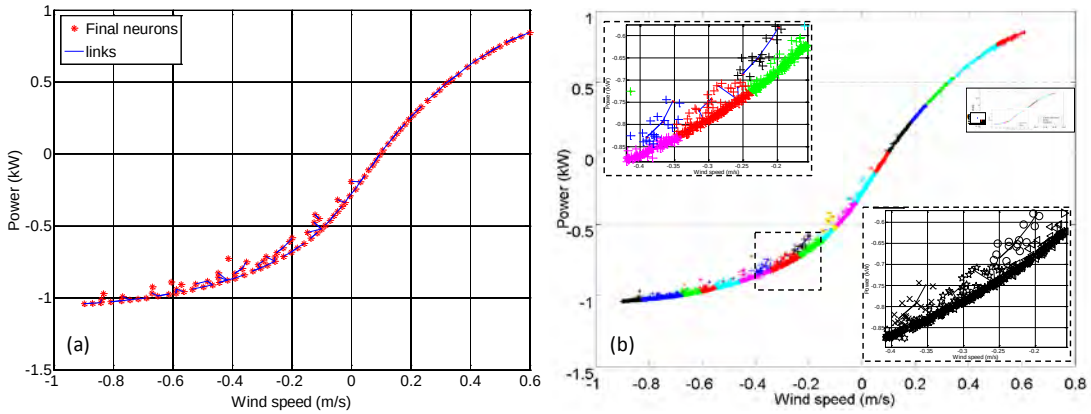

Fig. 3. Results of the linking (a) and merging (b) phases of GMR.

The same TS used for the GMR model was also used to train a feedforward Multi Layer Perceptron (MLP). The learning algorithm used is backpropagation with momentum [16]. The network has two layers of neurons, the hidden layer with 10 and the output layer with 1 neuron (since the output is mono-dimensional). A logistic sigmoid function and a linear function were respectively used as the activation function of the first and the second layer.
Figure 4 shows the results of the modelling obtained both on the TS and test set data, with the two models, while Table 1 summarizes their prediction accuracy.

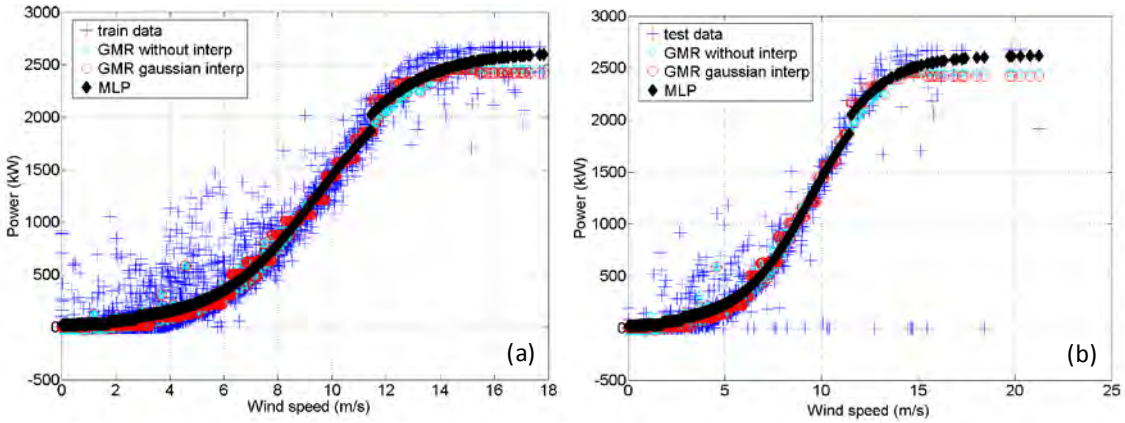

Fig. 4. Results of the GMR and MLP predictions on the training set (a) and the test set (b).

Their performances have been assessed computing the mean absolute error (MAE) and the symmetric mean absolute percentage error (sMAPE), using the test set data. The respective standard deviations (Std dev, in Table 1) have also been computed.
The sMAPE measure computes the absolute error in percent between the absolute value of the actual observation y_t and the absolute value of the forecast $\hat{y}_t$ across all observations t of the test set of size n [17]:

$$sMAPE = \frac{1}{n}\sum_{t=1}^{n}\frac{|y_t - \hat{y}_t|}{(|y_t| + |\hat{y}_t|)/2} * 100 \quad (1)$$

The MAE of MLP is worse than the one of the two GMR models, because GMR recognizes that the "thickness" of the data cloud around the average logistic sigmoid trend actually contains some information content and it is not just due to noise (see the links in Fig. 3(a)), whereas the MLP follows the average trend of the data, thus finding a smooth curve profile.

Table 1. Prediction accuracy of the models applied (GMR and MLP).

	MLP	GMR gaussian interp	GMR without interp
MAE (kW)	1990.60	436.11	458.63
Std dev of AE (kW)	2515.40	918.34	906.40
sMAPE (%)	68.03	64.19	68.35
Std dev of sMAPE (%)	76.25	73.73	76.40
minimum AE	71.79	1.02	0.47
maximum AE	9159.40	8585.10	8585.10

3.1. On-line monitoring by residual approach and control charts

Once the two non-parametric models mentioned above have been trained, they can be used to characterize the wind farm power in normal conditions, and therefore they can serve as an on-line wind farm power generation profile. The residual control chart techniques (statistical quality control) [18] are used to analyze residuals between model predicted power and observed power. The control chart approach allows the residuals and their variations to be monitored, thus detecting abnormal conditions of a turbine.

The means of the residuals obtained on the TS (μ_{Train}) and the test set (μ_{Test}), as well as their standard deviations (σ_{Train}; σ_{Test}) were computed. Once μ_{Train} and σ_{Train} are known, the upper and lower control limits of the control chart can be computed and used to detect the anomalies. Control limits for the control chart can then be derived using Eq. (2) [18]:

$$UCL_1 = \mu_{Train} + \eta\frac{\sigma_{Train}}{\sqrt{N_{Test}}}; \quad LCL_1 = \mu_{Train} - \eta\frac{\sigma_{Train}}{\sqrt{N_{Test}}} \quad (2)$$

