Renewable energy sources with occasional work will also be used directly through global and regional electric supply network, if and when it is acceptable for the electric power system. In this way water storage of hydroelectric power plants has the most significant role in realization of the green system, [2]. Numerous technologies of energy storage are known today (batteries, flywheel, pressure vessels, etc.), which differ in: size, energy storage costs, efficiency, lifetime, costs per cycle, etc., [3, 4]. It is well known that none of the present-day technologies could, in terms of ratings, be compared to storage by PSH, [4]. Precisely because of that, the concept of PSH is still the most significant EES today, which is a mature technology with large volume, long storage period, high efficiency and reliability, while capital cost per unit of energy is low, [5]. For this reason, with the present-day technology, it is possible to achieve the vision of continuous green energy production through *Concept-H* [1].

Implementation of this concept will depend primarily on the policy towards renewable energy sources, RES technological development, and economic conditions. Energy produced from RES is still significantly more expensive than conventional and therefore its production is subsidized. Therefore, the *Concept-H* in its initial implementation should be used primarily for daily energy peak shaving with a tendency towards daliy load leveling. Such implementation strategy would have the greatest ecological and economic effect.

2. Main settings of the proposed concept

2.1. Main elements of Concept-H

In the green scenario (Figure 2) continuous renewable energy sources (RES-C) are exploited directly, while intermittent energy sources, such as marine, wind and solar renewable energy sources (RES-I) are exploited indirectly through *Concept-H*. RES-I power plants deliver their energy to the Pump Station (PS) which pumps water into storage of HE power plants which then serve for daily, weekly and seasonal energy storage, while the consumer is supplied from

the associate PSH power plants, transforming intermittent energy supply into continuous and manageable energy supply as conventional storage of HE power plants, [6, 7]. Serial connection is based on two pipelines in classical concept of PSH. One pipeline pumps water from lower water resource into upper storage when RES produce energy and the other conveys water from the upper storage to turbines for production of hydro energy in accordance with the consumers' needs. In this way intermittent operation of RES-I does not affect hydro energy production according to the consumers' needs. In the proposed *Concept-H*, PSH is used for continuous production of energy, or energy storage for daily and seasonal peak load shaving.

The key driving elements of the solution are: (i) RES-I; (ii) energy storage unit (pump station and water storage); (iii) HE. Production and consumption balancing is performed in upper storage based on balance equation of storage volume and HE productivity, Figure 3. RES power plants are also in parallel (direct) connection with the regional EPS, because it is logical that RES-I power plant will directly deliver its energy excesses into the system, i.e. when the upper storage is full. It is also logical that energy surpluses in EPS are used for PSH operation.

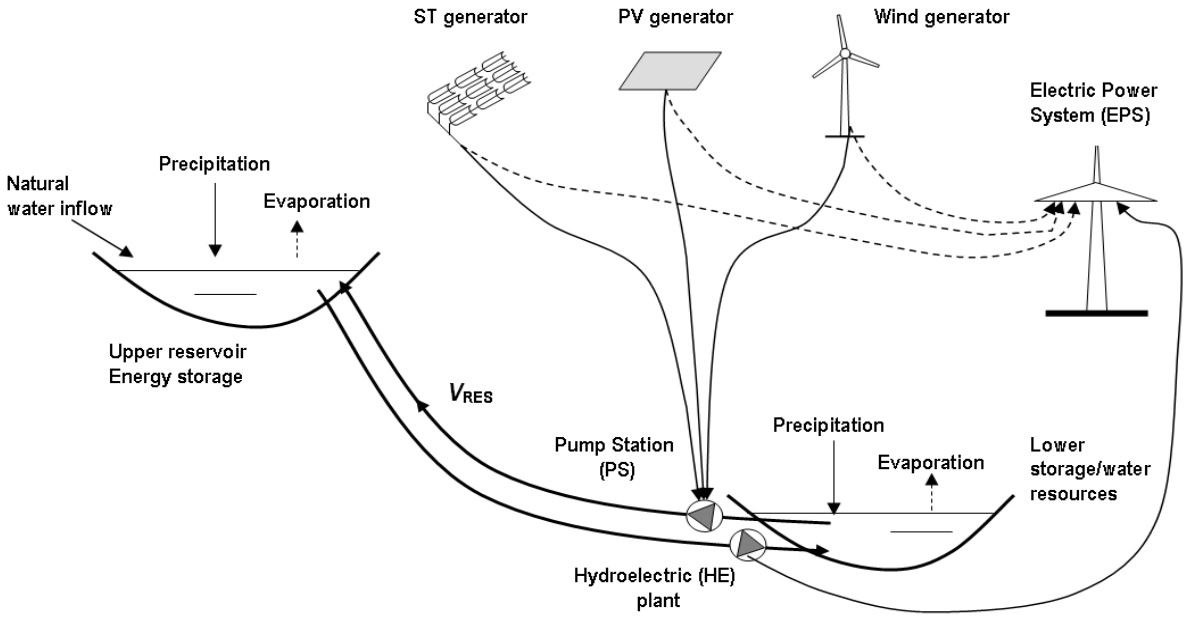

Fig 3. Concept-H: Hybrid power unit as the main building element of the future green energy scenario.

In this concept, water storages in energy power systems operate as energy storage. Hydroelectric power plants are very flexible and manageable in their work and quickly adapt to the needs of EPS. The biggest problems occur when hydrological conditions are not satisfactory. This problem is solved with the proposed *Concept-H,* because new non-natural water resources are created.

The basic unit for continuous production of energy is the hybrid power plant RES-PSH (i.e. *Concept-H)*. Hybridization can be applied to all RES-I energy sources, the most promising being with solar energy because, unlike wind power plants, it is a reliable source of energy, available at all locations where people live. In addition, solar energy enables rational daily balancing of energy production and consumption and thus the need for construction of small storage of PSH. Hybridization can be carried out with other sources of RES indirectly through energy system network.

The proposed solution is characterized by balance of energy and water. Energy balance of the hybrid electric power plant or the single time step is:

$$E_{hyb(i)} = E_{hyb(i-1)} + E_{PSH(i)} + E_{DRES(i)} \quad (1)$$

Where $E_{\mathrm{hyb(i)}}$ and $E_{\mathrm{hyb(i-1)}}$ are hybrid energy production in time stage i and i-1 respectively, $E_{\mathrm{PSH(i)}}$ is energy produced from PSH/HE, $E_{\mathrm{DRES(i)}}$ is energy which RES source supply directly to the energy power system in time period i. However, unlike $E_{\mathrm{PSH(i)}}$ which is reliable and manageable energy production, this energy supply is random, independent and uncontrollable energy production and thus is of minor importance for the EPS. Total energy production is:

$$E_{hyb} = \sum_{i=1}^{T} E_{hyb(i)} \quad (2)$$

Where T is total period used for production of energy (year).

Losses occur in energy transfers from one to the other ($E_{RES\text{-}I}$ into E_{PSH}), as well as in transport from the source to EPS. Total production losses ΔE period T are:

$$\Delta E = E_{RES-I} - E_{PSH} - E_{DRES}\,. \quad (3)$$

Losses due to energy transfer are inevitable and are the price paid for the sustainable and new quality in green energy production, Figure 3.

Water is the second resource needed for constant plant work. Water is necessary for filling of the system and compensation of losses due to evaporation, leakage and the like. Once fully filled, the system needs regular compensation of losses. Given that the system is integrated in the surroundings, part or all losses can be compensated by natural hydrological processes (precipitation, water inflow from catchment areas, etc.), or improved in special situations by external transfer of water mass inflow in the upper storage.

2.2. Water storage as energy storage

The equivalent reservoir energy balance for a single time step i is expressed as:

$$E_{PSH(i)} = E_{PSH(i-1)} + E_{nat(i)} + E_{RES(i)} - E_{prod(i)} - E_{evap(i)} - E_{loss(i)} \quad (4)$$

Where $E_{\mathrm{PSH(i)}}$ is the total equivalent reservoir stored energy in time period i and i-1 (MWh); $E_{\mathrm{nat(i)}}$ is the total natural potential energy inflow over time period i (MWh); $E_{\mathrm{RES(i)}}$ is the total energy inflow over time period i (MWh) generated (pumped) by energy from RES; $E_{\mathrm{prod(i)}}$ is the decision variable or the total energy outflow over time period i (MWh); and $E_{\mathrm{evap(i)}}$ and $E_{\mathrm{loss(i)}}$ is the energy outflow corresponding to the losses (evaporated volume and other losses) from the equivalent reservoir over time period i (MWh).

$E_{\mathrm{nat(i)}}$ during time period i is the sum of all reservoir natural potential energy inflows (river, rain). For a single reservoir, it is calculated by multiplying the natural water inflow discharge ($Q_{\mathrm{nat(i)}}$) by its mean productivity (ξ). Consumptive use water discharges (QC) must be subtracted from the natural inflows. Thus $E_{\mathrm{nat(i)}}$ is expressed as:

$$E_{nat(i)} = \xi(Q_{nat(i)} - QC_{(i)})\,. \quad (5)$$

$E_{\mathrm{RES(i)}}$ during time period i is the sum of all reservoir artificial potential energy inflows (RES). For a single reservoir, it is calculated by multiplying the artificial-RES water inflow discharge ($Q_{\mathrm{RES(i)}}$) by its mean productivity:

$$E_{RES(i)} = \xi \cdot Q_{RES(i)}\,, \tag{6}$$

$$Q_{RES(i)} = \frac{E_{RES}}{CF \cdot t \cdot (\rho \cdot g \cdot H_{n(PS)} \cdot \eta_{PS} \cdot \eta_{INV})} = \frac{E_{RES}}{CF \cdot t \cdot \xi_{MPI}}\,, \tag{7}$$

where $H_{n(PS)}$ is net head of pump station, η_{PS} is total available efficiency of pump station, η_{INV} efficiency of inverter and ζ_{MPI} is motor, pump and inverter productivity and t is time period. The energy outflow from the equivalent reservoir is the decision variable in the optimization problem, i.e. the desired energy production.

2.3. Relation between electric power of the RES generator and storage

The calculation of nominal power P_{el} for pumping water into upper storage and covering the demand for energy in a PSH in time step i is performed according to the characteristics of RES-I power plants (wind, PV and solar thermal). The equation for electric power of a RES-I generator (PV, ST or W) is derived from the equation used for dimensioning of the PV generator, presented in the paper [6] and which can generally be expressed as follows:

$$P_{el(i)} = \frac{2.72 \cdot 10^{-3} \cdot p_{RES} \cdot H_{TE(i)}}{\eta_{RES(i)}(T_a, v, \rho, \varphi) \cdot \eta_{MPI} \cdot E_{RES(i)}} \cdot V_{RES(i)}\,, \tag{8}$$

where p_{RES} (W/m^2) is equivalent value of RES-I power reference value (for solar systems it is 1000 W/m^2); η_{MPI} is efficiency of motor-pump unit and inverter; $\eta_{RES(i)}(T_a,v,\rho,\varphi)$ is exploitation efficiency of a RES, which depends on air temperature T_a, density ρ, wind velocity v and air humidity φ; $H_{TE(i)}$ (m) is total head, $V_{RES(i)}$ (m^3) is total water volume to be pumped by RES-I power plant into upper storage in order to satisfy daily energy consumption; $E_{RES(i)}$(kWh/m^2/day) is average daily energy from RES-I, available for energy production. Optimal power P_{el}* could be calculated in the similar way as is shown in the paper [6].

Apart from E_{RES} and the size of the consumer, expressed in Eq. (8) by $V_{RES(t)}$, it can be seen that upper storage volume V also has a dominant effect on P_{el}. The dependence of P_{el} on operating volume V of the upper storage is:

$$P_{el} = -a \cdot Ln(V) + b\,, \tag{9}$$

Where P_{el} is power of RES-I (W), V is operational volume storage (m^3), a,b – coefficients based on location and technological features. This relationship has been determined by the previous papers for PV and ST hybrid power plants, such papers have not yet been made for the wind power plants.

The interval $V_{min} < V < V_{max}$ which is called the boundary layer, serves as transition from the P_{max} value to the value P_{min}. Minimal value P_{min} is conditioned by the possibility of construction of storage (V_{max}) at a location. Therefore:

$$P|_{V=Vmax} = P_{min}\,. \tag{10}$$

As the period of daily insolation is always shorter than the daily period of planned energy production (24 hours), the minimum period of daily insolation, compared to the planned production of energy, determines the minimum dimensions of the storage volume and thus the maximum required power of solar power plant is:

$$P|_{V=Vmin} = P_{max}\,. \tag{11}$$

The boundary layer defines the size of storage volumes necessary to ensure the continuity of the planned production.

The constant "*b*" represents the maximum power of the plant that provides the total energy needed in the critical time step of the analysis period. The constant "*a*" represents the cumulative impact of factors for production of solar energy (technological and climate) in the period considered.

P_{el} and V are optimized according to characteristics of the problem. Based on the results of modelling it is possible to obtain more detailed information of interest to decision-making. Since the functional relationship between P_{el} and V is known (equation (9)), as well as the relationship between P_{el} and the area of collector field A of PV generator, it is possible to obtain the connection between the required A and V, according to:

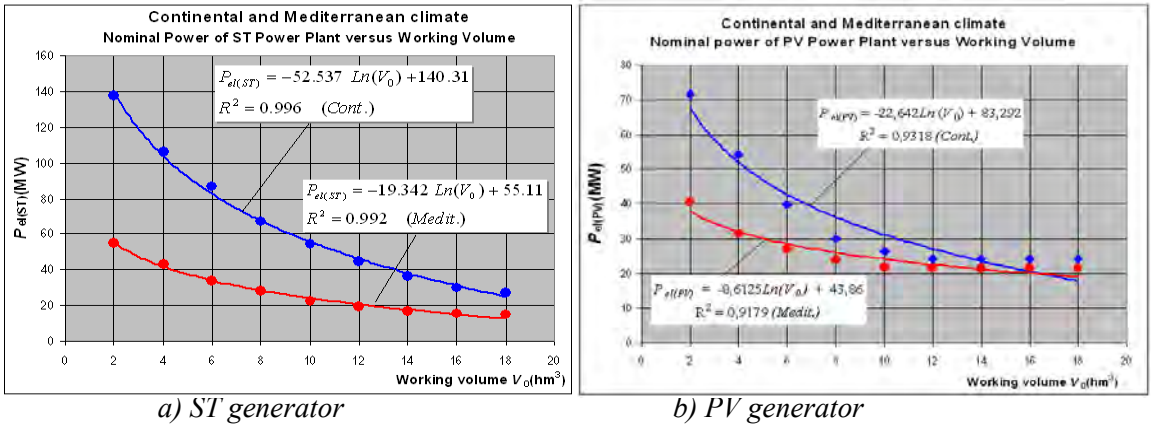
$$A = \frac{P_{el}}{1000 \cdot \eta_{oc}} = \beta \cdot \left(-a \cdot Ln(V) + b\right) \ (\mathrm{m}^2) \qquad (12)$$

Where η_{oc} is PV generator efficiency.

In this way, relations are obtained for the size of the three key structures of the hybrid PV-PSH power plant, the area of the collector field (A), power of the PV generator (P_{el}) and the working volume (V). The results for Solar Thermal (ST) power plant can be obtained in the similar way.

Other objects of interest for the sizing of the system are pumping station PS and HE. The capacity of pump station Q_{PV} is obtained based on modelling results as dependent variable used for evaluating the performance of the system, and HE capacity is set by building objectives.

The relation between P_{el} and V can also be observed through the required reserve power supply in the system. It is obvious that the upper storage has the key role in the proposed hybrid power plant management. Relation between P_{el} of RES-I power plants (PV and ST) and reservoir volume V and the required P_{el} depending on power supply reserve, Figure 4.



a) ST generator *b) PV generator*

Fig 4. Characteristic curves P_{el}=f(V) for ST and PV power plants for two climates areas.

3. Possible applications

Since this is a completely innovative solution, there are no practical results and the basic relationships of interest for the development and application can be obtained on the basis of previous research, basic theoretical assumptions and literature data. Key data relate to the

basic dimensions of power plant and its parts, production features, as well as economic, social and environmental impacts. Previous research [6, 7] shows that for Mediterranean climate (Island of Vis in Croatia) and continental climate conditions (Osijek, Croatia), the size of the hybrid system in the case of PV generator for these areas can be determined based on equations:

$$P_{PV\,(Medit.)} = -10.497\,Ln(V) + 44.21 \quad (13)$$

$$P_{PV\,(Cont.)} = -19.904\,Ln(V) + 65.123 \quad (14)$$

If these results were applied to the EPS, a general framework and dimensions of the solution could be obtained, using the *Concept-H*. The same was done in the case of Croatia [8], so that the reality of achievement of green energy policies [8] could be seen in Figure 5.

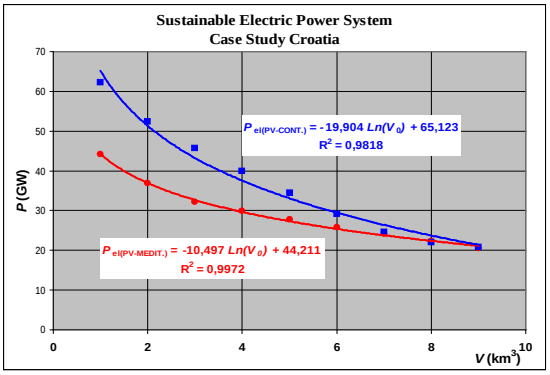


Fig 5. Scenario for Croatia.

In this way the possible applicability of the *Concept-H* at different locations and regions could be analyzed. The proposed *Concept-H* locally imitates the natural hydrological process, essentially generated by the same natural forces (solar energy and gravity), and, as a mostly closed system based on the use of natural renewable solar energy, it has a significantly smaller impact on the environment than other energy sources. In its operation it does not consume water, organic or other substances, does not create harmful residues and CO_2, and therefore provides opportunities to achieve sustainability objectives.