N_{Test} is the number of points in the test data set, but it can be adjusted to make the control chart less sensitive to the data variability and thus reduce the risk of false alarms. The parameters in Eq. (2) could be adjusted dynamically, based on ope rations of individual turbines. In the application described in this paper, N_{Test} was set equal to 10, while η was set to the widely used value $\eta = 3$ [9]. If μ_{Test} is above UCL_1 or below LCL_1, the power generation process at the generic sampling time $y_{TestSet} = [y(i), \hat{y}(i)]$ is considered to be deficient (or "out-of-control"), otherwise it is not considered abnormal, i.e. it is considered "in-control". Similarly, the control limits for σ^2_{Test} can also be calculated to detect out-of-control points, using control limits defined as a function of the variance of σ^2_{Train} [8; 9; 18].
Figure 5 shows the out-of-control points detected in the TS by GMR and the MLP on the basis of the limits defined by Eq. (2). Out of the 876 points of the test set, GMR detected 183 out-of-control points, while the MLP network detected 136 of them. It is possible to notice that GMR in this case is more conservative in the part of the curve closer to the cut-off wind speed. This is due to the choice of the parameters η and N_{Test}, but also to the fact that the MLP model tends to find a smooth solution, passing between the two data clouds in the last part of

the curve, whereas GMR remains closer to a constant value of the output power for wind speeds equal to or higher than the cut off speed, as it should be in case of ideal functioning of the turbines. It is also possible to notice that GMR detects some of the points above the left tail of the curve as "in-control" points, while MLP labels them as "out-of-control". This is due to the fact that GMR finds some links and, as a consequence, some branches of the mapping, also in this zone of the space (see Fig. 3). This is reasonable and in line with the results found in [9] using a parametric model and a non-parametric model based on the k-nearest neighbour (k-NN) algorithm. In fact, one of the main advantages of GMR, compared with feedforward neural networks, lays into the fact that, while for many functional (i.e. single-valued) approximation problems feedforward network can work well by minimizing a sum-of-squares error function, they can actually give rise to high imprecision in presence of multi-valued mappings, or mappings whose structure varies for different regions of the input space. The prominent feature of GMR is its capability to output all the solutions and their corresponding mapping branches.

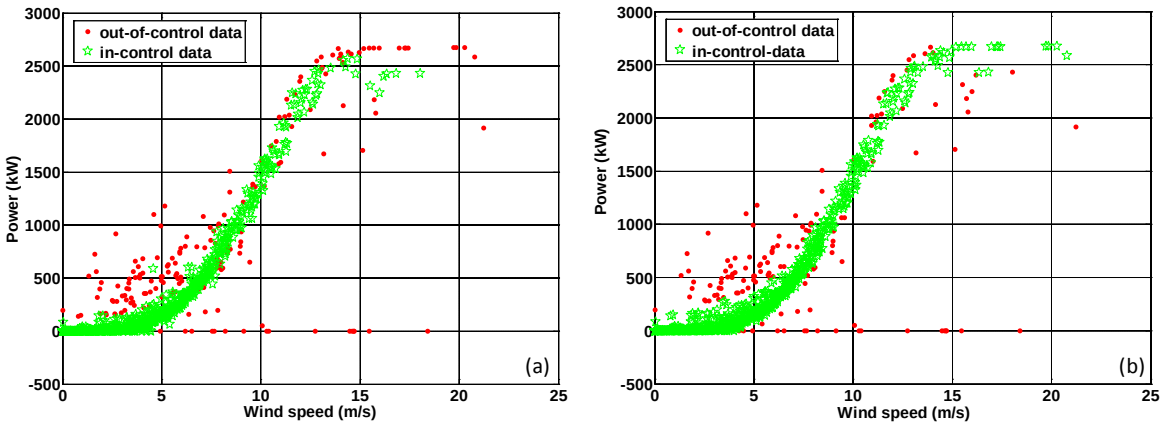

Fig. 5. Data (within the test set) detected as "in-control" and "out-of-control" according to the limits defined in Eq. (2), using GMR with Gaussian interpolation (a) and MLP (b).

4. Conclusions

The paper presents an application of a data-driven technique for mapping the power curve of a whole wind farm and shows its utilization for the creation of quality control charts. The results obtained with the proposed methodology are compared with those obtained with a "traditional" non-parametric method: a MLP neural network. A few other applications have already been presented in the literature, dealing with the same topic. The originality of this paper is twofold: on one hand, its application to the modelling of the power curve of an entire wind farm, instead of a single wind turbine; on the other hand, the utilization of GMR, which is an incremental self-organizing competitive neural network with adaptive linking among neurons, able to approximate every kind of mapping (function or relation) in both senses, i.e. $M(x,y): x \in \Re^m \leftrightarrow y \in \Re^n$. The models can be used as the reference power curve (on-line profile) for monitoring the performances of a w ind farm as a whole. In a real, on-line application, the models will be updated using the most current operational data.

The case study here presented demonstrated that the control chart approach produces satisfactory results in monitoring power curves. In future research, other data mining algorithms will be assessed for enhancing accuracy of non-parametric models. In particular, the application of Bayesian networks will be considered to identify links between anomalies and the specific reasons causing them, which is not possible simply using control charts.

Abstract: The last few years have proved that Vertical Axis Wind Turbines (VAWTs) are more suitable for urban areas than Horizontal Axis Wind Turbines (HAWTs). To date, very little has been published in this area to assess good performance and lifetime of VAWTs either in open or urban areas. At low tip speed ratios (TSRs<5), VAWTs are subjected to a phenomenon called 'dynamic stall'. This can really affect the fatigue life of a VAWT if it is not well understood. The purpose of this paper is to investigate how CFD is able to simulate the dynamic stall for 2-D flow around VAWT blades. During the numerical simulations different turbulence models were used and compared with the data available on the subject. In this numerical analysis the Shear Stress Transport (SST) turbulence model seems to predict the dynamic stall better than the other turbulence models available. The limitations of the study are that the simulations are based on a 2-D case with constant wind and rotational speeds instead of considering a 3-D case with variable wind speeds. This approach was necessary for having a numerical analysis at low computational cost and time. Consequently, in the future it is strongly suggested to develop a more sophisticated model that is a more realistic simulation of a dynamic stall in a three-dimensional VAWT.

1. Introduction

In the last few decades, the production of electricity from wind turbines has seen a rapid growth in many countries around the world. The major drivers are the recent need to reduce CO_2 emissions into the atmosphere and meet the growing demand for electricity [1]. One promising alternative for the future generation of electricity is the installation and integration of wind turbines in the built environment combined with other alternative sustainable systems [2], [3]. The benefits are mainly generation of electricity on the site where it is needed with reduction in transmission losses and cable costs [3].

In the late 1970s and early 1980s, very little research was conducted on V AWTs on understanding the aerodynamics and flow interaction between blades during the operation of a wind turbine [4]. Recently, the progress of small wind turbines in the built environment has been mainly focused on Horizontal Axis Wind Turbines (HAWTs) rather than Vertical Axis Wind Turbines (VAWTs). But several studies have shown that VAWTs are more suitable for urban areas than HAWTs [3], [5], [6], [7]. The advantages are mainly: omni-directional without a yaw control, better aesthetics to integrate into buildings, more efficient in turbulent environments and lower sound emissions [8]. In addition there is some research speculating

that VAWTs are appropriate for large scale of 10 MW or more, as VAWTs can operate mechanically better than HAWTs [9], [10]. They can withstand high winds due to their aerodynamic stall behaviour [5]. Generally, the aerodynamic analysis of a VAWT is very complicated, as the blades are called on to operate in unsteady flow, pitching relative to the mean flow and cutting the stream tube twice [5]. One important aspect to consider during the operation of a VAWT at low wind speeds is the generation of a phenomenon called dynamic stall. The phenomenon is mainly characterised by the development of vortices that will interact with the airfoil of the blades and have a substantial impact on the design and power generation of the wind turbine [11].

The main purpose of this work is to understand how ANSYS CFX 12.0 is able to approach the development of dynamic stall around the blades of a VAWT. Also, the final objective of the numerical study is to make a contribution in the field of dynamic stall as many straight-bladed VAWTs are called to operate. In this paper a number of simulations are explored to understand static and dynamic stall around the rotor of a 3 straight-bladed VAWT. To reduce time and memory costs a 2 -D case is explored for all numerical simulations. The Computational Fluid Dynamics (CFD) Software used was ANSYS CFX 12.0. Here, the three turbulence models analysed were the k-ε model, the standard k-ω model and the SST (Shear Stress Transport) model. The numerical simulations were studied for different tip speed ratios and compared with the small amount of experimental data available in literature.

2. Methodology

In order to understand the physics involved during dynamic stall of a straight-bladed vertical Darrieus wind turbine, a 2-D rotor is proposed and analysed. This 2-D approach is adopted for reducing time and computational costs. The airfoil analysed, for the VAWT, is a NACA 0018 and its characteristics are listed in Table 1. The rotor is composed of 3 blades and a central mast. The solid model of the rotor was generated with ProEngineer 4.0 and imported into ANSYS CFX 12.0.

Table 1: Properties of the rotor

NACA0018					
Cord c (mm)	Thickness t (mm)	Span s (mm)	Rotor Radius R_r (mm)	Number Blades N	Mast Radius R_m (mm)
490	88.2	50	3000	3	75

The mesh, as shown in Figure 1, is mainly composed of three sub-domains: one fixed sub-domain outside the rotor, one dynamic sub-domain around the blades of the rotor and one fixed sub-domain for the remaining part of the rotor. The mesh was generated by adopting a Sweep Method with one element deep and the total number of elements is 4.58×10^5, as listed in Table 2.

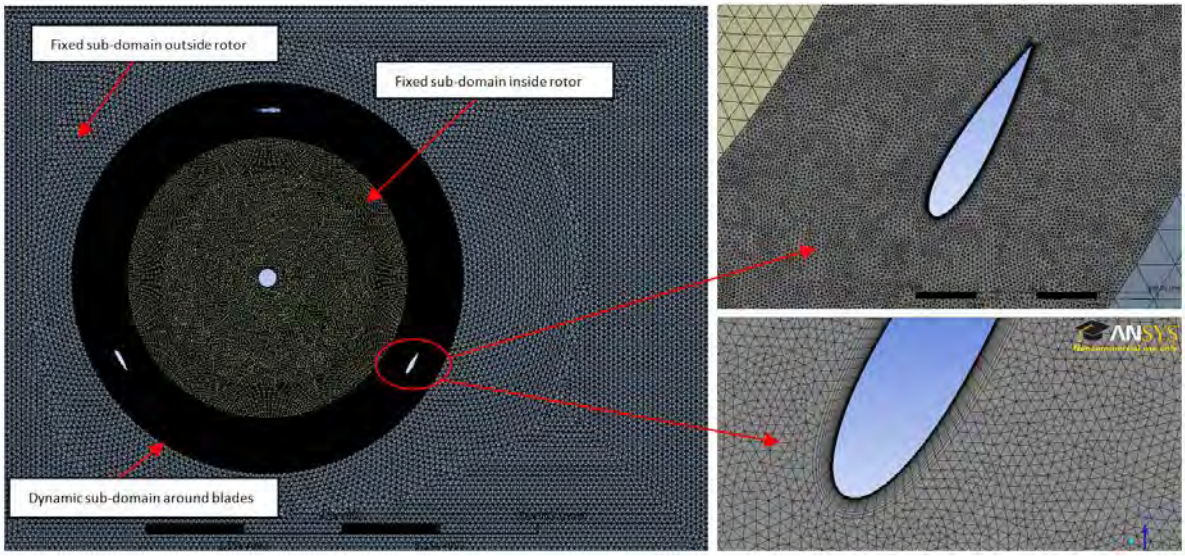

Fig. 1. Mesh for the 2-D rotor

Table 2. Sub-domain properties

Sub-domain	Number of elements
1) Fixed sub-domain outside rotor	$20*10^3$
2) Dynamic sub-domain around blades	$42*10^4$
3) Fixed sub-domain inside rotor	$18*10^3$
Total number of elements	$4.58*10^5$

All sub-domains were meshing by using only triangle elements, as they are more appropriate for simulations involved fluids [12]. The mesh around the blades of the rotor, which is a wake development region, was refined through the use of the facing sizing and inflation options available in ANSYS 12.0. In this region, the use of prism elements is able to capture boundary layer effects more effectively and efficiently. The three different meshes were linked together with the use of domain interfaces. Symmetrical boundaries were used for the top and bottom parts of the 2-D model with no-slip boundary conditions at the two sides. An opening boundary was chosen for the output and a constant wind speed of 6 m/s, with a turbulence intensity of 5%, was defined for the inlet. The two wall sides were placed at 4c from the diameter of the blades respectively. The outlet and inlet were placed 4c and 10c away respectively. Table 3 gives a summary of the parameters employed in the four different cases where different time steps and tip speed ratios (TSRs) were defined. For all transient simulations a total time was defined to give enough time for the flow to develop around the blades of the rotor. Finally, the residual target, in the convergence criteria, was set to be 10^{-4}.

Table 3. Input data for the four cases analysed

Simulation Case	Tip speed ratio	Angular speed (rad/s)	Time for one rotation (s)	Angle of attack (deg.)	Time Step Simulation (s)
Case 1	$\lambda_1=2.3$	$\omega_1=4.7$	$t_1=1.33$	$-30\leq\alpha_1\leq30$	0.0037
Case 2	$\lambda_2=3.0$	$\omega_2=6.0$	$t_2=1.05$	$-21\leq\alpha_1\leq21$	0.0029
Case 3	$\lambda_3=4.0$	$\omega_3=8.0$	$t_3=0.78$	$-15\leq\alpha_1\leq15$	0.0022
Case 4	$\lambda_4=5.0$	$\omega_4=10$	$t_4=0.63$	$-12\leq\alpha_1\leq12$	0.0017

The effect of different TSRs are presented and discussed in the conclusions section of this paper.