4. Comments and conclusions

This paper points to the possibility of realization of green energy scenario [8, 9, 10] by a concept, the so-called *Concept-H* [1]. It is a technological concept of hybrid RES-PSH systems which provides continuous energy production, the same as conventional energy sources. The solution in the proposed hybrid concept RES+PSH represents a production unit of sustainable energy supply based on natural resources which are free of charge and constantly available. The concept is very flexible in operation and construction. The accent is on hydroenergy, i.e. PSH as the main building unit, because this concept is flexible in implementation and provides continuous supply of „green“ energy and can be built in a wide range of climate areas, locations and water resources (fresh water, water with temporary flow, as well as on the sea). It can be implemented on the existing HE. The proposed production unit usually has very small impacts on the environment because it causes minimal changes in local and global hydrology and eco systems, and has a low level of potential danger for people and environment in case of incidental situations. Starting from the expected progress in the development of RES, especially PV [11], the proposed *Concept-H* may be one of the most promising solutions for achieving sustainable green energy scenario.

Abstract: Within the EC-funded research project *HYLOW - Hydropower converters for very low head differences* a floating energy converter - a so called Free Stream Energy Converter (FSEC) - for the energetic utilisation of currents with slow flow velocities (< 2.0 m/s) has been developed and will be optimized until 2012. In order to estimate the hydropower potential in case of deployment of the *FSEC*, a p otential analysis exemplarily for the northern part of the river *Ems,* at the border between *Netherlands* and *Germany,* was performed. Here, the *environmentally compatible hydropower potential* has a special importance. As expected, *this potential* is much lower than the *theoretical hydropower potential*. In addition to the efficiency of the energy converter, also the required water depth, existing protection areas and other uses are the main reason for the difference between the mentioned potentials in this investigation area.

Keywords: *Estuary River Ems, Environmentally compatible hydropower potential, Flow velocity*

Nomenclature (Optional)

P	*theoretical power* ... *W*	η	*efficiency factor* ... -
A	*flow trough area* ... *m²*	d	*water depth* ... *m*
ρ	*density of water* ... *kg/m³*	$L_{obstruct}$	*length of the obstructed area* ... *m*
v	*flow velocity* ... *m/s*	L_{demand}	*length of the demanded area* ... *m*
n	*number of energy converter like FSEC* ... -	w_{FSEC}	*width of energy converter as FSEC* ... *m*

1. Introduction

According to the European Small Hydropower Association (ESHA) in European rivers an unused small hydropower resource of 5 GW exists. An essential amount of this resource is available in terms of free stream energy with low flow velocities. The utilisation of this hydropower resource still constitutes an unsolved problem, because most current technologies are not cost effective (for low flow velocities and low discharge) and pose ecological risks to fluvial ecosystems due to blocking of the streaming water.

Within the EC-funded research project *HYLOW - Hydropower converters for very low head differences* a floating energy converter - a so called *Free Stream Energy Converter (FSEC)* - for the energetic utilisation of currents with slow flow velocities (< 2.0 m/s) has been developed and will be optimized until 2012. One important objective of the investigation with the *FSEC* is the development of an economic hydropower converter, which minimises the well known adverse ecological effects of small hydropower devices, since the proposed technique should be able to comply with the requirements of the European Water Framework Directive.

To estimate the hydropower potential in case of the deployment of a number of *FSEC´s* a hydropower potential analysis has been performed exemplarily for the northern part of the river Ems. One of the main objectives was the determination of the *environmentally compatible hydropower potential*. In the following paper, first the *FSEC* and the investigation area are described. After this, the results of the performed hydropower potential analysis are

described, the estimation results of the *theoretical* and the *environmentally compatible hydropower potential* are shown.

2. Free Stream Energy Converter

As mentioned before, the *Free Stream Energy Converter (FSEC)* is a floating energy converter for the energetic utilisation of currents with slow flow velocities. It consists of a Hydraulic Pressure Wheel (HPW), which is installed between two floating bodies. The floating bodies are connected with a bottom blade (Fig. 1). The *FSEC* has a length of 8 m, a width of 2.5 m and a draught of approx. 1 m. The width of the HPW is 1.2 m. This results in a flow trough area of 1.2 m². The design velocity is about 1 m/s - 2 m/s. The combined effect of the HPW, the floating bodies and the bottom blade should increase the efficiency by creating a small head differences between up- and downstream of the blade. Therefore, the hydrostatic pressure difference can be used for power generation in addition to utilisation of currents. [1].

Furthermore, within the *HYLOW* project, the expected influences of the *FSEC* on the environment were theoretically assessed and are investigated in field tests. Compared to conventional technologies, the operation of *FSEC* is environmental friendly. For example, the *FSEC* does not occupy the total river cross section, therefore the fauna and flora can migrate as well as sediment can be transported. As first measurements show, the water discharge and the flow conditions around the energy converter is changed only in a minor range. The *FSEC* also does not effect any pollution of the water. Because of that, the FSEC fits better with the ecological requirements according to the Water Framework Directive than the conventional technologies.

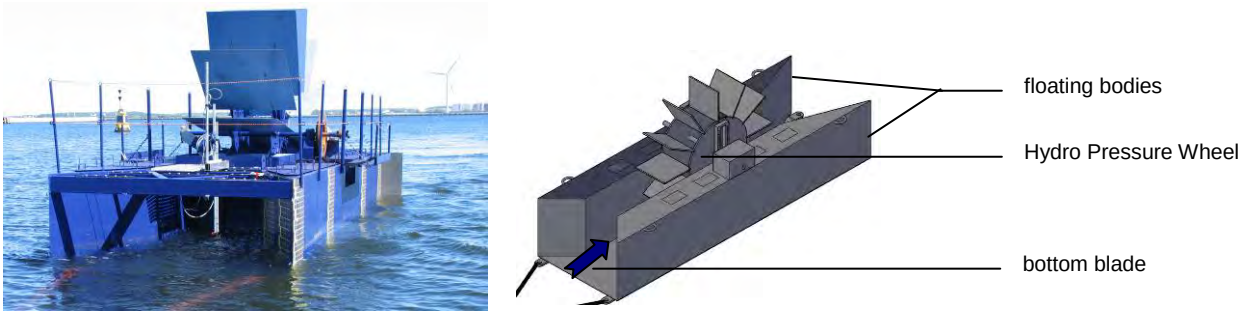

Fig. 1: Free Stream Energy Converter; length = 8 m, width = 2.5 m, draught = approx. 1 m

3. Categories of small hydropower potential

To characterize the areas for potential hydropower sites, different hydropower potentials are described. In publications different definitions for hydropower potential are available. In general the potential is divided into *theoretical, technical* and *realistic potential*. Several further sub-classifications exist.

The total availably energy is the *theoretical hydropower potential*, which can be calculated with following equation, (in which the efficiency factor is 1 for the theoretical potential):

$$P = \frac{1}{2} \cdot A \cdot \rho \cdot v^3 \cdot \eta \qquad (1)$$

The *technical hydropower potential* is only a part of the *theoretical hydropower potential*, which is realizable with existent techniques, at possible sites und complied with legal

regulations. In the range between the *technical* and *realisable hydropower potential*, the *environmentally complaint hydropower potential* and the *environmentally compatible hydropower potential* can be gradated, exemplarily. The definition criteria of mentioned potentials by [2] are mentioned in Fig. 2.

For our investigation within the *technical hydropower potential*, efficiency of the energy converter, requirements caused by dimension and operation of the *FSEC* and existing water uses are considered. The protection areas are taken into account in the *environmentally complaint hydropower potential*. Within the *environmentally complaint hydropower potential,* the impacts on the environment were considered (see chapter 6).

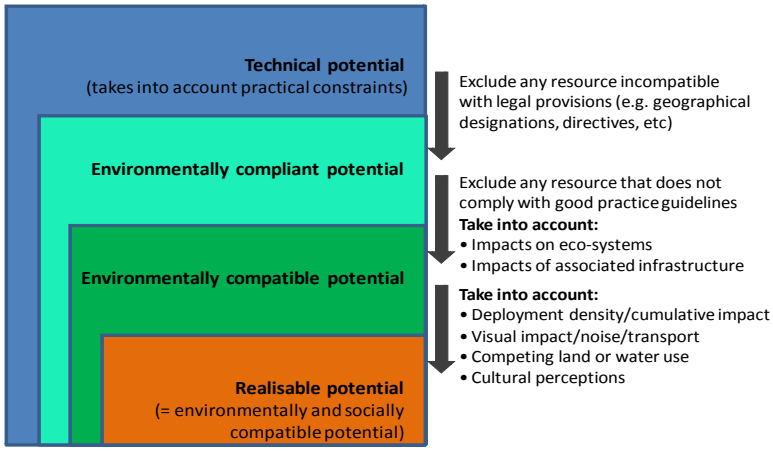

Fig. 2: Constraints to take into account when calculating the hydropower potential (after [2])

4. Investigation area – northern part of river Ems

4.1. Description of the investigation area

The investigation area is in the northern part of the river *Ems*, at the border between Netherlands and Germany. The river *Ems* has a typical river estuary which ends in the *North Sea* (Fig. 3). The river *Ems* is a typical European tidal river with mean tidal range of approx. 3.8 m and a distinctive river estuary. The average annual discharge is much higher than the average annual discharge of the river run-off, therefore not the river run-off but the discharge caused by the astronomical tide is the most important part of the total discharge and, hence, the most important factor influencing the flow velocities, too. The potential analysis for the river *Ems* can be stated to be exemplary for several rivers with tidal impact.

Fig. 3: Overview – investigation area (source: Google earth, modified)

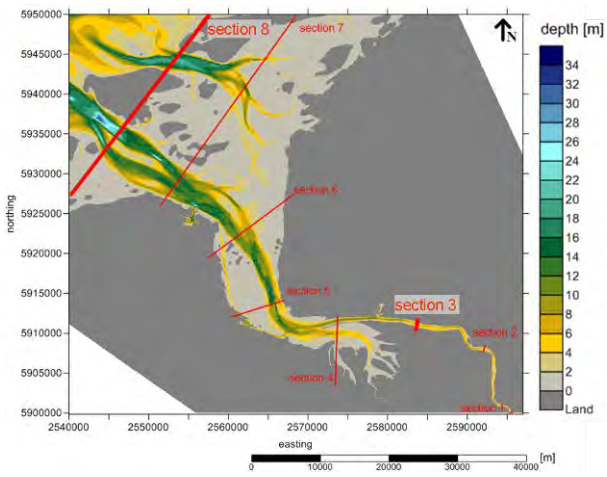

Fig. 4: sections for more detailed investigation, data source BAW

Within a detailed analysis, hydropower potentials were considered along 8 selected cross sections (see Fig. 4). Exemplarily, the investigation is described for the cross section 3 and 8. Section 3 is a typical river section. At this section the river *Ems* has a maximum depth of d = 7.2 m and a width of w = 560 m. The section 8 is typical for an estuary near the sea. The width of this section is about w = 28.000 m and the highest depth is about d = 22 m. Section 8 crosses the border area between Netherlands and Germany and is mainly situated in a protection area, as well as section 4 to section 7.

4.2. Data base

The data for the potential analysis at the *Ems* area is based on results of the Mathematical Model UnTRIM. The Federal Waterways Engineering and Research Institute used this numerical model to emulate and forecast the hydrodynamic conditions in the river *Ems* [2].

For the hydropower potential analysis the results of the simulation scenario with a constant mean run-off of 90 m³/s (average conditions) were used. The available results are representing the mean conditions of the astronomical tide and are available for approx. one day with a temporal resolution of Δt = 10 min and a spatial resolution of Δs = approx. 30 m x 30 m. For the potential analysis the temporal resolution was reduced to Δt = 1 hr and a spatial resolution of Δs = 50 m was used.

It can be assumed that the temporal variability of the natural flow conditions in the river, e.g. neap-spring differences, seasonally changing river run off have only negligible effects on the results of the potential analysis. Hence, the selected average conditions are extrapolated to assess the yearly potential.

4.3. Flow velocity

The mean tidal range is approximately 3.8 m and is varying along the river. The flow velocity varies with the tide and is in maximum about 2 m/s in the whole selected investigation area. Obviously, the flow direction varies also with the tide. The tidal wave is nearly totally reflected in the investigation area which means, that between low tide and high tide, the flow is directed in the upstream direction and between high tide and low tide the flow is directed in the down-stream direction. The mean (surface) flow velocities (on basic of one day) are shown in Fig. 5. As expected, the maximum flow velocities occur in the deep flow channels of the river and, correspondingly, the flow velocities are comparatively low in the shallow water areas.

Because of the bathymetry, the tidal range at section 1 with about 3.8 m is higher than the tidal range at section 8. The tidal range at section 8 is about 2.75 m. At both sections, the highest flow velocities are around v = 1.6 m/s. The flow velocity curves are proportional to the water depth at both sections. Hence, the highest flow velocities are at the sites with high water depth. The mean flow velocity varies along the cross section. A cross section sites with a water depth higher than 4 m, the mean flow velocities are about 1 m/s in section 3 as well as in section 8.

5. Theoretical hydropower potential

The *theoretical potential* is assessed as areal potential and based mainly on the flow velocity. The power output is determined for each grid on basis of the mean flow velocities with equation 1. For the comparison with other results, the flow trough area is defined with 1 m² and the efficiency factor is defined with 1. A bi-directional converter is assumed, which is

able to use the flow in both flow directions of the tide. In Fig. 6 the estimated *theoretical hydropower potential* for the investigation area is displayed. At several locations the estimated power output is higher than 1.2 kW. For most of the areas, the estimated theoretical power is between 0.2 kW and 0.8 kW.

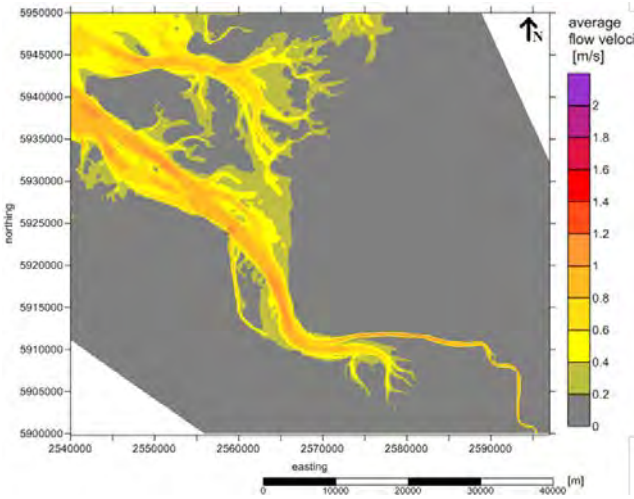

Fig. 5. average flow velocity, data source BAW

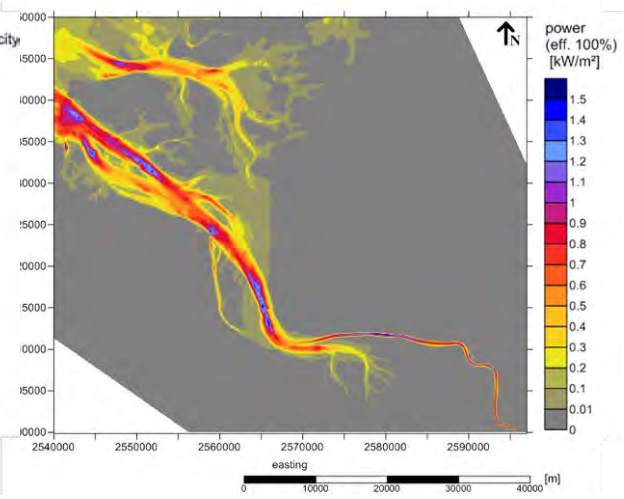

Fig. 6: theoretical power for the investigation area

An assumed realistic efficiency factor leads to decreasing estimates for the technical power. The definition of the efficiency factor for the *FSEC* is an objective of currently investigation and is not determined finally until now. With an assumed efficiency of 30%- 40% the maximum power is about 0.4 kW to 0.5 kW, with is in the range of the *technical hydropower potential*. The further factors, as water depth, other uses of the river or yearly operating hours are neglected, here. It will be considered in the following chapter.

6. Environmentally compatible hydropower potential

6.1. Considered aspects

As mentioned above, the *technical hydropower potential* considered the practical aspect, whether a deployment is possible regarding the technical requirements and other exiting site-uses (see chapter 3). One important aspect is the required space for the energy converter. All 8 considered cross sections are width enough to deploy a *FSEC*. For the *FSEC* (Fig. 1) the depth of the river is a restrictive factor (practical constraint). For the necessary river depth the draught of the *FESC* (1 m), the low water level and a necessary distance between river bottom and *FSEC* ("under keel clearance") have to be considered. The distance between bottom and *FSEC* is necessary, to ensure the floating behaviour of the *FSEC* and also to ensure the pass for the aquatic fauna and sediment below the *FSEC*. Its minimum is defined with 1 m. The low water level is strongly dependent on the local tidal range. The highest tidal range of the section is approx. 4 m, in section 1. Thus, the low water level is defined with -2 m NN. In the sum the required average water depth is 4 m including all sections of the river with river beds lower than -4 m NN.

In addition to the restrictive factor "required depth" existing uses of the river (competitive water uses) reduce the area to deploy the energy converter. In the investigation area, existing uses are mainly the use of the river as a waterway. In addition, uses like roadstead and spoil ground are of importance. The deployments of energy converter in the navigation canal are prohibited, in order to protect the navigation. A permission of hydropower deployment

outside of the navigation canal will be decided individually under consideration of the energy converter and the chosen deployment site.

Areas which are identified by a legal restriction, e.g. protection areas, or other environmental designation will be considered by the *environmentally compliant hydropower potential* (see chapter 3). A large part of the investigation area is defined as natural protected area.

At the latest by the implementation of the Water Framework Directive (WFD) it is not licensable to obstruct the whole river section with anthropogenic water uses. Also within the *environmentally compatible hydropower potential* the impact of uses is considered (see chapter 3). As mentioned above, the operation of the *FSEC* has only a minor effect on the environment. As a result, the use of the environmental friendly converter, like the *FSEC*, is a contribution for the *environmentally compatible hydropower potential.*

It is conceivable to deploy several energy converters in some converter fields. In this case, a distance between the single energy converters is required; especially in order to provide the river continuity, which is a main objective in the WFD. For the following analysis it is assumed that uses of 25 % of the river section is a minor impairment of the water bodies and therefore licensable. To not influence the operation mode and therefore the power output negatively, the distance between the single converters or to other uses and boundary are also important. Rightly this aspect is part of the *technical hydropower potential*.
The lateral distances between energy converters or to other uses/users or any other boundaries is chosen to 2 times of the converter width and is 5 m. In this paper the hydropower potential is only described along cross sections, therefore, the distance between the converter in down or upstream direction is not described.