2.1. Dynamic Stall

Although VAWTs have several advantages over HAWTs, the aerodynamics around the blades is very complicated [11]. VAWTs, during their operation, are called to work under both static and dynamic stall conditions. Consequently, the blades are subjected to cyclic forces due to the variation of incidence angle of the blade relative to the wind direction [13]. Although the presence of dynamic stall at low TSRs can have a positive impact on the power generation of a wind turbine, the formation of vortices can generate other problems such as vibrations, noise and reduction of fatigue life of the blades due to unsteady forces [13]. Larsen et al. [14] show that dynamic stall is mainly characterised by flow separations at the suction side of the airfoil. This can be summarised in four crucial stages: 1) Leading edge separation starts, 2) Vortex build-up at the leading edge, 3) Detachment of the vortex from leading edge and build-up of trailing edge vortex, 4) Detachment of trailing edge vortex and breakdown of leading edge vortex. The sequence of these four flow events will generate unsteady lift, drag and pitching moment coefficients with a large range of flow hysteresis dependent on the angle of attack [15]. The expression of the angle of attack α adopted for the simulation, without induction factor, is given by Eq. (1):

$$\alpha = \arctan\left(\frac{\sin\theta}{\lambda - \cos\theta}\right) \tag{1}$$

where θ is the azimuth angle and λ the TSR. In this study, as shown in Table 3, four different cases are analysed with different parameters that are highly dependent on the TSRs.

2.2. Turbulence Models

Wang et al. [16] show that the most popular turbulence models, adopted in the CFD community, are mainly Direct Numerical Simulation (DNS), Large Eddy Simulation (LES) and Reynolds-Averaged Navier-Stokes (RANS). The DNS method today requires a large amount of computing resources and time. The LES method is more appropriate for 3-D simulations. Therefore, the only method adopted for this 2-D numerical study was the RANS method. The three RANS turbulence methods analysed, due to low computational costs, are: the standard k-ω model, the standard k-ε model and the SST model. A more detailed description about the turbulence methods can be found in the book by Wilcox [17].

3. Results

In this section of the paper a number of numerical simulations are analysed for different TSRs. The numerical simulations obtained during the present study are mainly compared with the study carried out by Wang et al. [16], as this previous numerical study showed a good agreement with experimental data. However, it should be point out few differences between the two numerical studies. The main differences are summarised and listed in Table 4.

In this numerical study, a number of cycles of the rotor were calculated at different TSRs until a periodic solution was achieved. The total time was set to be 4s to give enough time for the rotor to reach a period state in all four cases.

Table 4. Main differences between the two numerical methods

Present Study	Wang et al. Study
ANSYS CFX	FLUENT
Rotor with 3 blades and central mast	Single pitching blade
Free-stream turbulence intensity 5%	Free-stream turbulence intensity 0.25%
Variable time step with angular velocity	Constant time step
Triangle elements	Quadrilateral elements
$\alpha=\arctan(\sin\theta/\lambda-\cos\theta)$	$\alpha=10^0+15^0\sin(\omega t)$
Wake interactions	No wake interaction
No converged steady state	Initial input from converged steady state

In Fig. 2 and Fig. 3, the left side, show graphically the results obtained for this numerical analysis, while the right side compare the CFD results of Wang et al. with experimental data by Lee and Gerontakos [18]. Furthermore, Fig. 2 and 3 show how the lift and the drag coefficients, C_l and C_d, are affected by different angles of attack and TSRs. The curve shapes are in good agreement with the experimental data obtained by Lee and Gerontakos. Here, the final results are more realistic and less fluctuating than the CFD simulation conducted by Wang et al [16]. Also, a strong instability at high angles of attack is observed and is thought to be due to the deep dynamic stall that is typical for low TSRs. However, the few exceptions are the absence of a second peak on the curves due to the presence of a trailing edge vortex and the lack of intersection points between upstroke and downstroke paths that are seen in the experimental graphs on the right.

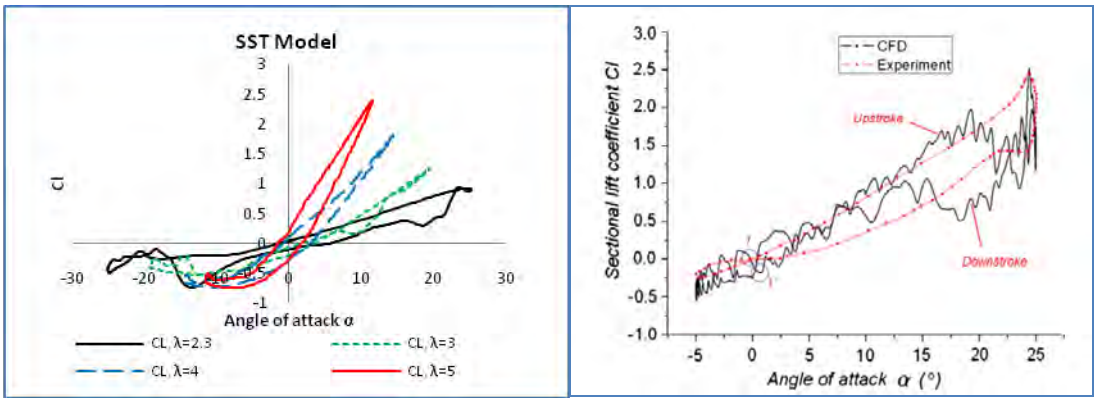

Fig. 2. Lift coefficient C_L for the two numerical studies and experimental data

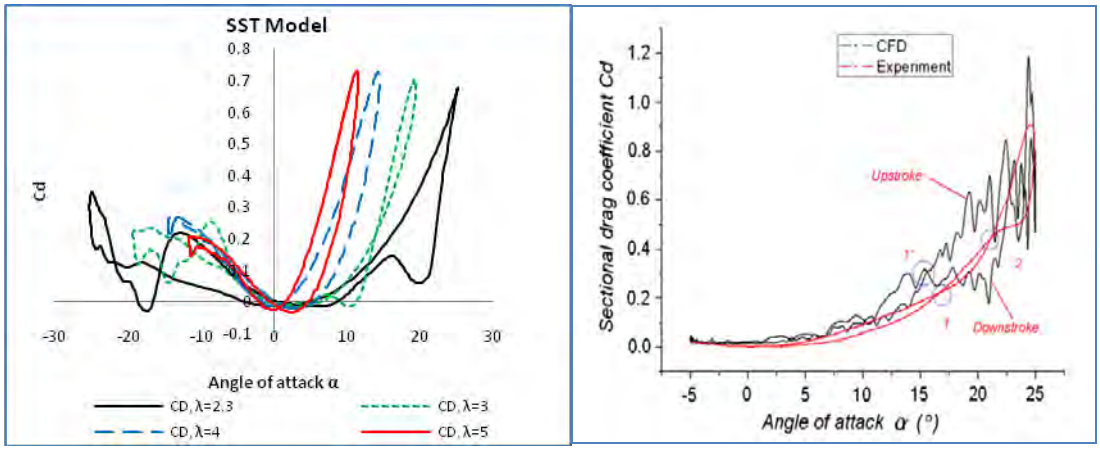

Fig. 3. Drag coefficient C_D for the two numerical studies and experimental data

However, the development of several peaks, especially for negative angle of attacks and low TSRs can be associated with the development of upstream wakes that will interact with the downstream blades. Also the presence of a central mast will generate several wakes that will affect the flow downstream. The different hysteresis loops in Fig. 2 and 3, show clearly the development of two phenomena called dynamic and static stall. Dynamic stall typically will develop at high angle of attacks for $\lambda<4$ and is characterised by its fluctuating nature, while static stall will take place at low angle of attacks for $\lambda \geq 4$ with smoother curves and less intersection points. One important consideration is that the range of angle of attack is different from the experimental data obtained by Lee and Gerontatos. This is mainly due to the use of Eq. (1) instead of using $\alpha=10^0+15^0\sin(\omega t)$ that is typically adopted for the case of a pitching motion single blade.

Finally, the numerical results are analysed by comparing the evolution of the shed vorticity with the experimental data available in the field of dynamic stall. Fig. 4 shows the vorticity field at $\theta=120^0$ for the three turbulence methods adopted in this numerical study. The SST method shows a good agreement with the experimental data obtained by Ferreira et al. [19] and Wang et al. [16] than the k-ω and k-ε methods that are more dissipative. This turbulence method is able to show the generation of specific vortices at the leading and trailing edges respectively. A more detailed explanation will be given in the next section for the SST method, as the results best agreeing with experiments

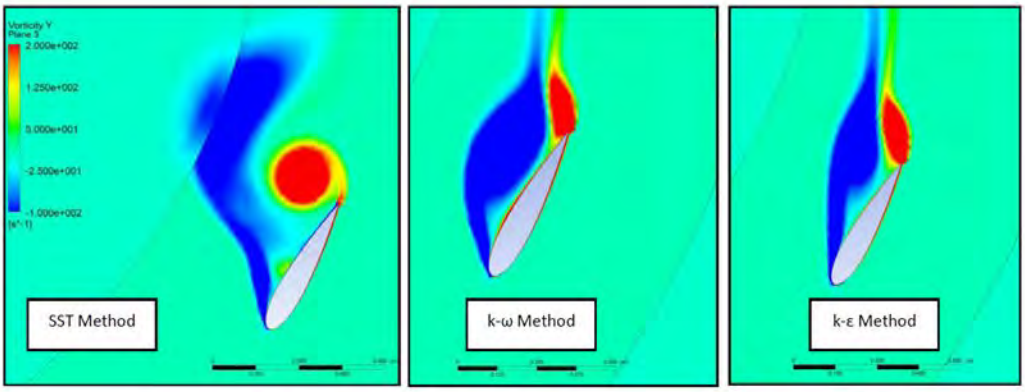

Fig. 4. Vorticity field for θ=120º for the three different turbulence methods

3.1. SST Results

In this section only the SST method is analysed in its several stages during a complete revolution of the rotor when a periodic solution is achieved. Fig. 5 clearly shows the several stages involved through dynamic stall for a TSR of 2.3 at different azimuth angles θ. This specific TSR was chosen because it corresponds to the case with deep stall. Fig.5 shows that for an azimuth angle θ between 180^0 and 240^0 the flow is almost attached to the blade. Then at an angle of $\theta=260^0$ a leading edge vortex will start to develop and expand until 280^0. Also, in this stage there is the generation of a trailing edge vortex that will detach at approximately 300^0. Afterwards, there is a progressive reattachment of the flow to the blade with leading and trailing edge vortices moving downstream. At $\theta=360^0$ there is again the presence of a second small leading and trailing edge vortices that will disappear between 20^0 and 40^0. Then the development of a third leading edge vortex will take place at 60^0 followed by a trailing edge vortex at 80^0. Finally, the flow will start to become laminar and to reattach to the blade until the same dynamics will start again from the beginning stage. From the final results it can be stated that the SST model shows a good agreement with the four stages related to dynamic

stall mentioned above. Furthermore, this 2-D study has the advantages of showing how the two kinds of vortices will move down and eventually affect the physics of the blades that are called to work downstream.

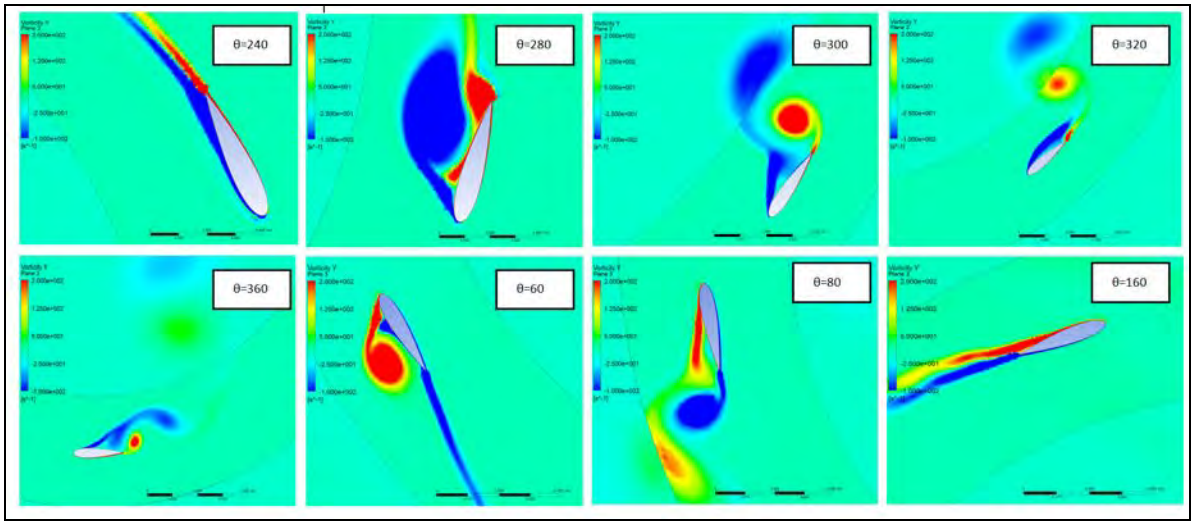

Fig. 5: Vorticity field at different azimuthal angles θ for the SST model at λ=2.3