It is distinguished between the demand of area for the deployment of the *FSEC* and the obstructed area caused by an *FSEC*. The obstructed area includes only width of the *FSEC*. The demanded area includes over more to the width of an *FSEC* the required distance between two successive energy converters, to other uses or to banks. For the calculation of the obstructed areas and for the demanded area the equation (2) and (3) are used, respectively.

Obstruct area: $L_{obstruct} = n \cdot w_{FSEC}$ (2)

Demand of area for deployment: $L_{demand} = n \cdot w_{FSEC} + 2 \cdot (n+1) \cdot w_{FSEC}$ (3)

In the following chapter it is determined how many energy converters like e.g. *FSEC* or other similar converters could be deployed along selected sections.

6.2. Results

The application of the mentioned aspect and the determination of the different hydropower potentials are described exemplarily along cross section 3 and 8 (see chapter 4). The power was determined based on the mean flow velocity and only at sites with water depths greater or equal to 4 m. The determined power and competitive uses along section 3 and section 8 are displayed in Fig. 7 and Fig. 8.

In case of section 3, the waterway utilizes 125 m of the total section of approx. 560 m. An average water depth higher than d = 4 m is available along a 410 m stretch of the section. More upstream of the river *Ems*, almost the total cross section length with a water depth

higher than d = 4 m is used by the waterway (e.g. section 1), therefore a deployment of the *FSEC* is not possible, there. The section 8 has a length of approx. 28,000 m. Thereof, approx. 13,500 m are land areas, for example the island *Borkum*. Only along approx. 7,000 m of the section length the average water depth is higher than 4 m. In addition, approx. 4,400 m of the remaining approx. 7,000 m are already in use or are protected areas. Along both sections possible deployment sites for the *FSEC* are remained (green lines in Fig. 7 and Fig. 8).

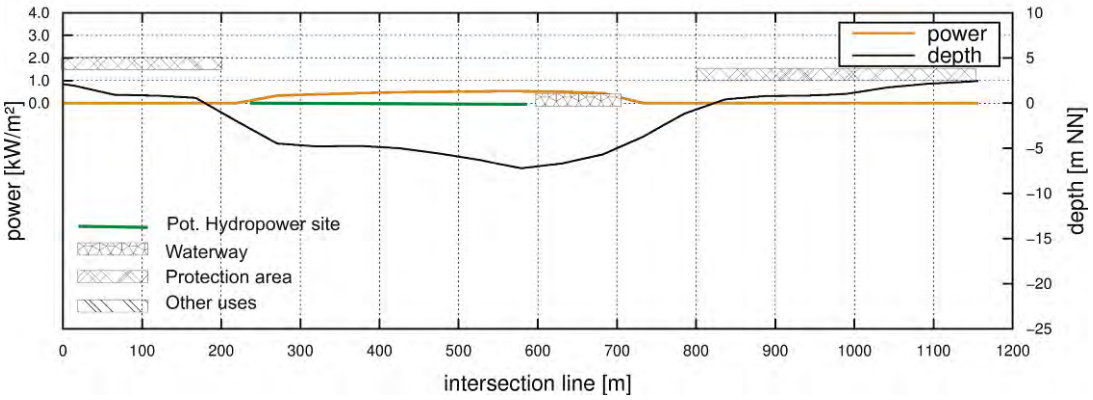

Fig. 7: Potential sites for hydropower uses and competitive uses, section 3 (power based on mean flow velocities)

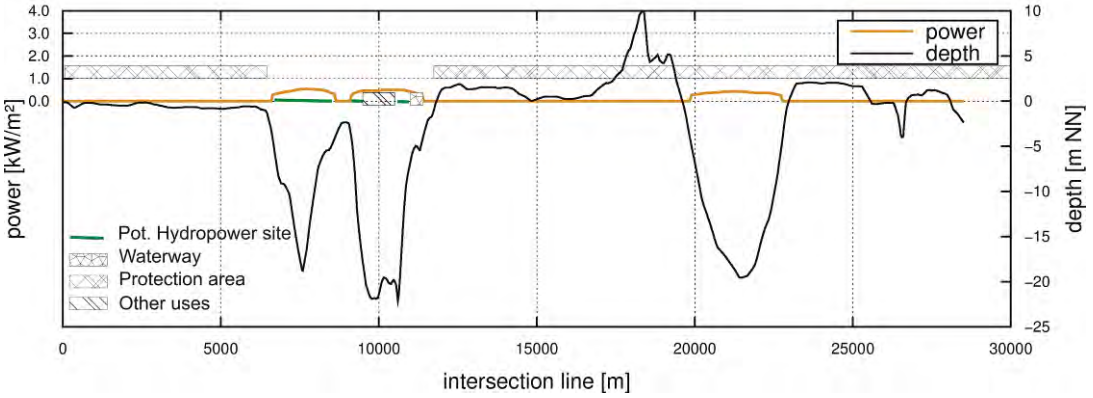

Fig. 8: Potential sites for hydropower uses and competitive uses, section 8 (power based on mean flow velocities)

Tab. 1: Properties of the sections

	Section 1	Section 8
Length of river cross section, only water areas (m)	560	16,590
Length of river cross section with existing uses/ protections area (m)	125	4,424
Length of river cross section d > 4 m (m)	411	7,003
25 % of river cross section length (m)	141	4,147

In Tab. 1 and Tab. 2 the properties and the *environmentally compatible potential* for the selected sections are presented. Along section 3 approx. 300 m and in the section 8 approx. 2,600 m could be used for the deployment of hydropower converters like the *FSEC*. Along all sections the obstructions of the river because of already existing uses are only minimal and therefore neglected. These results, that converter fields of possible 37 energy converters along section 3 and possible 343 energy converters along section 8 could be deployed. Accordingly, 16% of the river cross section 3 and 5% of the river cross section 8 would be obstructed.
For these possible energy converters fields the *environmentally compatible hydropower potential* is estimated with equation (1) on the basis of the assumptions that: all possible number of energy converter are installed, the average flow velocity v = 1 m, the flow through

area A_{FSEC} = 1.2 m² and the efficiency factor η = 0.3. If all 37 energy converters along section 3 and all 343 energy converters along section 8 could be installed, the potential is estimated with 7 kW and 62 kW (see Tab. 2). The operation period depends mainly on maintenance periods and weather conditions. With a realistic 5000 ope rating hours per year, the *environmentally compatible hydropower potential* is estimated with 33 MW/y for section 3 and 308 MW/y for section 8.

Tab. 2: useable resources of sections

	Section 1	Section 8
Length of river cross section d > 4 m minus length of other uses/ protections area (m)	287	2,579
25 % of river cross section length minus length of other obstructing uses (m)	141	4,147
Possible number of energy converters	37	343
Ratio: obstructed length / river cross section length (%)	16	5
Potential based on v_m = 1 m/s, A_{FSEC} = 1,2 m², η = 0.3 (kW)	7	62

7. Conclusion

The *realistic hydropower potential* will be lower than the afore-determined *environmentally compatible hydropower potential*. Furthermore the economical aspect was not considered in the paper. After the optimization procedure, the investigation costs will be calculated and put in relation with the expected power output. The estimated yearly performance per *FSEC* of approx. 890 kW/y is - compared to conventional energy converters - relatively low, but the advantage of *FSEC* is, that it has only small influences on the environment. The river *Ems* is an appropriate area for the deployment of the *FSEC*, because energy converters could be deployed in many sites and the flow conditions are continuous over the year. For example the discharge in rivers without tidal impact is seasonally different and depends of precipitation. In several rivers the flow velocity or the water depth are too low.

Abstract: Recently, availability decrease due to increase of midnight electric power demand has risen necessities to improve economic efficiency of the pumped-storage power plants in South Korea. The necessities cause to extend a preventative maintenance cycle, especially an overhaul cycle. But, unconditional extension cannot be implemented because it may generate unanticipated failures due to insufficient maintenance. So, first, in this study, possibility of extension of the preventative maintenance cycle is identified via investigation on preventative maintenance situation of overseas and domestic hydropower plants. Second, a methodology to optimize the preventative maintenance cycle considering both reliability and economic efficiency is presented via review of the previous reliability studies and considering characteristics of the pumped-storage power plant. The methodology consists of the eight parts including selection of principal components and subcomponents, identification of damage mechanisms in the principal components/subcomponents, FMEA(failure mode effect analysis), derivation of replacement and repair time of the principal components/subcomponents, design of preventative maintenance cycle plan, reliability analysis, economic assessment, and derivation of the optimized preventative maintenance cycle. Also, as a result of application of the methodology to an aged pumped-storage power plant in South Korea, the overhaul cycle has been extended from 4 years to 7.5years. Last, effect of replacement of some aged principal subcomponents such as rotor runner and generator stator on economic profits is investigated via application of the methodology to the aged pumped-storage power plant.

Keywords: *Pumped-Storage Power Plants, Replacement, Preventative Maintenance, Reliability, Economic Efficiency*

1. Introduction

Recently, it has been reported that availability of pumped-storage power plants decreases due to increase of midnight electric power demand in South Korea[1]. This low availability has been risen necessities to improve economic efficiency of the pumped-storage power plants. The necessities cause to extend a preventative maintenance cycle, especially an overhaul cycle. But, unconditional extension cannot be implemented because it may generate unanticipated failures due to insufficient maintenance.

All over the world, some studies has been performed about life extension, modernization and preventative maintenance of hydro and pumped-storage power plants[2-12]. In South Korea, life extension and modernization methodology for hydro power plants was established and applied to the aged hydro power plants several years ago but the methodology to optimize systematically an overhaul cycle wasn't developed[2]. The previous studies didn't investigate effect of aged pumped-storaged component replacement on economic profits considering reliability and economic efficiency.

Therefore, first, in this study, possibility of extension of the preventative maintenance (overhaul) cycle is identified via investigation on preventative maintenance situation of overseas and domestic hydropower plants[3-8]. Second, a methodology to optimize the preventative maintenance cycle considering both reliability and economic efficiency is presented via review of the previous reliability studies[6, 9-12] and considering characteristics of the pumped-storage power plant. Also, the optimized overhaul cycle is derived via application of the methodology to an aged pumped-storage power plant in South Korea. Last, effect of replacement of some aged principal subcomponents such as rotor runner and

generator stator on economic profits is investigated via application of the methodology to the aged pumped-storage power plant.

2. Investigation of Preventative Maintenance Situation

Table 1 presents the preventative maintenance cycles of hydro or pumped-storage power plants in some countries[3-8]. A class means complete overhaul for all components and B class means partial overhaul for some components. From the table, it is found that the preventative maintenance cycles of pumped-storage power plant in South Korea are shorter than those of other countries. It is identified that the A class preventative maintenance cycles of TEPCO and J-POWER have been gradually increased from 6years and will be 15years in the future by interview with working staff of TEPCO and J-POWER[7]. Also, It is confirmed that the recent availability of pumped-storage power plants in Japan is less than 10% similarly with South Korea. In some cases, Japan industries have taken and repaired the damaged principal components such as turbine runner, guide vane and generator rotor at maker's fabrication shops out of the site during A class overhaul period in order to improve their reliability to level of new products, but South Korea industries have repaired all the damaged principal components at the site.

As a result of this investigation, it is possible to extend the A class preventative maintenance cycle of pumped-storage power plants in South Korea like Japan. But, it is necessary to review in more detail and extend sequentially the cycle in order to extend to 10~15 years because there is difference in preventative maintenance method between South Korea and Japan.

Table 1. Preventative maintenance cycles of South Korea and overseas pumped-storage power plants.

Classification			A Class Preventative Maintenance Cycle (years)	Standard Period (days)	
South Korea/other countries	Company	Power Plant		A	B
South Korea : pumped-storage[3]	A	L	4 (A-B-A)	80	18
	B	M	4 (A-B-B-A)	76	12
	C	N	5 (A-B-A)	80	18
	D	O	4~6 (A-B-B-B-A)	80	16
	E	P	4 (A-B-A)	80	18
South Korea : hydro	KHNP[4]	-	4 (A-B-A)	-	-
	K-Water[5]	-	5 (A-B-A) or 6 (A-B-B-A)	-	-
Japan : hydro including pumped-storage[6]	-	-	9~15 or depends on equipment condition	-	-
Japan : pumped-storage[7]	TEPCO	Tamhara	12~18 (20,000hours)	150~180	21~28
	J-Power	Okki	15	125	8~10
USA : pumped-storage[8]	-	-	Average 10 (5~16)	75~150	-

3. Review of the Previous Studies about Reliability Assessment

Fig. 1 shows an optimization result of Snowy Mountains Hydro-electric Authority[9] for the complete overhaul cycle of hydro power plants by using the commercial program, RCM Turbo[13]. As shown in the figure, cost of unplanned maintenance increases drastically due to increase of breakdown probability with time span between planned activity while cost of

planned maintenance decreases continuously with the time span. So, sum of two costs has minimum value and the time corresponding to the value is an optimum overhaul cycle. However, this methodology cannot consider reliability reduction according to operation time beyond unit preventative maintenance cycle.

Japan Electricity Association presented a methodology to determine economic maintenance cycle of hydro-electric power equipments[6]. The methodology uses the same concept with Fig. 1.

Fig. 2 presents Vasilevski et al.'s methodology to investigate change of reliability with preventative maintenance cycle in order to determine optimal overhaul cycle and re-construction time[10]. As shown in Fig. 2, reliability reduction trend vs. operation time is changed with overhaul cycle, re-construction should be carried forward before reliability reaches critical value, and it mean that the overhaul cycle has to be adjusted as late as possible to be re-constructed. But, this study didn't present the method to set up critical failure probability and didn't consider economic efficiency so has practical problem.

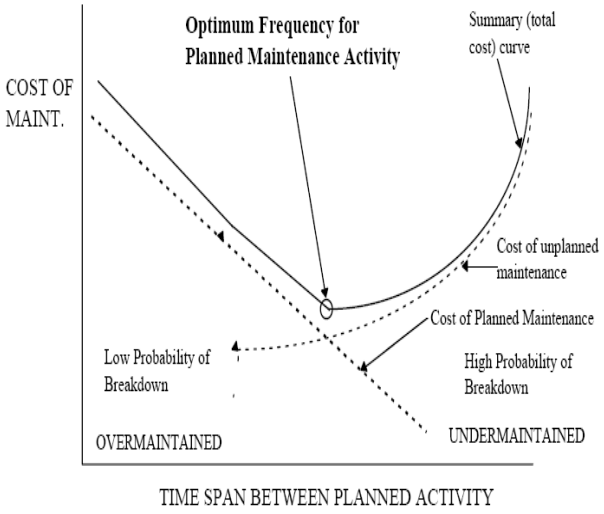

Fig.1 Maintenance cost optimization curve of Snowy Mountains Hydro-electric Authority[9].

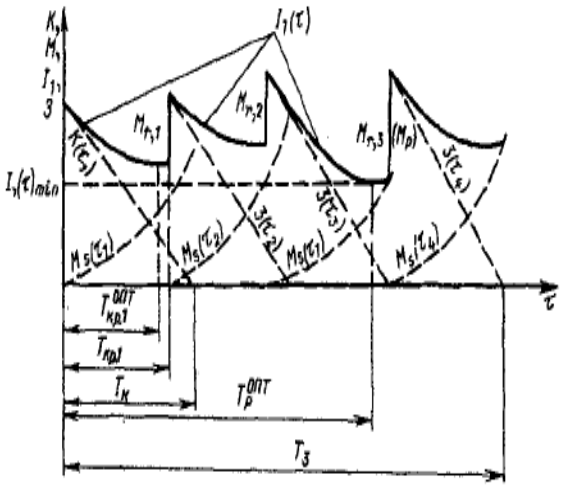

Fig.2 Vasilevski's methodology to determine optimal overhaul cycle and re-construction time[10].

EPRI TR-111488 presented outline of SRCM(streamlined reliability-centered maintenance) program for hydroelectric power plants instead of RCM(reliability-centered maintenance) that requires huge amounts of data and information[11]. EPRI TR-114160[12], which is a follow-up report of EPRI TR-1114888, presented three key factors(sound/cost-effective SRCM process, a software tool to manage consistently/effectively SRCM data and project management/working culture change) to succeed in performing SRCM and explained requirements for three key factors. However, purpose of the EPRI studies[11, 12] isn't optimization of overhaul cycle but deduction of preventative maintenance tasks for reliability improvement.

4. Methodology to Optimize Overhaul Cycle

Based on the review results of previous studies, this paper presents a methodology to optimize overhaul cycle considering both reliability and economic efficiency. Basic assumptions are used to develop the methodology as follows:

- Reliabilities of component and system should be drastically increased by A class preventative maintenance(overhaul).
- In cases of subcomponents or components applied only to B class preventative maintenance, effect of B class preventative maintenance on reliabilities of component/ system is insignificant.

Fig. 3 depicts overall flow chart of process to optimize overhaul cycle of pumped-storage power equipments. As depicted in the figure, item "task selection and comparison" of the RCM/SRCM methodology is removed because purpose of the methodology is to determine optimal overhaul cycle. Also, FFA(functional failure analysis) is performed including in FMEA(failure modes and effects analysis). Overall process consists of selection of target subcomponents/components, derivation of aging related damage mechanisms for the target subcomponent/components FMEA, calculation of repair/ replacement years, planning of preventative maintenance scenario, reliability analysis, economic efficiency analysis, and derivation of optimal overhaul cycle.

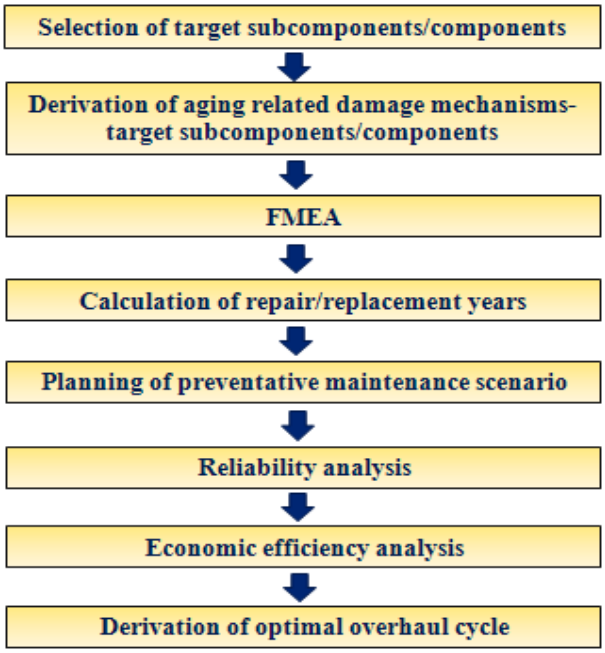

Fig.3 Overall flow chart of process to optimize overhaul cycle of pumped-storage power equipments.