4. Conclusions

A numerical analysis of the physics involved during dynamic stall of a rotor of a straight-bladed VAWT, composed of 3 bl ades with profile NACA0018, was conducted at four different TSRs. In this study three RANS turbulence models have been explored for the four cases analysed. The lift and drag coefficients are in good agreement with the study carried by Wang et al, but a number of differences have been found between the two studies. The most relevant are the absence of a second peak on the curves due to the development of the trailing edge vortex and the lack of intersection points at high TSRs. But at low TSRs there is an increase in the number of intersection points especially for negative angles of attacks that can be related to deep dynamic stall. This instability is mainly associated with the development of upstream wakes from upstream blades and mast that interact with the downstream blades. In this numerical study, the analysis has proved the presence of two different phenomena called dynamic and static stall that are highly depended on the TSRs adopted. In here the SST model is examined in terms of vorticity distributions around the blades. In general the method shows more reasonable accuracy with some existing wind tunnel experiments than the k-ε and k-ω turbulence methods that seem to be more dissipative. Also, the method is able to show the main four phases involved during dynamic stall. But one important observation for the SST method is the presence of single-vortices instead of having several small vortices that are typically found around the airfoil for PIV dynamic stall tests. A better improvement can be achieved in the future investigation of a 3-D case where the LES and the DES methods are strongly recommended. The two methods will take into consideration the 3-D nature of the vortices developed during dynamic stall. In general this paper gives a substantial contribution to the aerodynamics involved at different TSRs and angles of attack for a 2-D rotor with central mast. This is necessary because the development of dynamic stall in VAWTs can have a substantial impact on both the design and power generation of a wind turbine.

Abstract: wind as a significant renewable source of energy along with different ways for its optimum utilization is attended. At this paper, initially different types of wind turbine power control systems are introduced briefly, then advantages and disadvantages of them, are evaluated in practical and theoretical aspects. At the following, governing generated power formulation is proved briefly, then the effective parameters on power, e.g. wind velocity, wind temperature are studied and simulated in MATLAB software. Then practical data from an actual stall control wind turbine entered and related curves are investigated. Based on these data, performance of an actual pitch control wind turbine is estimated and related curves are investigated. At the following, using Weibull theory, real power-time curve and estimated power-time curve, monthly produced energy of turbines are estimated. And finally Specific Power Performance (SPP) is defined and shown that pitch control system produced energy more than stall control system at the same rotor swept area.

Keywords: *Wind Turbine, Power Control System, Pitch Control, Stall Control*

1. Introduction

The human progresses in various scientific and industrial fields have increased the need to generate energy and to investigate its various resources. Providing this energy from fossil sources like oil and gas is not reasonable because of various reasons such as environmental pollutions, reduction of reservoir of these resources and the next generation's requirements for them. These facts along with economic problems and the increment of fuel cost have encouraged the researchers in various countries to pay more attention to renewable energies. Therefore, the wind, as one of the renewable energy resources, and its optimal exploitation methods, have been noticed so that the predictions indicate that in 2020 the portion of wind in generating the energy required for human activities will be more than 375 TWh. The design of wind turbines depends on the conditions of the location they are installed, and most of them are designed to generate power with the minimum possible cost at low wind speeds. Thus, if the wind speed exceeds a specified limit, some of the important parts of turbine may be harmed. The designers use various control systems to prevent these harms and also to optimal exploitation of turbines. The most important control systems are stall control, pitch control, and yaw control, from which the pitch control is the most common system [1 to 3] .

Of course, some researches were also performed to design other control systems. One of them is "control of wind turbine using memory based method" by Song [4]. Using this method, the turbine chooses the optimal power control method based on the previous experienced conditions. Another new method was also presented in the paper titled as "multi variable control strategy for variable speed variable pitch" by Bakhezzar et al. [5] . Using the doubly fed induction generator to control the voltage induced by rotor in the generator has been noticed by the researchers in the recent years. Fernandez and Garcia investigated this subject in a paper titled as "comparative study on doubly fed induction generator (DFIG) wind turbines operating with power regulation" [6] . Modeling and controlling this type of generators were performed by Hee Song Ko [7] .

In this paper, the control systems of wind turbines were investigated comprehensively. In addition to theoretical facts, technical and empirical points were also involved. Furthermore, the power generated by different control systems was compared in this study. The effect of local conditions of the place considered for installing the turbine, such as wind blowing conditions, on the selection of the appropriate control system was also discussed in this paper.

2. Investigation of generated power

The one-dimensional BEM theory was used to investigate the power generation of wind turbines [3] . Based on this theory, the rotor of wind turbine can be modeled as an ideal impenetrable disk. Because there is no friction between air and the rotor, and the wake flow speed has no rotational component. The shape of stream lines thorough the rotor will be similar to figure (1). This disk decreases the speed from V_0 at the upstream to u at the rotor plate, and to u_1 at the back of rotor. At normal speeds, the flow can be assumed incompressible, and the speed and pressure variations can be assumed as shown in figure (1) .

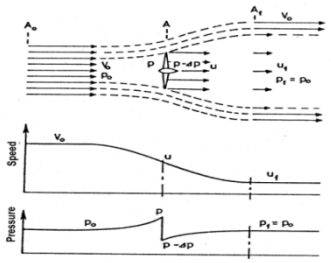

Fig. 1. Demonstration of streamlines, axial speed and pressure up- downstream of rotor.

Using axial momentum equation, it can be proved that:

$$u = \frac{1}{2}(V_0 + u_2) \tag{1}$$

Also, the usable power in a cross section area equal to the area swept by rotor (A) is:

$$P_{avail} = \frac{1}{2}\rho A V_0^3 \tag{2}$$

The dimensionless power coefficient is obtained by dividing the power by the usable power:

$$C_P = \frac{P}{\frac{1}{2}\rho V_0^3 A} \tag{3}$$

And finally, the induction factor is defined as:

$$u = (1-a)V_0 \tag{4}$$

It can be observed that for $a = 1/3$, $C_{P,\max} = 16/27$.

3. Investigation of power control systems

3.1. Stall control systems

Blade design of this type of turbines is so that they naturally control the power generated by turbine. These rotors with constant pitch are designed to operate near the optimal tip speed in moderate winds. In turbines with this type of control system, an asynchronous generator is often used by which the rotor rotational speed is kept approximately constant. A rotating tip located at the end of the rotor is usually used as the aerodynamic brake. This device which is activated by centrifugal force, is subjected against the wind flow with a 90° angle, and limits the rotor momentum by applying the opposite torque due to the drag force.