Fig. 4 presents flow chart to select the target subcomponent and components. As presented in the figure, the subcomponents and components subject only to B class preventative maintenance are exclude from target in accordance with the basic assumption about effect of B class preventative maintenance on reliability. Fig. 5 shows flow chart to derive the aging related damage mechanisms for the target subcomponent and components.

Fig. 6 depicts flow chart of FMEA process. First, effect of each damage mechanism on intended function (e.g. structural integrity or performance) of subcomponent is evaluated. Second, based on the evaluation results, effect of the damage occurred on subcomponent on

component/system is evaluated. Third, next step, check whether subcomponents or components can be repaired or replaced during B class preventative maintenance or not. Last, if repair or replacement is impossible during B class preventative maintenance, draw up a final list of the relevant aging damage mechanisms for the target subcomponents/components.

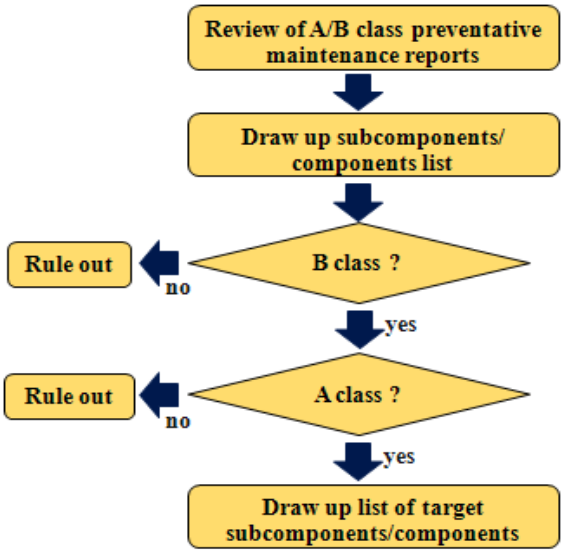

Fig. 4 Flow chart to select target subcomponents and components.

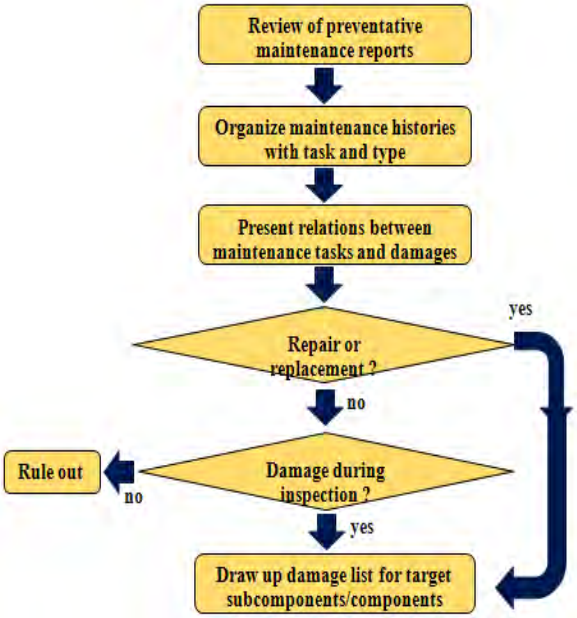

Fig. 5 Flow chart to derive the aging related damage mechanisms for the target sub-components/components.

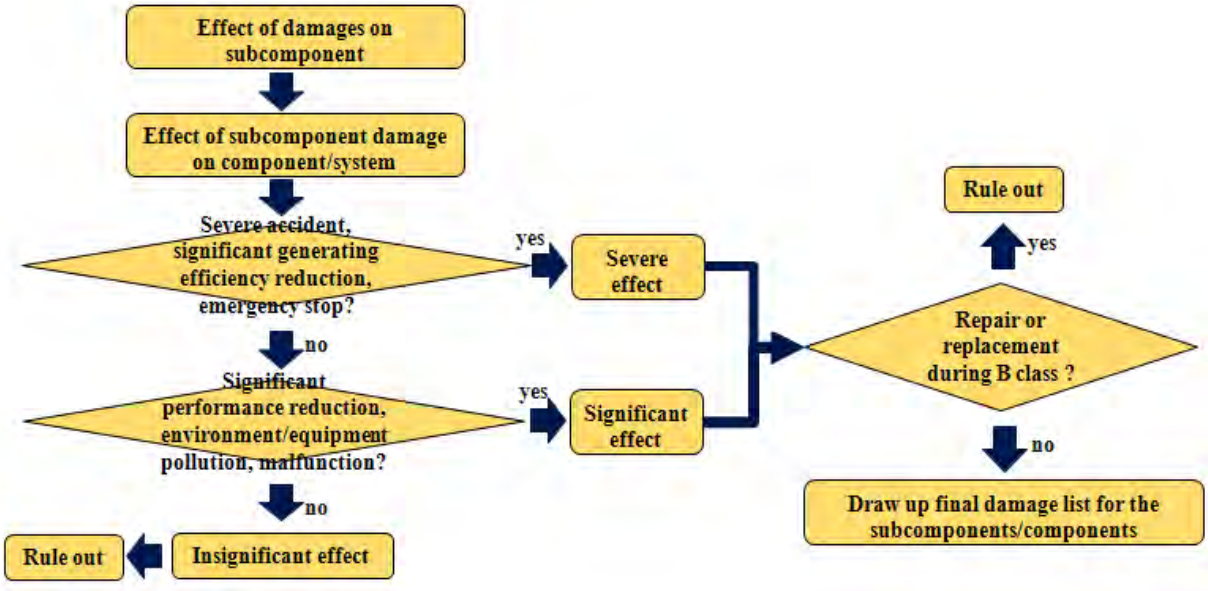

Fig. 6 Flow chart of FMEA.

Analyzing A and B class preventative maintenance histories for the final list derived via the process presented in Fig. 6, real repair/replacement cycles(minimum/mean) for the subcomponent-damage mechanism are derived. These repair and replacement cycles are used as an input for derivation of CHRF(cumulative hazard rate function) coefficients.

A preventative maintenance scenario has to be prepared because reliability has variation with order of maintenance class and number within unit cycle. For example, A-B-A, A-B-B-A, A-B-B-B-A, etc.
Fig. 7 shows flow chart of reliability analysis. If repair and replacement data are enough to evaluate, CHRF coefficients of equation (1) are directly derived via the numerical analysis using the repair and replacement cycles.

$$H(t) = a_0 + a_1 t + a_2 t^2 \quad (1)$$

$$R(t) = exp(-H(t)) \quad (2)$$

$$F(t) = 1-R(t) \quad (3)$$

where $H(t)$ is CHRF, $R(t)$ is reliability function, $F(t)$ is CDF(cumulative damage function) for failure time. If repair and replacement data are not enough to evaluate, CHRF coefficients are derived by using real repair/replacement data, reference reliability curve[14] or database[15], and Bayesian updating technique.

Finally, the overhaul cycle to derive minimum CPUT(cost per operating unit time) value at the target period is determined as an optimal overhaul cycle. CPUT for each preventative maintenance scenario is calculated by equation (4).

$$CPUT(t) = \frac{t_p[C_P R_{min} + C_U(1-R_{min})]}{t\int_0^{t_p} R(s)\,ds} \quad (4)$$

where C_p is preventative maintenance cost, C_u is post-accident preservation cost, t_p is unit cycle time, t is target period of scenario, R_{min} is minimum reliability within unit cycle.

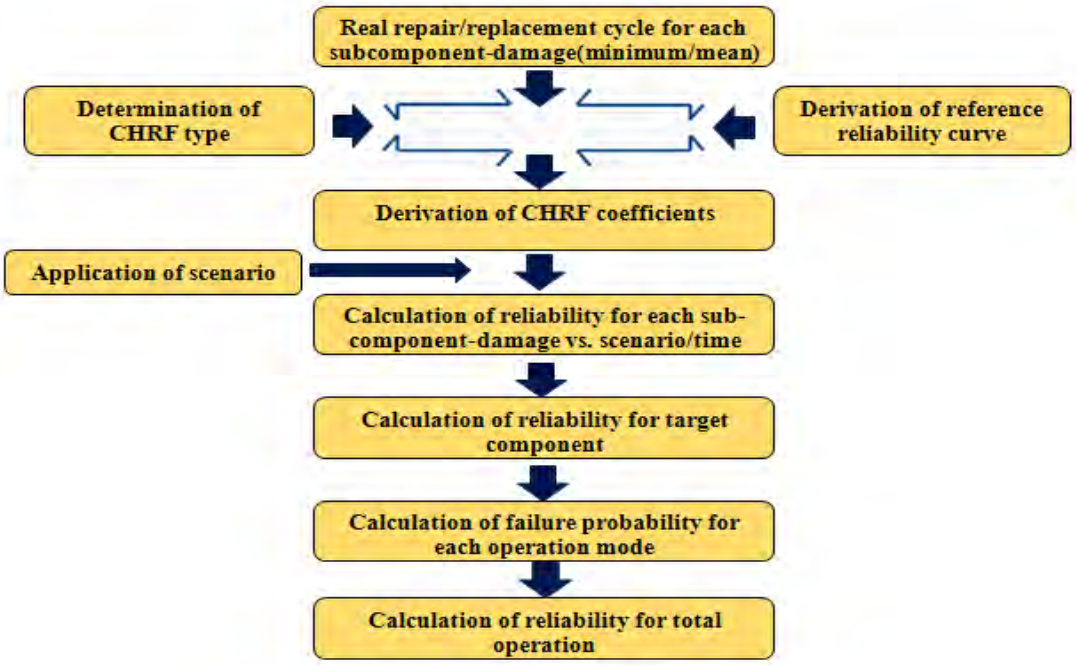

Fig. 7 Flow chart of reliability analysis.

5. Application Results

Table 2 presents overview of a pumped-storage power plant for application of the developed optimization methodology.

Table 2 Overview of a pumped-storage power plant for application of the methodology.

Items		Unit	Generation	Pumping
Operating time		years	24	
Capacity		MW	300×2	370×2
Pump turbine	Type	-	Francis	
	Max./min. head	m	345/288	355/310
	Max. output	kW	310,000	370,000
Generator/ Motor	Type	-	Vertical Inductive	
	Output	kVA	335,555	294,752
	Voltage/current	kV/A	18/10,763	18/10,763
Pony motor	Type	-	-	Vertical Inductive
	Output	kW	-	12,000
	Revolution speed	rpm	-	300
	Voltage/current	V/A	-	6,600/1,712

Fig. 8 depicts variation of reliability vs. time for various overhaul cycles of scenario 1(A-B-B-A). As depicted in the figure, reliability decreases continuously with time but increases after B or A class preventative maintenance. It is identified that improvement of A class is greater than B class in the viewpoint of reliability. Also, the overhaul cycle becomes longer, reduction degree of reliability is greater.

Fig. 9 shows CPUT variation vs. target operating time after the first overhaul completion for various overhaul cycles of scenario 1. As shown in the figure, the target operating time increases, CPUT value decreases irrelevantly to overhaul cycle. It is identified that CPUT has a minimum value at overhaul cycle, 7.5years when the target operating time for scenario 1 is more than 10 years. In other words, if the target operating time for scenario 1 is more than 10 years, optimal overhaul cycle is 7.5years. As a result of application of the methodology to an aged pumped-storage power plant in South Korea, the overhaul cycle has been extended from 4 years to 7.5years.

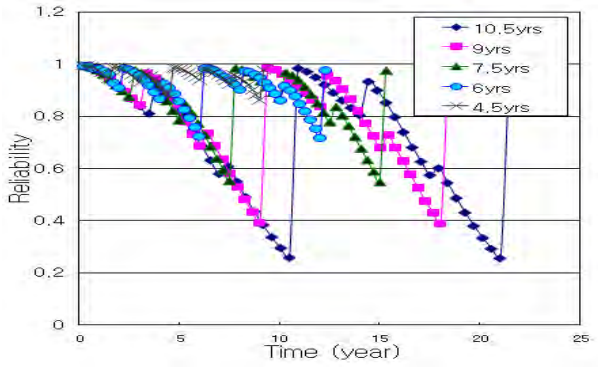

Fig. 8 Reliability of unit vs. time according to various overhaul of scenario 1.

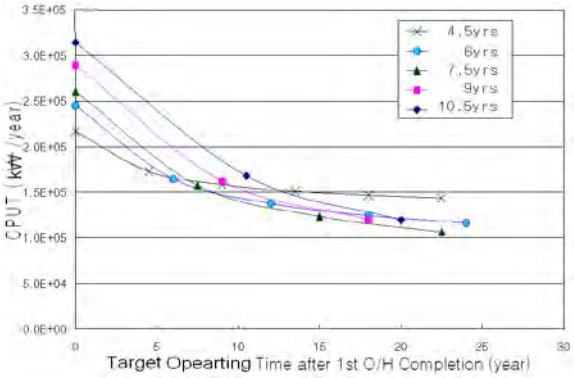

Fig. 9 CPU of unit vs. target time according to various overhaul cycles of scenario 1.

Table 3 presents CPUT variation according to replacement of principal components such as runner and generator. From the table, it is found that generator replacement has greater effect than runner replacement. When replaced with the runner and the generator to bring more economic benefits.

Table 3 CPUT variation according to replacement of runner and generator.

Component	Nothing	Runner	Generator	Runner & Generator
CPUT(kW/year)	1.2349×10^5	1.1611×10^5	1.1352×10^5	1.0491×10^5

Note) Scenario 1, Overhaul cycle: 7.5years, Target operating time: 15years

6. Conclusions

From the study to optimize overhaul cycle of pumped-storage power plants, the following findings are derived:

- As a result of this investigation, it is possible to extend the A class preventative maintenance cycle of pumped-storage power plants in South Korea.
- A methodology to optimize the preventative maintenance cycle based on the reliability and economic efficiency is presented, which can investigate variation of reliability and economic efficiency of generating unit vs. overhaul cycle.
- As a result of application of the methodology to an aged pumped-storage power plant in South Korea, the overhaul cycle has been extended from 4 years to 7.5years.
- When replaced with the runner and the generator to bring more economic benefits.

Risk assessment of river-type hydropower plants by using fuzzy logic approach

S.Kucukali[1,*]

[1] *Cankaya University, Department of Civil Engineering, Balgat, 06530 Ankara, Turkey*
** Corresponding author. E-mail: kucukali78@hotmail.com*

Abstract: In this paper, a fuzzy rating tool has been developed for river-type hydropower plant projects risk assessment and expert judgments have been used instead of probabilistic reasoning. The methodology is a multi-criteria decision analysis which provides a flexible and easily understood way to analyze project risks. The external risks, which are partly under the control of companies, have been considered in the model. The eleven classes of risk factors were determined based on the expert interviews, field studies and literature review as follows: site geology, land use, environmental issues, grid connection, social acceptance, financial, natural hazards, political/regulatory changes, terrorism, access to infrastructure and revenue. The relative importance (impact) of risk factors was determined from the survey results. The survey was conducted with the experts that have experience in river-type hydropower projects. The survey results revealed that the site geology and environmental issues were considered as the most important risks. The new risk assessment method enabled a Risk Index (R) value to be calculated, establishing a 4-grade evaluation system: low risk having R values between 1.2 and 1.6; medium risk, between 1.6 and 2; high risk, between 2 and 2.4; extreme risk, between 2.4 and 2.8. Applicability of the proposed methodology was tested on a real case hydropower project namely Kulp IV which was constructed on Dicle River in East Anatolia in Turkey. The proposed risk analysis will give investors a more rational basis on which to make decisions and it can prevent cost and schedule overruns.

Keywords: *Hydropower, Risk Analysis, Fuzzy Logic.*

1. Introduction

Renewable energy projects life cycle is full of various risks which will cause cost and schedule overrun or project failure. The surveys conducted by Gronbrekk et al. [1] and Komendantova et al. [2] identified the highest risk as political and regulatory changes for renewable energy projects in developing countries. Similarly, Ernst and Young [3] identified the most important business risk for 2010 as regulation and compliance.

Construction of river-type hydropower plants involves uncertainties because of various external factors such as site geology, grid connection, and environmental issues. These factors increase the construction costs and duration. For example, in one of the river-type hydropower plant in Turkey, namely Kulp IV, the cost of civil works increased by a factor of two because of unpredicted geologic structure at the tunneling site. In another example, the judges have ruled against hydroelectric power plants in 33 completed cases in Turkey, issuing a stay of execution decision or canceling the construction altogether because of the environmental issues.

In the literature there are several studies considering the risk analysis in construction projects [4] but risk analysis in renewable energy projects, especially for hydropower plants is very limited. In classical project risk analysis techniques, risk rating values are calculated by multiplying impact and probability values and direct analysis of these linguistic factors is often neglected [5]. Most existing risk analysis models, such as Monte Carlo simulation and tornado chart, are based on quantitative techniques which require numerical data. Kangari and Riggs [6] note that probabilistic models suffer from detailed quantitative information which is not normally available in the real construction world. However, much of the information related to risk analysis is not numerical [7]. Rather, this information is expressed as words or

sentences in a natural language. These conceptual factors can be expressed in linguistic terms that are, so called fuzzy information [8]. Uncertainty factors such as "poor geology" or "unstable policy" fall into this category. The aim of this paper is to introduce a new approach for hydropower projects risk assessment through the fuzzy set concepts.

2. Methodology

The eleven classes of risk factors were determined based on the expert interviews, field studies and literature review. The risk factors and their evaluation criteria are listed in Table 1. The risk factors are: site geology (geotechnical properties of the construction site), land use (right to use of the land for the construction of hydropower scheme), environmental issues (impact on ecosystem), grid connection (connection to the power system), social acceptance (impact on local community who use the river or the surrounding lands), financial (the status of the inflation and interest rate), natural hazards (earthquake, flooding and landslide), political/regulatory changes (level of political stability), terrorism (human-made disasters), access to infrastructure (road, electricity and water), revenue (cash flow). It should be noted that the financial, political/regulatory changes and terrorism were regarded as risks related to country conditions and their evaluation were done based on [9], [10].

In order to determine the relative importance (impact) of the risk factors, a survey was conducted with the experts from the banks and companies that have experience in the construction of river-type hydropower schemes. 14 experts were participated to the survey. The participants were asked to grade the importance of the risk factors regarding their importance and seriousness of concern. They graded the risk factors using a scale between 1-4, where 1 represents "low" and 4 "very high". The experts ranked site geology and environmental issues as the most important risks for river-type hydropower plants (Fig.1).

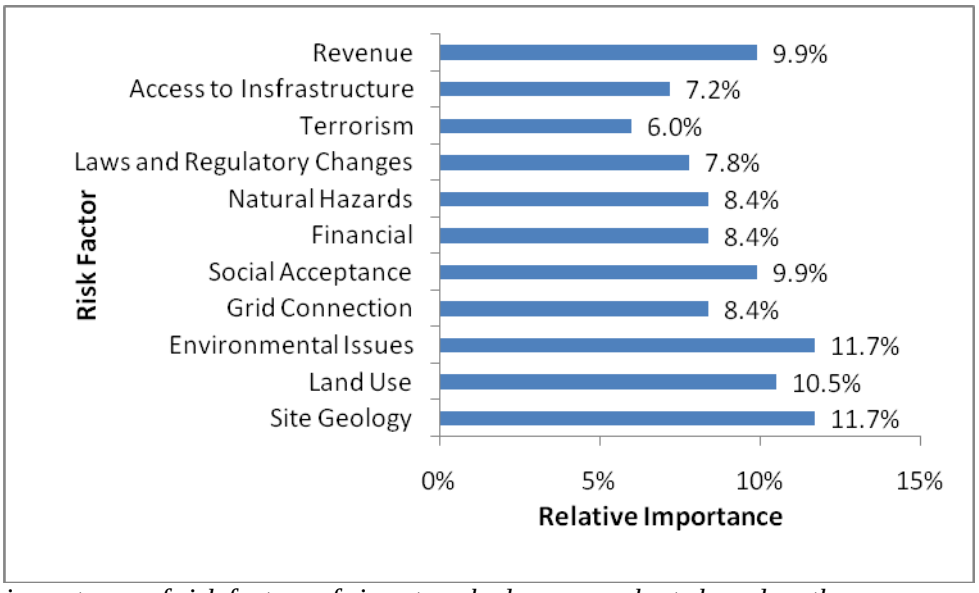

Fig.1 The importance of risk factors of river-type hydropower plants based on the survey results

Table 1. Evaluation criteria of risk factors in river type hydropower plants

Risk Factor	Score (1)	Score (2)	Score (3)	Score (4)
Site Geology	Rock mass quality is very good-good: RQD=%60-100	Rock mass quality is fair: RQD=%40-60	Rock mass quality is poor-very poor: RQD=%0-50	Soil with high ground water level
Land use	Property of Treasury	Forest	Private property: Agricultural land	Private property: Residential area
Environmental Issues	Project has detailed Environmental Impact Report	Project has Environmental Impact Report	Project has no Environmental Impact Report	Project is in an ecological sensitive area.
Grid Connection	Close to power system	Near to power system	Far to power system	Connection to the power system has some limitations
Social Acceptance	Project has detailed Social Impact Report	Project has Social Impact Report	Project has no Social Impact Report	Local community benefit from the river or the surrounding lands
Financial[a]	Economic performance of country is very high	Economic performance of country is high	Economic performance of country is medium	Economic performance of country is low
Natural Hazards	Low risk	Medium risk	High risk	Very high risk
Change in Laws and Regulations[a]	Political risk of country is low	Political risk of country is medium	Political risk of country is high	Political risk of country is very high
Terrorism[b]	Terror risk index of country is low	Terror risk index of country is medium	Terror risk index of country is high	Terror risk index of country is extreme
Access to Infrastructure	Very easy	Easy	Difficult	Very difficult
Revenue	Design discharge is high reliable	Design discharge is medium reliable	Design discharge is low reliable	Design discharge is unreliable

[a] country related risk and its evaluation is based on [9], [b] terrorism risk index is based on [10]

For each 11 parameter, an 1x4 input matrix was developed, each column corresponding scores 1- 4. If the score for a parameter is 3 and the input matrix (*I*) for the parameter is:

$$I = \begin{bmatrix} 0 & 0 & 1 & 0 \end{bmatrix} \quad (1)$$

Each parameter has an identical membership grading matrix. The fuzzy grading matrices were developed considering the degree of error a scoring observer may cause due to subjectivity and bias in the assessment process [11], [12]. Eq. (2) shows the fuzzy grading matrix (*FG*) used in this study:

$$FG = Score \begin{matrix} 1 \\ 2 \\ 3 \\ 4 \end{matrix} \begin{bmatrix} 1 & 0.4 & 0 & 0 \\ 0.2 & 1 & 0.2 & 0 \\ 0 & 0.2 & 1 & 0.2 \\ 0 & 0 & 0.4 & 1 \end{bmatrix} \quad (2)$$

The fuzzy assessment matrix (*FA*) was obtained by multiplying input matrices (*I*) with fuzzy grading matrix (*FG*) of the parameter,

$$FA_j = I_j \times FG_j \quad (j = 1\,to\,11) \quad (3)$$

where, j is the row number of the fuzzy assessment matrices. The membership degree matrix (*MD*) was obtained by multiplying weight of parameters (*w*) with fuzzy assessment matrix (*FA*) and summing the columns resulting in a one row matrix;

$$MD = w \times FA \quad (4)$$

A decision parameter computation was agreed upon f rom several scenarios considering membership degree versus attributes curves and formulation of Risk Index (R) was given as

$$R = \frac{1 \times A_{12} + 2 \times A_{23} + 3 \times A_{34}}{A_T} \quad (5)$$

where the area under the curve between the attributes i and j is named A_{ij} with: i =1,2, 3, and j = 2, 3, 4, . The total area under the curve is A_T. This enabled a R isk Index (*R*) value to be calculated, establishing a 4-grade evaluation system: Low risk having R values between 1.2 and 1.6; medium risk, between 1.6 and 2; high risk, between 2 and 2.4; extreme risk, between 2.4 and 2.8. The risk scale index represents the minimum and maximum values calculated by Eq.(5).

3. Investment Costs of Hydropower Schemes

Hydro power is the backbone of carbon dioxide free energy generation, about 22% of the world's electricity production comes from hydropower installations [13]. Hydropower plants can be classified into two categories: storage and river-type. In storage type hydropower plants, dams are used to retain river flow in a reservoir. A river-type hydropower plant diverts a portion of river through a channel or tunnel (Fig.2). River-type hydro power plants are dependent on the prevailing flow rate and can present problems of reliability if the flow varies greatly with time of the year or the weather [14]. Small hydropower (SHP) plants are mostly included in this category.

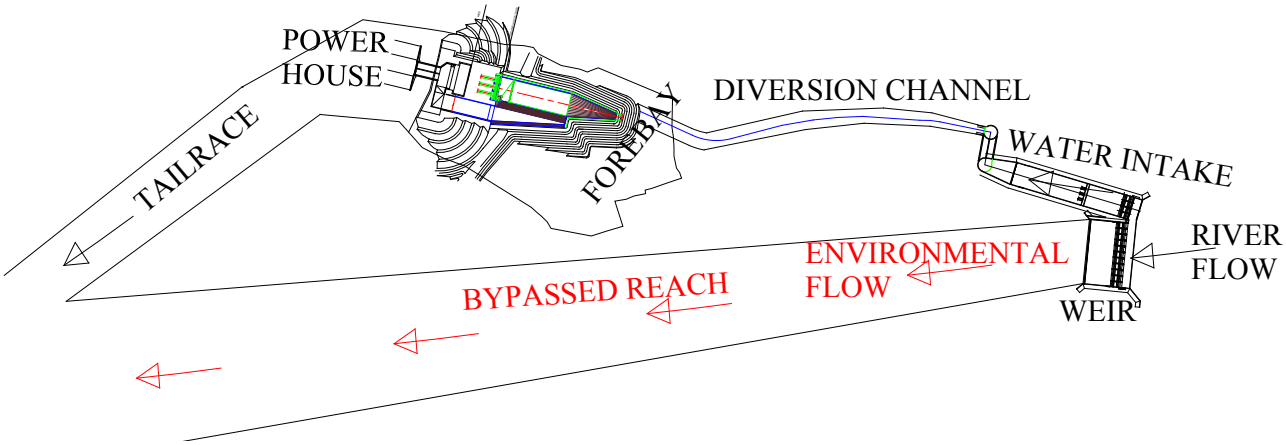

Fig.2 Site plan and components of a river-type hydropower plant

Hall et al. [15] determined the specific investment cost (total investment cost of the project divided by the installed capacity) of river-type hydropower plant in USA in the range of 2000-4000 $/kW. Also, they reported that the civil works account for 65-75% of capital cost. Each hydropower project is site specific that can explain the wide range of investment costs. Gordon [16] identified the main factors which can lead to cost overrun as the rate of inflation and site geology. The specific investment cost (SC) of a hydro power plant is the function of the net head (H) and installed capacity (P). It is well known from the literature that the SC increases as the head and installed capacity decreases [17], [18]. The investment cost a hydropower plant can be classified as follows: project design, land use and permits, financial, civil works, electro and hydro mechanical equipment, and grid connection (Table 3).

4. An Application of the Proposed Methodology

The developed risk assessment technique was applied to a real-time hydropower project namely Kulp IV which was constructed on Dicle River in Diyarbakır in East Anatolia. The characteristics of the project are as follows: Gross head=77 m, discharge=20 m^3/s, output=12.68 MW, energy=36.64 GWh/year, tunnel length=1885 m. Table 3 presents the investment cost analysis of Kulp IV hydropower plant. Actual cost of civil works and grid connection increased by a factor of two because of the poor geology and the technical demands by TEIAS, respectively. Table 4 shows the application of the risk assessment to the hydropower project. In the assessment fuzzy grading matrix provides more room for the justification of relationships between variables on the basis of fuzzy words. The project risk evaluation was done based on the criteria presented in Table 1. For example, Turkey has been ranked as extreme for Terrorism Risk Index by Maplecroft [9]. Therefore the risk factor of terrorism has a score of 4 for the project. Yet, project has no Environmental impact report, which yields the score of environmental issues as 4. By applying this method to other risk factors, the Kulp IV hydropower project Risk index was calculated as 2.26 which means project involves high risk.

Table 3. Analysis of the investment cost of Kulp IV hydropower plant (P=12.7 MW)

Description	Estimated Cost ($)	Actual Cost ($)	Rate of Increase	Share of Total Cost	Reason
Project design	1,090,000	1,180,000	8.3%	2.2%	Additional project designs
Civil works	12,500,000	25,700,000	105.6%	48.6%	Poor geology (serpentine) at the tunneling site
EME[a]	6,790,000	7,490,000	10.3%	14.2%	Under estimated costs of Technical equipment demand
HME[b]	8,900,000	4,800,000	-46.1%	9.1%	The prices of DSI are very high compared to the market.
Grid connection	2,600,000	5,400,000	107.7%	10.2%	Technical demands by TEIAS and length of the power supply line was increased
Land Use and Permits	2,200,000	2,600,000	18.2%	4.9%	The cost of the forest usage permit was not taken into account
Financial	3,100,000	5,700,000	83.9%	10.8%	Increase in interest rates because of the financial crisis

5. Conclusions

In this research, a new methodology is proposed for risk rating of river-type hydropower plant projects. The relative importance of the risk factors was determined from the expert judgments. The survey results showed that the most concerned risks are site geology and environmental issues. These results are in agreement with the Gordon [16].

Applicability of the proposed methodology has been tested on a real case. Findings of the case study demonstrate that the proposed methodology can be easily applied by the professionals to quantify risk ratings. The advantage of the proposed methodology is it will give investors a more rational basis on which to make decisions and it can prevent cost and schedule overruns. Forecasting the measure of risk of a river-type hydropower plant can be made by any decision maker with the help of the fuzzy rating tool described in this paper.

Abstract: This work focuses on the hydraulic aspects of a Pump as Turbine (PAT) when subjected to different working conditions, including accidental situations. This will provide useful information for the choice of the most adequate solution and will ensure a correct design and safe operation of the installed equipments. This work is supported by experimental data obtained in a series of tests performed at the university's laboratory and by calibrated computational modelling. The obtained data was used to perform a sensitivity analysis on the relation between discharge variation, runaway time and rotational speed and make inferences about the expected peak overpressure in an accidental situation. Based on the results, the hydropower system may be characterized by a relevant set of calculated parameters that are of extreme utility in the construction and calibration of a computational model capable of accurately predicting different scenarios and alternatives.

Keywords: *Dynamic effects; Reversible hydro; Safety solutions; Hydraulic transients.*

1. Introduction

In the operation of hydropower systems it is inevitable the occurrence of variations in the flow, being true either in routine manoeuvres, either in accidental or exceptional unforeseen events. To ensure the safety and reliability throughout the system life, it is very important that these dynamic effects and the associated risk factor are considered in the early stages of each design and the overpressures are accurately estimated [1, 2]. A detailed analysis for each operating situation is vital for understanding the dynamic behavior of hydro-mechanical equipment and their interaction with the flow and hydraulic circuit. This study is based on a parametric characterization of the different components of a hydro system as a support for a CFD modeling.

2. Methodology

2.1. Simulation-based modelling

2.1.1. Method of Characteristics

The quantitative analysis of unsteady flow through long conveyance systems is based on the fundamental hydrodynamic principles described by the dynamic (Eq. (1)) and continuity (Eq. (2)) equations [3]:

$$\frac{\partial V}{\partial t} + g\frac{\partial H}{\partial x} + \frac{fV|V|}{2D} = 0 \qquad (1)$$

$$\frac{\partial H}{\partial t} + V\frac{\partial H}{\partial x} + \frac{c^2}{g}\frac{\partial V}{\partial x} = 0 \qquad (2)$$

The previous equations can be used given the following conditions: the fluid in the pipe is homogeneous and mono-phase; the flow is mainly one-dimensional and the velocity profile is considered uniform through the cross-section of the pipe; the pipe axis remains static; the fluid and the pipe walls have physical linear elastic properties. For each calculation time step,

each pipe will be divided in a finite number of stretches bounded by the calculation sections building the rectangular mesh presented in Figure 1.

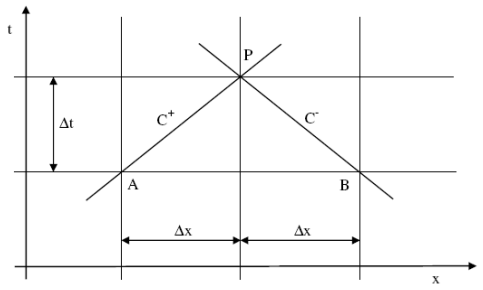

Figure 1 - Method of characteristics calculation grid.

The positive and negative characteristic equations can be written as follows:

$$Q_P = C_P - C_a H_P \tag{3}$$

$$Q_P = C_n + C_a H_P \tag{4}$$

in which:

$$C_P = Q_A \frac{gA}{c} H_A - \frac{f\Delta t}{c} Q_A |Q_A| \tag{5}$$

$$C_n = Q_B \frac{gA}{c} H_B - \frac{f\Delta t}{c} Q_B |Q_B| \tag{6}$$

and:

$$C_a = \frac{gA}{c} \tag{7}$$

Eq. (3) and Eq. (4) are only valid along the positive and negative characteristic lines, respectively. The values of C_P and C_n are known for each time step, although for the interior points of the mesh there are two unknowns, Q_P and H_P. These values can be determined by solving simultaneously Eq. (3) and Eq. (4):

$$Q_P = 0.5(C_P + C_n) \tag{8}$$

At both ends of each pipe it is only possible to define one characteristic line, so in order solve the system another equation is needed. This additional information may be obtained through the introduction of a boundary condition. Depending on the simulated system this boundary may be another pipe (with different characteristics), a reservoir, a turbine, a pump, a valve, a protection device or any other component analytically describable.