3.2. Pitch control systems

In a turbine with pitch control system, all blades can rotate about the root, and thus, the attack angle changes simultaneously throughout the rotor length. One of the most conventional mechanical mechanisms of the rotor pitch control contains a piston inserted inside the turbine main shaft. This piston changes the rotor pitch by its reciprocating movement using a mechanism installed forward the turbine hub. Obviously, the lift coefficient has a direct relation with the attack angle [1] . Therefore, decreasing the attack angle reduces the lift force and the power. Thus, pitch control system can control the output power by rotating the rotors. Also, referring the power curve of this type of turbines, it is obviously found that since the rotors can rotate slowly, the power curve is smoother and the power peaks are reduced [3] . To overcome the problem caused by great peaks in power for high speeds in a wind turbine with pitch control system, a system named as "OptiSlip" produced by Vestas was used.

From technical point of view, using pitch control mechanisms to control power necessitates the use of very strong hydraulic systems to generate and transfer very high pressures (120 Bar for medium wind turbines, and even more for greater turbines). Providing this hydraulic system affects the turbine total price. In places with high air turbulence, the pitch control system should operate harder. This results in overheating the hydraulic oil, and finally, lengthy turbine stops by safety system. This reduces the turbine productivity.

3.3. Active stall control systems

There is another method which uses the combination of pitch and stall control systems. In this system, to achieve the maximum efficiency at low wind speeds the rotors are repositioned like a wind turbine controlled by pitch. At high speeds, the rotors are rotated slowly against the wind to get stall. With this type of control, a smoother limited power is achieved compared with pitch control turbines. Combining both systems facilitates the required stops in emergency cases and restarting wind turbines compared with stall control. This type of system is less common today [2] .

3.4. Yaw control systems

In this control system, instead of limiting the output power using pitch or stall controls, the turbine yaw is controlled. The machines which use pitch and stall control systems usually have yaw control. This system receives the data related to wind flow direction from the turbine wind gauge and tries to turn the nacelle so that the maximum air flow rate enters the rotor disk. In a machine controlled by yaw system, at high wind speeds, the rotor turns against the wind direction to reduce the air flow rate in rotor, and thus, the generated power decreases.

4. Study procedure

4.1. Weibull distribution method theory and its application in estimating the available wind electricity energy generation

Considering the random nature of wind with long-term measurements in various time periods, Weibull Density Function was used to compute the wind energy [8] .

$$F(V) = \frac{k}{c}\left(\frac{V}{c}\right)^{k-1} e^{-\left(\frac{V}{c}\right)^{k}} \tag{5}$$

F (v), the cumulative distribution function, is:

$$F(V) = 1 - e^{-\left(\frac{V}{c}\right)^{k}} \tag{6}$$

Where V is the wind speed, c and k are scale parameter and shape parameter, respectively. These parameters can be computed using "Maximum likelihood" method with iteration from the following equations:

$$k = \left(\frac{\sum_{i=1}^{n} V_i^{k} Ln(V_i)}{\sum_{i=1}^{n} V_i^{k}} - \frac{\sum_{i=1}^{n} Ln(V_i)}{n} \right)^{-1} \tag{7}$$

$$c = \left(\frac{1}{n}\sum_{i=1}^{n} V_i^{k}\right)^{\frac{1}{k}} \tag{8}$$

Where V_i , is the speed at time period i and n is the number of the wind non-zero speeds. The continuous distribution of wind flow in the studied region is obtained using Weibull curve. The generated energy is estimated by combining this curve and the power curve of wind turbines. The energy of a wind turbine in a month is investigated by following equations:

$$E_{Month} = N_0 \int_{V_{Cut-In}}^{V_{Cut-Out}} P(u)\, f(u)\, du \tag{9}$$

Where N_0 is 744 hours/month, f(u) is Weibull function and P(u) is power curve.

4.2. Location of study

Location of the present study was Paskulan wind farm in Manjil, a city in Iran. Its pressure can be assumed about 1 Atmosphere with a good precision. The average air temperature during the test period was $13.67^{\circ}\mathrm{C}$. Therefore, the average air density was $1.231\,\mathrm{kg/m^3}$.

4.3. Wind blow condition

Since the wind patterns of a region repeat annually, the Weibull curve obtained in March 2003 [9] can be used to estimate the wind condition in March 2009 with a good accuracy. Based on this curve, weibull shape parameter (k) was 1.68, weibull scale parameter (A) was 11.7 m/s and average wind velocity was 10.4 m/s. As mentioned before, stall and pitch control

systems are more applicable compared with the other control systems. Thus, in the following was concentrated on the sample turbines with these two control system types.

First, based on Eq. (3), the effective parameters on the power generated by turbine considering the weather conditions of the studied region were simulated in MATLAB software for two turbines with different control systems.

The first turbine is of 550 kW type and was made by NEG-MICON Company. It uses stall control system. The second turbine is of V47-660 kW type and was made by Vestas Company. It uses pitch control system and is equipped with OptiSlip. The power curves of above turbines for the ideal case and for the air conditions of the mentioned wind farm were shown in figures (2).

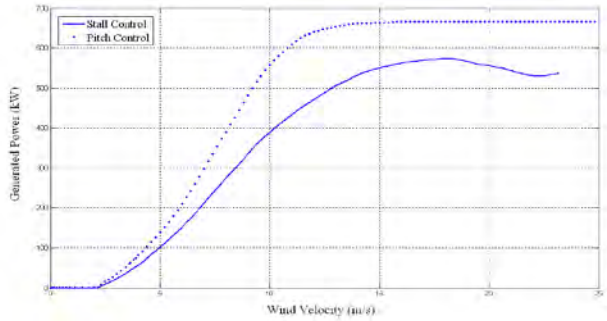

Fig. 2. Ideal power curve wind turbines.

For 550 kW wind turbine, it's obvious that maximum generated power, is 550 KW occurs at 18 m/s. Power curve after reaching to maximum point, will be decreased. In the following, this curve will be compared with practical curve. For 660 kW wind turbine, it can be obviously observed that the power generated by the turbine is uniform compared with the past and remains constant after reaching the maximum value. This maximum power value occurs at speed of 15 m/s.

In the following, the power generated by 550 kW turbine is investigated in the real mode. The values used in this section were recorded by the logger located on these turbines. This system measures and records the turbine generated power data, wind speed, wind temperature, and some other parameters with 10 minute time intervals, And during the studied time period 4463 time intervals were recorded that, the turbine was active only during 1501 intervals. During the other intervals, the turbine was in stop mode due to maintenance and blowing wind with very high speeds (cut-out), or other unforeseen characters. In figure (3), the real generated power was shown versus the active times.