2.1.2. Turbine

The functioning of a turbogenerator can be characterized by a specific valve-type with adapted characteristics associated to customized closure maneuvers. Even though this solution may roughly simulate the vast majority of systems and situations, it does not consider the

specific parameters of the turbine, nor does it consider the overspeed of the turbine wheel and its complex interaction with the conveyance system. On this matter an innovative formulation was proposed for the simulation of the dynamic behavior of a turbogenerator based on a set of significant parameters that characterize a turbogenerator, allowing the evaluation of overspeed induced extreme upsurges and its propagation along the hydraulic circuit [4, 5, 6, 7, 8, 9] . This methodology simulates the turbine as a hydraulic resistive element, where the head lost by the flow is characterized by the basic formula of a hydraulic orifice equipped with dynamic discharge and rotational speed coefficients:

$$Q_P = C_g Q_R \left[1 + \frac{\alpha_R - 1}{\beta_R - 1} \left(\frac{N}{N_R} \sqrt{\frac{H_R}{H_u}} - 1 \right) \right] \sqrt{\frac{H_u}{H_R}} \tag{9}$$

in which q_P and h_P are respectively the relative flow through the orifice and available head at a certain time step. The factor C_g is the gate opening coefficient that defines the maximum discharge for a given head and rotational speed, as a function of the gate opening. The factor C_S accounts for the runner's rotational speed, adjusting the flow in each time step accordingly with the following formulation:

$$C_S = 1 + \frac{\alpha_R - 1}{\beta_R - 1} \left(\frac{n}{\sqrt{h}} - 1 \right) \tag{10}$$

where n stands for the dimensionless value of the rotational speed. The parameters $\alpha_R = \frac{Q_E}{Q_0}$ and $\beta_R = \frac{N_E}{N_0}$ are established for each turbomachine and represent the relation between the runaway situation and rated conditions, respectively for the flow and rotational speed. These values may be obtained from the manufacturers of the turbo equipments. The variation of the rotational speed for each time step depends on the inertia of the rotating masses, I, and the equilibrium between the hidraulic torque, T_H, and the magnetic torque, T_M. This relation may be expressed through the rotating mass equation:

$$\frac{d\omega}{dt} = \frac{60}{2\pi} \left(T_H - T_M \right) \tag{11}$$

in which ω is the angular speed (rpm). From Eq. (11), it is possible to conclude that for T_M = 0, the acceleration of the runner depends only on the hydraulic torque (T_H) and the inertia of the rotating masses, I. The hydraulic torque actuating in the rated operating conditions is given by the following equation:

$$B_{H,0} = \left(\frac{60}{2\pi} \right) \frac{\gamma \eta_0 Q_0 H_0}{N_0} \tag{12}$$

in wich η_0 = rated efficiency; Q_0 = rated flow; H_0 = rated net head; N_0 = rated runner speed. Assuming a linear variation of the discharge with the rotating speed under runaway conditions, the hydraulic torque at each timestep may obtained by multiplying the initial torque by a corrective factor, b, given by the following equation where $e = \frac{\eta}{\eta_0}$:

$$b = \frac{B_H}{B_{H,0}} = h^{3/2} C_g \frac{e}{n}\left[1 - \frac{\frac{n}{\sqrt{h}} - 1}{\beta_R - 1}\right] \tag{13}$$

The evaluation of the efficiency is a complex matter that depends on a vast set of parameters. This value may be considered to vary accordingly to the following approximate equations [4, 9].

$$\begin{cases} \eta_0 \dfrac{N}{N_0} & \text{for } N<N_0 \\ C_g\left(\dfrac{N_E}{N_E - N_0} - \dfrac{N}{N_E - N_0}\right)\eta_0 & \text{for } N>N_0 \end{cases} \tag{14}$$

2.1.3. Pumping system

The pump operation may be accurately simulated using the method of characteristics incorporating specific boundary conditions. Pump manufacturers generally provide the characteristic curves for their pumps as a function of the wheel diameter. These curves relate flow, manometric head, efficiency and power for a specific rotational speed and can be approximately represented in the first quadrant of operation (H,Q) by a second degree polynomial (Eq. (15)) [10]. Should this methodology be applied, a check valve should be installed at the downstream pump section to avoid reverse flow.

$$H_0 = AN^2 + BNQ - CQ^2 \tag{15}$$

The values A, B and C are constants and can be estimated from three known pairs of values (*Q, H*) of the pump characteristic curve. If correct data is available, a higher degree polynomial may be considered to enable a multi operating zone simulation. Although pump characteristic curves in the pumping zone operation are usually easy to obtain, the same is not true for the remaining zones. Figure 2 presents a schematic of a pump with the upstream and downstream connecting pipes and hydraulic grade line.

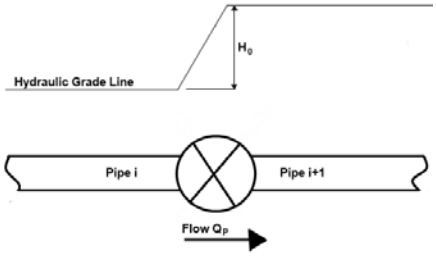

Figure 2 - Schematic drawing of a pump.

Referring to Figure 2 and considering the continuity equation, the relation, $Q_{P,i} = Q_{P,i+1}$, can be written. If the losses at the junctions are neglected, Eq. (16) gives the relation between head and discharge, in which *N* is the rotational speed:

$$H_{P,i+1} - H_{P,i} = AN^2 + BNQ - CQ^2 \tag{16}$$

when $A_i = A_{i+1}$, substituting Eqs. (3) and (4) into Eq. (16) the following polynomial is obtained, which can be solved for Q_P.

$$CC_a Q_P^2 + (BNC_a - 2)Q_P + \left(AC_a N^2 + C_n + C_P\right) = 0 \quad (17)$$

Once the flow Q_P is known, the heads $H_{P,i}$ and $H_{P,i+1}$ can be calculated for each time step. The total or partial shutdown of the pump as the cause of severe transient regimes may also be simulated. In this case the variation of the runner speed is given by Eq. (11) in which the hydraulic torque can be calculated based on efficiency data provided by the manufacturer.

2.1.4. Valve

Valves are installed in hydro systems to regulate the flow (or the pressure) by opening, closing or partially obstructing the pipe section. They can also be utilized to isolate system components in order to enable maintenance procedures or even their replacement. Figure 3 presents the schematic of a valve in hydraulic ciruit.

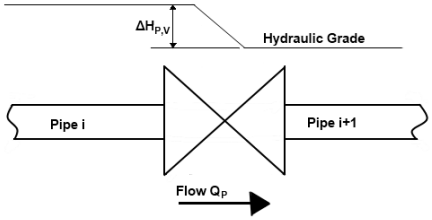

Figure 3 - Schematic of a generic valve.

The boundary condition for a valve can be written based on steady state head loss equation. The flow through the valve, Q_P, remains constant and the head loss can be written as the difference between the head at upstream and downstream valve section:

$$\Delta H_{P,V} = H_{P,i} - H_{P,i+1} = K_V \frac{Q_P^2}{2Ag} \quad (18)$$

in which K_V is a head loss coefficient obtained experimentally that depends on the Reynolds number, the type of valve and its opening at each time step. Substituting Eq. (3) or (4) in Eq. (18) a second degree polynomial equation is obtained:

$$\frac{K_V C_a}{2gA^2} Q_P^2 + 2Q_P - \left(C_P + C_n\right) = 0 \quad (19)$$

Solving for Q_P, the flow through the valve is obtained for each instant of simulation and subsequently the upstream and downstream head. For the situation where the valve is fully open, the head loss may be neglected and the flow can be determined by solving Eq. (8) or a fixed value should be considered. For the determination of the parameter K_V, a set of empirical results for each type of valve is presented in [11].

2.2. Model validation

Some supporting experimental tests were carried out in the Hydraulic lab of DECivil/IST, in order to analyze the behaviour of a reaction type turbomachine in different operation conditions. The hydraulic circuit is composed by a pipe of High-density polyethylene (HDPE), with an internal diameter of *0.043 m* and a length of *100 m*, which connects the pressurized vessel to the turbomachine. At the downstream end the water is discharged into a free surface tank. Both the air vessel and the free surface reservoir are responsible for

imposing a constant head respectively on t he upstream and downstream section. An intercalated pump is responsible for setting a recirculated constant flow. The turbomachine is a horizontal, single-stage pump-as-turbine, PAT*, KSB model Etanorm 32-125*. The generator was connected to the national grid via a l arge electrical transformer. Figure 4 presents a comparison between experimental pressure head variation and the corresponding simulation in the event of a full load rejection followed by a valve actuation.

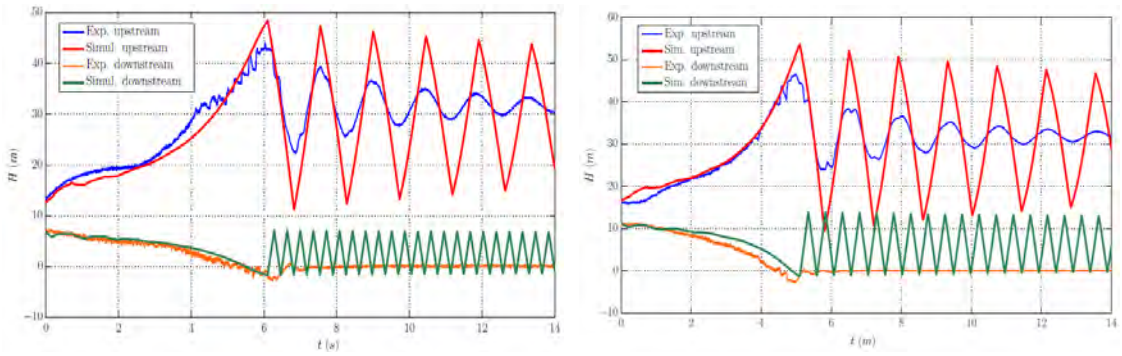

Figure 4 - Comparison between simulation and experimental results for Q = 4.2 l/s and Q=3.9l/s

3. Overspeed and dynamic effects

Based on a general hydropower system, a detailed analysis of the runaway effect without the interference of the closure of the flow control shutter (e.g. guidevane) or any special protection device was established. This was done in order to fully isolate and better understand the phenomenon under analysis. Under these conditions several independent computer simulations were carried out for a broad set of pairs of values of inertia, I, and specific speed, n_S. Figure 5 shows the upsurge on the upstream section of a turbine for the different combinations of parameters. For the lower values of n_S, the overspeed results in a flow reduction, causing an upsurge in the hydraulic system. On the other hand, turbines with high specific speeds are associated to an increase in flow when a load rejection occurs, resulting in sub-atmospheric pressures in the pipeline.

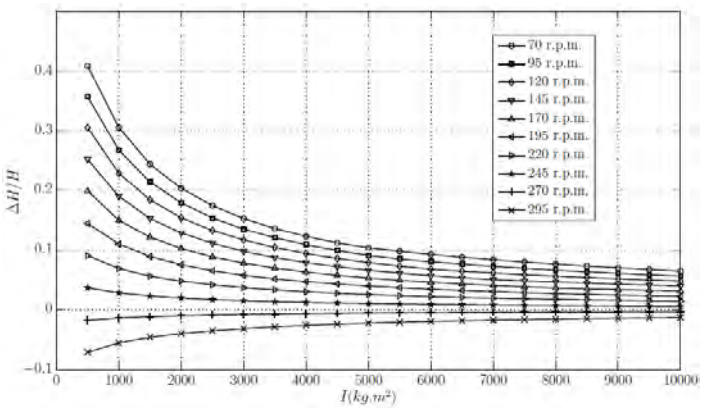

Figure 5 - Extreme relative pressure head as a function of I and n_S.

4. Load rejection and closure of flow control device

From the different emergency operations a hydropower system endures throughout its service life, the full load rejection followed by the actuation of a discharge shutter may stand among the most severe situations. Considering the same turbomachine used in the paragraph 3, the influence of the length, L, of the pipeline and its interaction with the safety valve closure time, t_C, was studied. For this purpose, a set of simulations were carried out in order to

calculate the maximum upsurge for different combinations of values, obtaining the results presented in Figure 6.

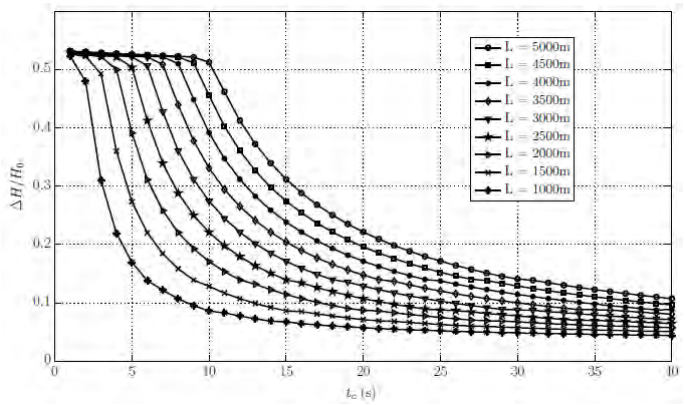

Figure 6 - Maximum relative overpressure for different combinations of L and t_C.

For all pipeline lengths, when approaching the elastic time constant, T_E, the maximum values of ΔH rise very quickly. It should be noted that below a certain value of t_C, for each different penstock length, all the curves tend to a common maximum value. This is the domain of what is called a fast manoeuvre, $t_C < T_E$, in which the transient peak overpressure depends only on the celerity of the elastic waves, c, and the mean flow velocity, U_0, given by the Frisel-Joukowsky formula.

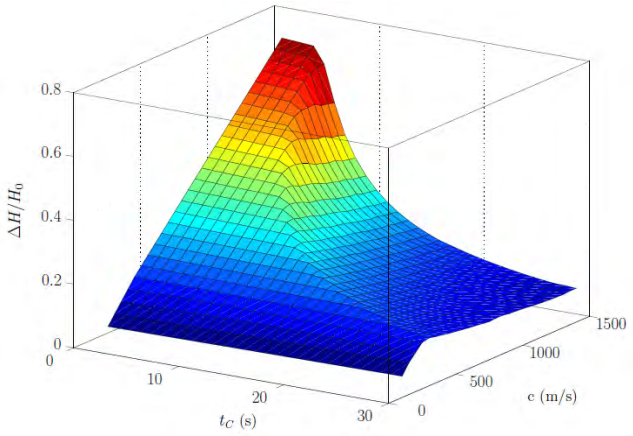

Figure 7 - Maximum relative overpressure for different combinations of c and t_C

Figure 7 was generated by utilizing the developed computational model, to show the maximum overpressure reached for different combinations of values of the celerity, c, and closure durations, t_C, for a fixed penstock length $L = 4000m$. When observing closely, it becomes evident that the classification of a closure manoeuvre as fast ($t_C < T_E$) or slow ($t_C > T_E$) is a relative concept that depends on the celerity of the elastic waves, thus on the pipe properties. In fact, the lower the value of c, the bigger the value of t_C must be in order to perform a slow closure manoeuvre. For a slow manoeuvre, the maximum pressure head depends essentially on the mean fluid velocity and on the flow control valve closure time. The maximum value can be estimated based on the by Michaud formula. Unlike what happens in a fast manoeuvre, the maximum overpressure is independent from the wave speed celerity.

5. Results

Both the experimental and the simulation results demonstrate the turbine load variation, in particular the runaway condition has a relevant impact on the discharge and, given the right circumstances, can be the sole cause of severe transients in hydropower systems. This is

especially evident for certain combinations of values of n_S and I that can result in a significant flow reduction during a short time interval. The comparison between the developed model and the experimental test results suggests a good estimation for the maximum transient overpressures, presenting conservative values valid for hydro and pumping design. This formulation based on modular linkable components proved to be flexible enough to allow the easy setup of a v ast set of different scenarios that are able to simulate the majority of situations. This methodology has the ability of predicting the runner overspeed of turbogenerators, as well as pumping stoppage and its effect on the flow along the pipe system.

Abstract: Micro hydro systems can be regarded as a renewable energy source resulting from the natural hydrological cycle, it is by some considered sustainable due to the lack of impoundment of water and assumed negligible environmental impact. Experience with wind energy has highlighted that as the uptake of renewable energy technologies increases so government policies need to keep pace if public complaints and rejection of these technologies is to be averted. Studies on micro hydropower, particularly in an urban setting where propagation of noise is a planning issue, have been very limited. This paper focuses on the acoustic environmental impacts of micro hydropower considering a Reverse Archimedean Screw (RAS). Acoustic samples were taken directly above the RAS, and on a 5m interval along a transect and then at, 30m and 60m along another transect. Two further transects were considered and sampling was made at 30m and 60m. Initial results indicate that during normal operation at 25kW the screw would be barely perceptible beyond 60m; the weir provides significant masking of the turbine noise. It also shows that the noise generated is directional in nature at this site.

Keywords: *Micro hydro, Acoustics, Noise, Renewable energy, Environmental impact.*

1. Introduction

It is widely recognised that worldwide energy demand and use is continuing on an apparent, unceasingly ascending trend as, rapid population growth, economic development and therefore inherent demand for fuel increases [1, 2]. The world energy mix is depicted by the International Energy Agency (IEA). According to their *World Energy Outlook* (2008) [3]; renewables accounted for around 13% of global energy in 2006. This figure is predicted to rise to around 14% in the IEA 2030 reference scenario; and 24% in the IEA 450 (2030) policy scenario (based on policies under consideration). Oil and gas shares are predicted to be around 50% in both 2030 scenarios whilst coal lost some of its market share to an increase in the use of renewables (including biomass and waste), and nuclear energies.

The role of hydropower as a renewable resource varies dependent on the scale of the installation. As discussed by Frey and Linke [5], many legislative organisations do not consider large-scale hydro power to be a renewable resource when determining eligibility for government support. However, as argued in the paper, this is not a question of renewability but of sustainability. Although micro and pico hydro systems are assumed to be more environmentally friendly due to the lack of impoundment of water and assumed negligible environmental impact [4-6] emerging literature indicates that detrimental environmental impacts can be caused by smaller scale schemes [4].

Paish (2002) [4] indicates that small scale hydro developments in Europe will be the main area for hydro development in the future as the majority of large scale sites have already been exploited and micro hydro schemes seem to be growing in development and government support in the UK [2, 6]. In the urban setting, the issue of noise generation from visible systems can be a significant factor in the viability of the scheme, and the time period over which it is run. As part of a wider on-going research on the above issues, this paper will focus on initial results from a study of the impacts of a hydro scheme on the acoustic environment.

As there is recognised potential for hydro schemes in cities due to existing infrastructure, it would appear that there is need for such a study.

Three sites (semi-rural) within the UK using a Reverse Archimedean screws (RAS) to generate electrical power have already been identified as causing a noise nuisance. However, this tends to be associated with poor installation/design faults rather than general noise nuisance during normal operation. Any noise nuisance, whether design faults or operational, may be escalated within a densely populated and built-up urban setting. If micro-hydro is to penetrate into our cities then noise evaluation will become a key issue in the planning and design of such schemes. An extensive but not exhaustive literature search has demonstrated that this type of research has yet to be undertaken. Government policies may need to change to support these technologies and make them more viable; however, evidence is required to enable the government to establish the true impact on the environment of such technologies.

It is known that hydropower sites are most efficient at a particular speed, head and flow [4]. However, the relationship between the power output, river flow and sound power levels is not known. The following study will present measurements taken in the field to evaluate the sound generated from a RAS scheme in New Mills, running at a power output of 25kW, with a total head of 3+ metres, and in comparison to the existing sound produced by water flowing over a weir.

2. Methodology

Acoustic measurements were carried out around a 2.6 x 11m tri-blade RAS, with a fixed rotation of 28.03min^{-1} generating at 25kW and a river flow of around 2.17cumecs, located in a parkland setting, within an urban environment. *Figures 1 and 2* show plans, and photos of the site respectively. There do not appear to be any standards, or current methods for acoustic sampling of micro hydro turbines in the field in the UK possibly the world. It was therefore prudent to utilize BS 7445 and BS 4142 and the field site's complex geography to design a sampling strategy. Acoustic samples were taken along transects shown in *figure 1*. All samples were taken at 1.4m above the ground surface and where possible over 3m away from any facades. Acoustic samples were also taken directly above the RAS to enable the sound power level to be derived. On transects (a), (b) and (c) samples were taken at 30m and 60m from the RAS. Transects (b) and (c) also included a sample at 90m. Samples were then taken at 5m intervals along transect (d). Sampling directly to the side of the RAS was deemed unsuitable due to the presence of a wall. *Figure 2* is a photo of the site taken from above; the right hand image shows the bridge from which it was taken

After numerous visits, it was determined that the site's acoustic characteristics do not alter significantly over time. However, a sample of the acoustic environment was carried out using WinMLS (Windows Maximum Length Sequence), at a fast sampling rate to determine the required acoustic sampling time at each sampling instance. Two minute samples were deemed sufficient for this study.

In addition to the acoustic sampling, *figure 1 also,* shows the location of two pressure gauge sensors, which have been installed to allow future work on river flows, efficiency and acoustic impacts of the turbine at this site.

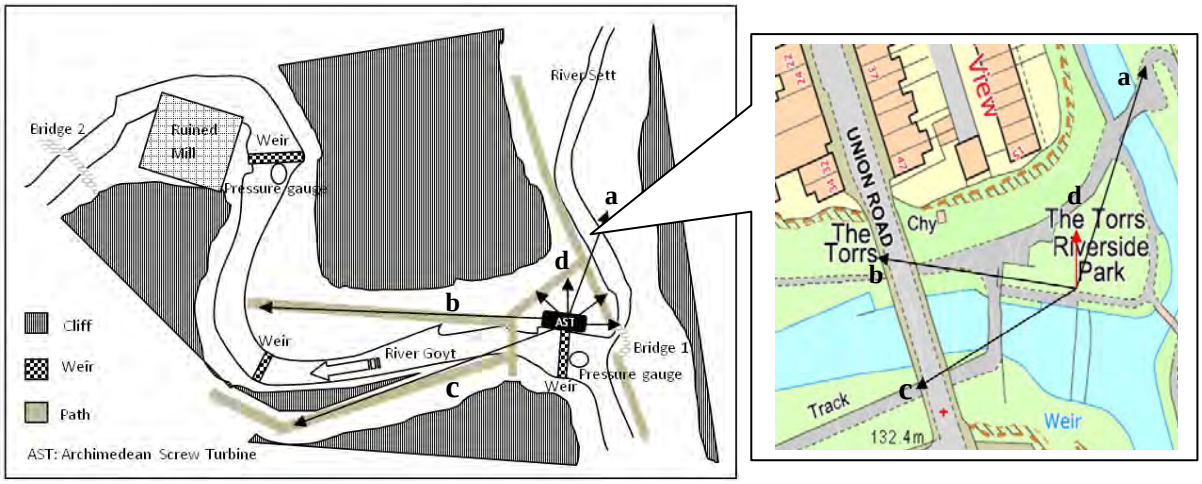

Figure 1. Location of the RAS studied, including the positions of the sampling transects (arrows) a, b and c, short red arrow is transect d. also shown is the positions of the pressure gauge sensors (for future work), and the location of the injection (Bridge 1), and sampling points (Bridge 2)

Figure 2. (Left) plan view photo of the RAS at New Mills and (right) a photo looking across the top of the weir to the angled transect (left-hand arch) and same axis (second arch in from right) NB: the bridge is indicative of the stone cliff heights around the site.

Sound Pressure Level (SPL) samples were taken (unweighted Leq) at each point along the transects using Class 1, MP231 microphones and WinMLS 2008. This was repeated when the RAS was running, and when all the water was diverted over the weir and the fish pass. A laser range finder and tape measure were used to give accurate distance of the sampling points from the weir and RAS for accurate sound propagation calculations and soundscape analysis. Processing of the acoustic samples was undertaken in the lab using WinMLS 2008. The main acoustic assumption is that the background soundscape is the same as when the screw is operational.

3. Results & Discussion

It is noted that in this paper, only limited results available are presented, and further measurements are being made. However, the results are of interest as there is no known data published for the sound propagation from RASs in the literature.

At a distance of 90m, the effects of other weirs downstream from the site were found to mask the sound from the RAS. Therefore, data from the 90m samples are not analysed further. *Figure 3* shows the SPL at increasing distances from the RAS along transect (d). As expected,

higher frequencies attenuate at a greater rate, see *figure 3*. The attenuation along distance is significant, and at a typical frequency, 500Hz, the SPL attenuation is about 10dB.

Observations of 1/3 octave plots and signals, *figures 4, 5 and 6* and recordings from the near field, transect (d); indicate a near white noise soundscape environment. By this, it is meant that the sound environment sounds like white noise. This near white noise is generated mainly by the water falling over the broad crest weir. Further to this a noticeable drop in amplitude in the signal can be observed with distance and between on and off, though less so. The spectrum plots of zero metres from screw, *figure 4*, indicate that there is a 3dBA difference between the screw being off and on which in acoustic terms contributes a barely legible amount [7].

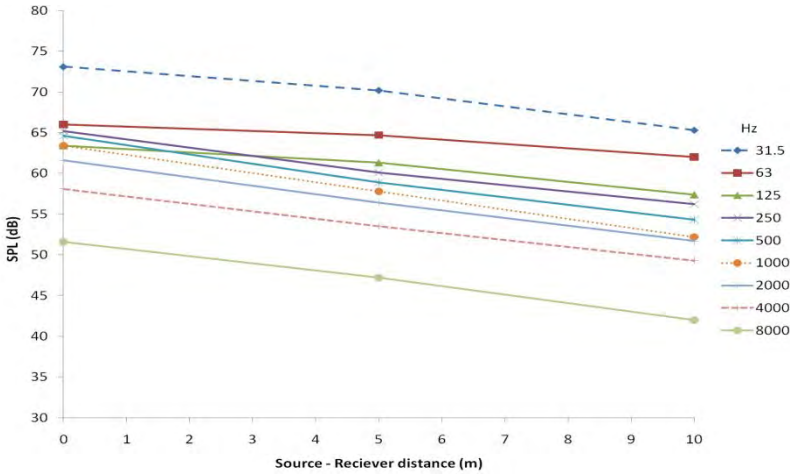

Figure 3. Background SPL when the flow is diverted from the RAS over the weir. Measurements taken along transect d (red arrow, figure 1) of SPL at a range of frequencies with increasing source - receiver distance.

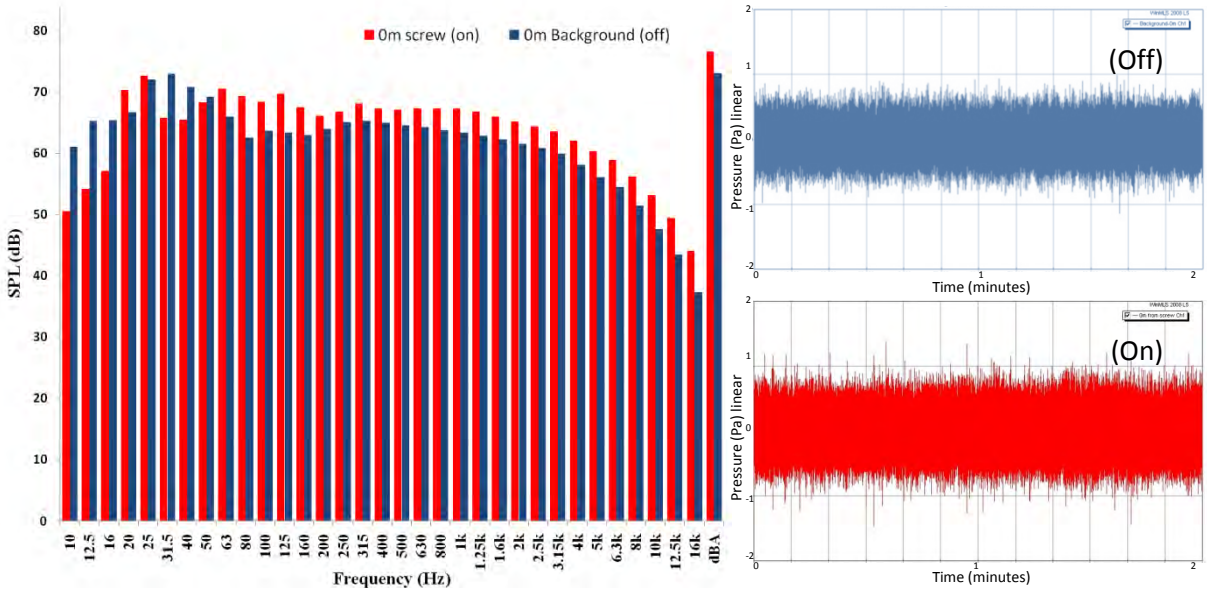

Figure 4. 1/3 octave spectrum plots of the SPL with 2 minute signal, when the RAS is operational at 25kW (red) and when the RAS is off, flow is diverted over the weir (blue) taken from directly above the RAS zero metres from screw.

At lower frequencies, the SPL with the RAS being off is 7-10dB higher. This might be due to the reduced volume of water falling over the weir when the RAS is running at 25kW,

reducing the low frequency component as less water falls into the weir pool. This may also explain the increase in SPL in the mid ranges. A similar pattern can be observed in the plots of samples taken 5m from the RAS, *figure 5*; and again at 10m, *figure 6*. However, there is less of a difference between the dBA results; with a difference of around 1dB and the mid to high frequency ranges being of a similar nature. However, lower frequencies are higher in amplitude during the background sampling than when the screw is operational, which may also be due to reflections from surrounding walls or being more exposed to the weir through an opening in the wall next to the screw and a function of directivity. *Figures 4-6* show a decrease in signal amplitude with distance.

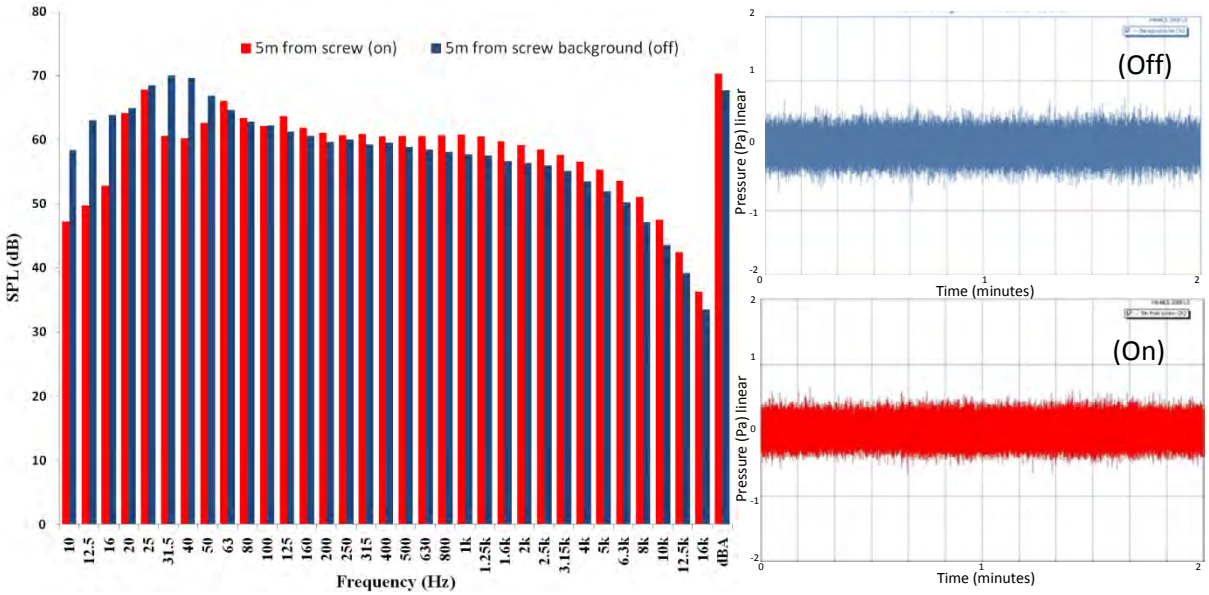

Figure 5. 1/3 octave spectrum plots of the SPL and 2 minute signal, when the RAS is operational at 25kW (red) and when the RAS is off, flow is diverted over the weir (blue) at 5m from screw.

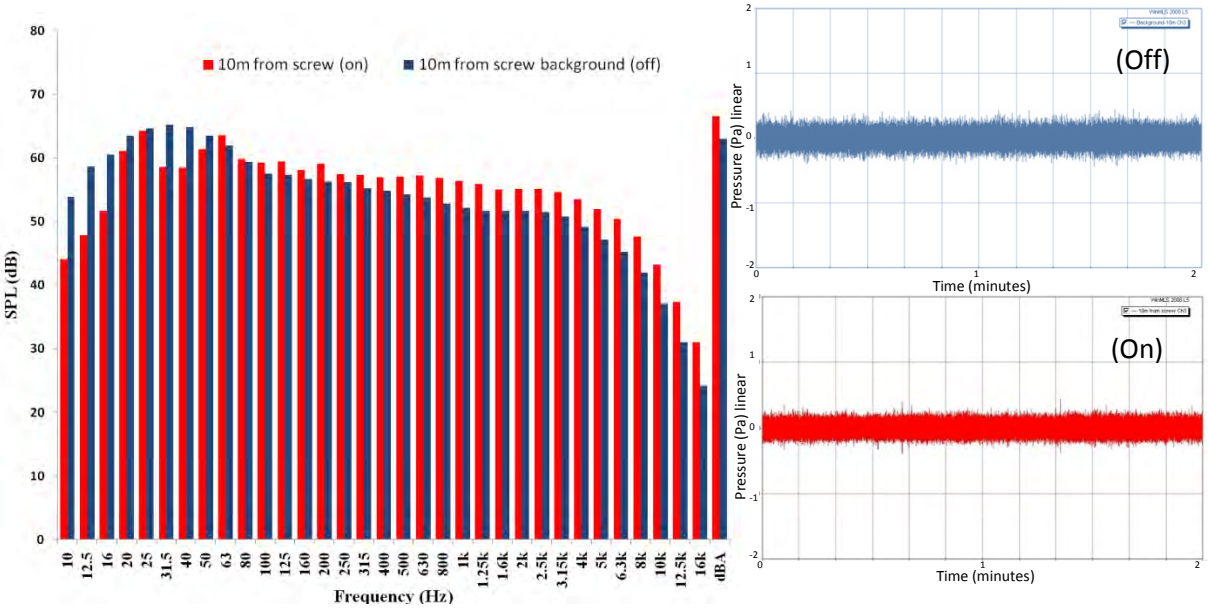

Figure 6. 1/3 octave spectrum plots of the SPL and 2 minute signal when the RAS is operational at 25kW (red) and when the RAS is off, flow is diverted over the weir (blue) at 10m from screw.

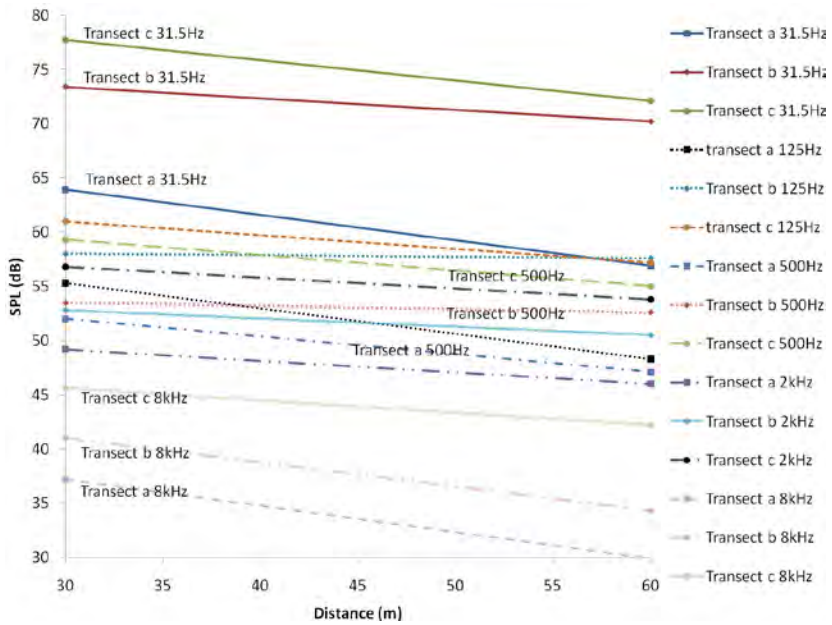
Table 1 and figure 7 show the SPL with increasing distance from the RAS along the three different transects a - c when the flow is diverted over the weir and the RAS is off. The

amplitudes are higher along transect (c) than (a) or (b), however this transect is located 10m from a stone cliff and road bridge, and it was noted on site that reflections were audible. The background data was all collected within a 40 minute period.

Table 1. Sample of background full octaves, SPL (dB) by frequency and transect distance figure 7, includes the frequencies not shown in this table.

Frequency [Hz]	SPL (dB) transect a 30 m	SPL (dB) transect b 30 m	SPL (dB) transect c 30 m	SPL (dB) transect a 60 m	SPL (dB) transect b 60 m	SPL (dB) transect c 60 m
250	51.8	55.0	61.4	44.3	53.1	55.3
1000	49.9	53.3	57.7	47.5	52.3	55.0
4000	46.1	49.7	53.6	40.7	45.5	50.5
dBA	60.3	63.6	68.1	56.5	61.5	64.6

At 30m on transect (b); there is a swash noise from water flowing over irregular rocks in the river next to the sample point. There are similar geographical features at this sample point to transect (c), which may increase the reflections in the area, including the large stone bridge, ruined walls and stone cliffs, though these cliffs are situated further away, and the ground is generally softer and grass covered between. There is an increase at 125Hz between the 30m and 60m sampling points on this axis (b). This may be related to other sound sources in the area, such as weirs present further downstream, or reflections in the area. It should also be noted that the large stone bridge near to the sampling point (*Figure 2*), is a road traffic bridge and this may explain the greater SPL low frequency results.



Along transect (a), running perpendicular to the RAS, the results taken at 30m and 60m sample points are noticeably lower in amplitude than (b) and (c) see *figure 7 and table 1*. As with the previous background plots *figures 3, 7 & 8*, the SPL of 31.5Hz is higher than that with the screw operational, see *figure 9*. *Figures 8* and *9* compare the SPL measured along transect (d) when the RAS is both on and off.