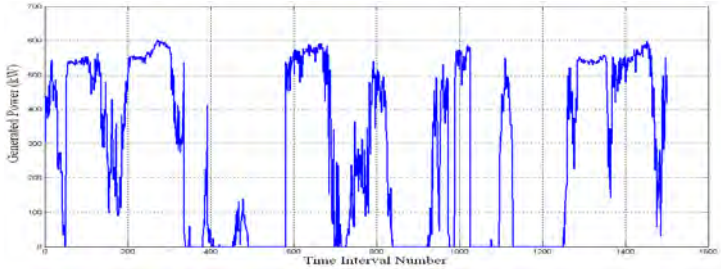

Fig. 3. Demonstration of Power vs. Time intervals for stall control wind turbine in real mode.

The power curve for active time intervals was shown in figure (4).

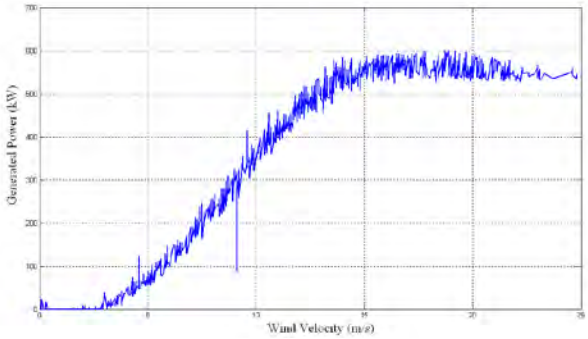

Fig. 4. Demonstration of Power curve for stall control wind turbine in real mode.

Comparing figures (2) and (4) reveals that there is a marked difference between the power generated in real mode and the power computed in ideal mode obtained with constant power values presented by the manufacturer and based on the weather conditions of the studied location.

The reason of this difference is that the turbine characteristics presented by the manufacturer (such as power coefficient and power curve based on standard DIN ISO 2533) are related to the generated power of 550 kW, but in fact, the turbine maximum mechanical power is 600 kW (about 10% more than the nominal power), and it was observed that with turbine optimum operation, this maximum value of power is exploitable.

The percentage error curve versus the wind speed was shown in figure (5).

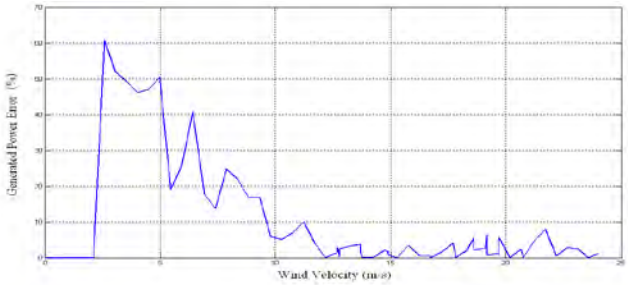

Fig. 5. The percentage error curve versus the wind speed for stall control wind turbine.

As shown in this figure, at speeds lower than 2.5 m/s the turbine does not start to operation to generate remarkable power, thus, there is no percentage error. At near cut-in speeds, the percentage error is very high. The reason is the small value of generated power; therefore, it's not noticeable. It can be observed that the percentage error reduces with increasing speed and remains lower than 10% after the speed of 10 m/s.

Based on equation (9) and using trapezoidal numerical integrating method for the studied time period, 224110 kWh of energy generation was estimated.

By computing the area under the power-real time curve by trapezoidal numerical integrating method, the real power generated during this time period reached 68672.9 kWh. Considering the fact that turbine was active only in 1/3 of the time period, if assumed the turbine will operate in such a way this time interval, estimated energy using this method and Weibull function has 9.758 % variations. Now assume the pitch regulated turbine installed in the previous location and subjected to the previous wind conditions. Assuming that the turbine

stop time, due to periodical repairs or possible malfunctions and not generating power at speeds more than cut-in value, is equal to the corresponding value of stall controlled turbine, and the turbine operates in ideal conditions, the power-time curve of this turbine was estimated by figure (6).

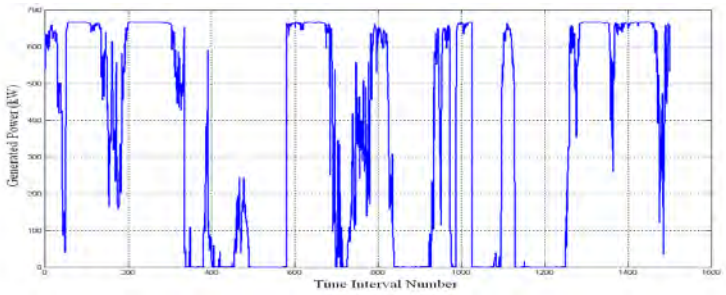

Fig. 6. Estimated Power Vs. Time intervals for pitch control wind turbine.

Comparing figures (6) and (3) obviously reveals that the variations of the power generated by pitch controlled turbine are very smaller than the corresponding values of stall controlled turbine. By numerical integrating in this period, it was found that 90670 kWh of energy is exploitable from this turbine.

Based on Weibull theory and using equation (6) and trapezoidal numerical integrating method for the studied time period, 299690 kWh of energy generation was estimated.

Considering the fact that the turbine was active during 1/3 of the period, the estimated value by Weibull theory has a good consistency with the value estimated using power curve. If assumed the turbine will operate in such a way this time interval, estimated energy using this method and Weibull function has 11.1634 % variations.

By defining Specific Power Performance (SPP) as follows, the value of this parameter for pitch controlled and stall controlled turbines were presented in table (1).

$$SPP = \frac{Generated\ Energy \quad (Kwh)}{Rotor\ Swept\ Area \quad (m^2)} \tag{10}$$

Table 1. Specific Power Performance for various turbines

Type of Power Control system	Rotor Swept Area	SPP based on Weibull function	SPP based on power-time curve
Stall Control	1325 m^2	169.13	154.1
Pitch Control	1735 m^2	172.73	155.38

As it can be observed, the value of Specific Power Performance for wind turbines using pitch control system is about 0.8 - 2.13% greater than the corresponding value of the wind turbines using stall control system.

5. Conclusion

In this study, the governing generated power formulation was first proved. Then, the types of power control systems were investigated theoretically and practically. It was found that selecting the appropriate power control system for optimum exploitation of turbine depends on the conditions of the intended location to install the turbine. It's possible that using pitch

control system results in turbine failures due to the numerous times of operation; and thus, it reduces the turbine efficiency. Then, Weibull theory for estimating the energy generated by turbine was introduced and investigated. Then, power curves of two different wind turbines under the wind conditions of the studied region sketched using MATLAB. Then, the practical values of energy and power generated by stall controlled turbine were obtained and investigated based on the data received from the turbine installed in the region. Then, the power and energy generated by pitch controlled turbine were estimated. Finally, by defining Specific Power Performance and comparing two different control systems, it was found that SPP Value for pitch controlled turbine is about 0.8-2.13% greater than the corresponding value of stall controlled turbine. In choosing the appropriate wind turbine for installation in a site, this low difference along with more prices also should be considered.