Figure 7. Example frequencies of the observed attenuation and SPL along transect a, b and c while the turbine is off. Lines between points are for demonstration purposes only and to aid pattern identification. The standard equation for attenuation of a line source with distance [11] was performed at 45m and it was found that deviation from the theoretical values is -1.6 to +2.1dB.

With a doubling of distance between 30 and 60m, in free-field conditions attenuation would be 3dB. Half the frequencies measured have higher attenuation levels than the 3dB whilst the other frequencies attenuate at a lower rate. It is thought that these differences are a function of the sampling environment as no corrections were added to the data, e.g. surface roughness differences or directivity. The variation in SPL differs depending on the frequency from

0.1dB to 9.1 dB, with an average difference between background frequencies and operational frequencies of 4.5dB at 0m, 3.3dB at 5m and 1.6dB at 10m. At 31.5Hz the SPL when the RAS is not operational is greater than when it is. These results are for a period when river flow enables the RAS to produce 25kW; further research is required to understand the generation of noise at a range of flows and electrical power outputs, and to validate the results presented.

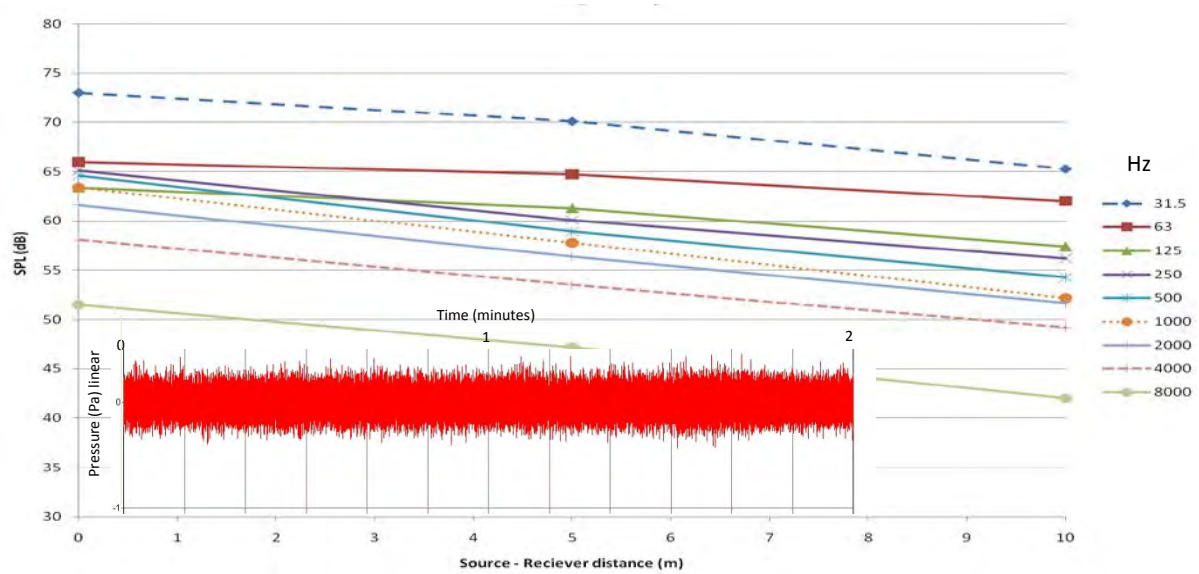


Figure 8. SPL by frequency from 0-10 whilst the turbine is off along transect a, where the insert is the 2 minute sample of the signal measured at 0m.

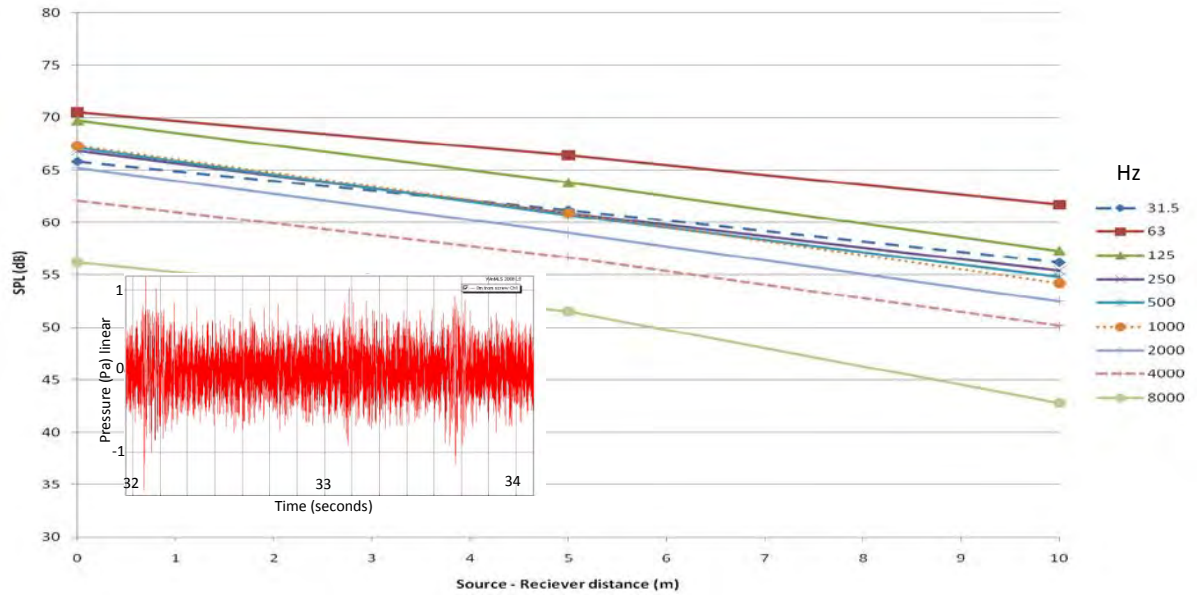

Figure 9. SPL by frequency from 0-10m whilst the turbine is switched on along transect a, where the insert is a 2 second sample of the signal measured at 10m between 32 and 34 seconds. A cyclic impulse can be seen within the signal plotted less than 2 seconds apart. This fits with the tri-blade rotational speed of the RAS which would include the blades entering/exiting the water.

4. Conclusions & Future Work

Initial results indicate that during normal operation at 25kW the screw would be barely perceptible beyond 60m, and adds just 3dB to the background environment and thus in many cases have negligible urban environmental impact running at 25kW. The weir has a significant masking effect on the RAS sound output. Further to this, the results indicate a directional aspect to the sound propagation from a RAS. However, whether this is a feature of the site or a feature of the RAS design is yet to be determined.

The RAS is not operational below 20kW, and therefore this study demonstrates the noise propagation at low flows. Future work will consider a range of flows from this increasing to the RAS design capacity of 53kW. Future work will also include a more detailed study of the RAS at New Mills with greater near field sampling and over shorter sampling periods to limit any extraneous noise sources from the results. Evaluation of other RAS sites will be carried to enable modeling and validation of the sound propagation. This will be used to assess the effect of various interventions in reducing noise nuisance from a RAS in an urban setting. Some further results will be presented at the conference.

Abstract: We have developed a new energy harvester for harnessing energy from the Kármán vortex street behind a bluff body in a water flow. It converts flow energy into electrical energy through oscillation of a piezoelectric film. Oscillation of the piezoelectric film is induced by pressure fluctuation in the Kármán vortex street. Prototypes of the energy harvester are fabricated and tested. Experimental results show that an open circuit output voltage of 0.12 V_{pp} and an instantaneous output power of 0.7 nW are generated when the pressure oscillates with an amplitude of ~0.3 kPa and a frequency of ~52 Hz. This approach has the potential of converting hydraulic energy into electricity for powering wireless devices. The low output power of the device can be improved by an optimization design procedure or by adopting a piezoelectric material with higher piezoelectric constants. An array of these devices with multiple resonant frequencies may be considered for energy harvesting from ambient flow sources.

Keywords: *Energy Harvester, Piezoelectric, Kármán vortex street*

1. Introduction

Recent development of wireless sensor networks allowing real-time industrial process monitoring, machine health monitoring, environment monitoring, healthcare applications, and traffic control demands an economical source of energy not requiring fuel or replacement of finite power stores. Considerable effort is focused on use of renewable energy coming from natural resources such as flowing water, rain, tides, wind, sunlight, geothermal heat and biomass. Renewable energy from small-scale hydro, modern biomass, wind, solar, geothermal and biofuels accounted for 2.7% of global final energy consumption in 2008 and is growing very rapidly [1].

Small hydro systems using turbines/wheels can be used to convert mechanical energy from water flow into electricity. Krähenbühl et al. [2] designed an electromagnetic harvester based on a turbine driven by water pressure drop in throttling valves and turbo expanders in plants that outputs 150 W power with a rotation speed of 490000 rpm. Their device comprises a turbine and a permanent generator. A detailed electromagnetic machine design, rotor dynamics analysis and a thermal design were required to construct their energy harvester. Holmes et al. [3] reported an electromagnetic generator integrated with a microfabricated axial-flow microturbine. The power output of the fabricated microdevice can be as high as 1.1 mW per stator when operated at a rotation speed of 30000 rpm, but the fabrication processes for their prototype involve deep reactive ion etching, multilevel electroplating, SU8 processing and laser micromachining. Herrault et al. [4] presented a rotary electromagnetic generator to harvest the mechanical energy of an air-driven turbine. The fabrication of their device requires electroforming, magnet demagnetization and laser machining. A maximum output power of 6.6 mW is attained when their device is driven at a rotation speed of 392000 rpm by an air turbine. The devices of Krähenbühl et al. [2], Holmes et al. [3] and Herrault et al. [4] require elaborate techniques for fabrication of their stator-rotor subcomponents and high rotation speeds for efficient energy harvesting. A device with simpler structure design

and ease of application may be needed to extract energy from fluid motion for microsensor and communications applications.

Installations with miniaturized pipe-line systems may provide an alterntive for harvesting small scale water flow energy. Sanchez-Sanz et al. [5] assessed the feasibility of using the unsteady forces generated by the Kármán street around a micro-prism in the laminar flow regime for energy harvesting. They presented design guidelines for their devices, but fabrication and demonstration of the proposed device are not shown in their work. Allen and Smits [6] used a piezoelectric membrane placed behind the Kármán vortex street formed behind a bluff body to harvest energy from fluid motion. They examined the response of the membrane to vortex shedding. The power output of the membrane is not presented. Taylor et al. [7] developed an eel structure of piezoelectric polymer to convert mechanical flow energy to electrical power. They have focused on characterization and optimization of the individual subsystems of the eel system with a generation and storage units in a wave tank. Design and deployment of the eel system need further investigation. Tang et al. [8] designed a flutter-mill to generate electricity by extracting energy from fluid flow. Their structure is similar to the eel systems of Allen and Smits [6] and Taylor et al. [7]. They investigate the energy transfer between the structure and the fluid flow through an analytical approach. These authors utilized the flow-induced vibrations of fluid-structure interaction system to extract energy from the surrounding fluid flow [9]. The eel structures of Allen and Smits [6], Taylor et al. [7] and Tang et al. [8] have the potential to generate power from milli-watts to many watts depending on system size and flow velocity, but a power-generating eel has not been demonstrated.

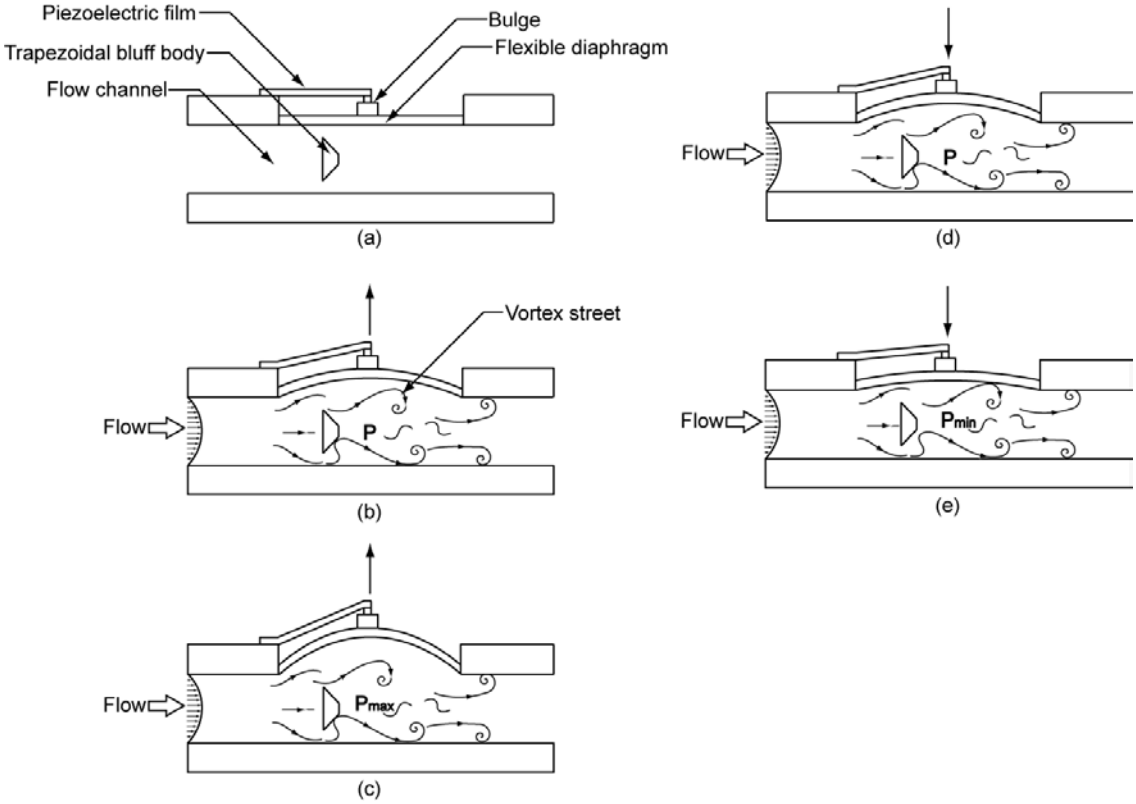

Fig. 1. Operation of a piezoelectric energy harvester.

In this report, we demonstrate a new device for energy harvesting from pressure fluctuations in the Kármán vortex street, where a piezoelectric film is placed on top of a flexible

diaphragm, which is located in the wake of a bluff body. The piezoelectric film oscillates on a flexible diaphragm due to the vortices shed from the bluff body in a water flow. As illustrated in Fig. 1(a), a flow channel with a flexible diaphragm is connected to a flow source. A piezoelectric film of a cantilever type is glued to a bulge affixed to the top surface of the flexible diaphragm. A bluff body is placed in the flow channel. Pressure in the flow channel behind the bluff body may fluctuate with the same frequency as the pressure variation caused by the Kármán vortex street. Fig. 1(b) shows that the pressure in the channel causes the diaphragm and the piezoelectric film to deflect in the upward direction. As the pressure increases to the maximum, the diaphragm reaches its highest position (Fig. 1(c)). When the pressure drops, the diaphragm and the piezoelectric film deflect downward (Fig. 1(d)). As the pressure decreases to the minimum, the diaphragm reaches its lowest position (Fig. 1(e)). Thus, by placing the energy harvester in a flow source, the oscillating movement of the diaphragm with the cantilever piezoelectric film attached to it makes the energy harvesting possible.

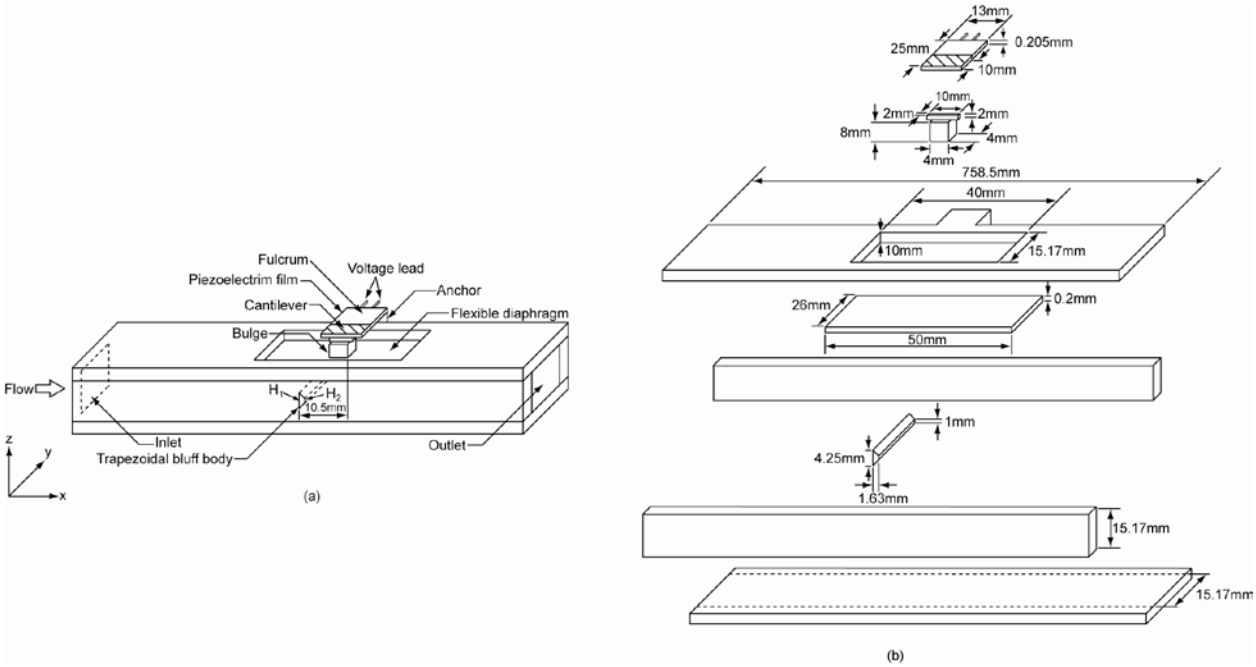

Fig. 2. (a) An assembled energy harvester. (b) Components of the energy harvester..

2. Methodology

2.1. Operational principle

A piezoelectric energy harvester considered in this investigation is shown in Fig. 2(a). Fig. 2(b) is an exploded view of the energy harvester. The dimensions of the energy harvester are indicated in Fig. 2(b). It consists of a flow channel, a bluff body, a polydimethylsiloxane (PDMS) diaphragm bonded to the channel, and a piezoelectric film attached to the PDMS diaphragm through a bulge made of acrylic blocks. Flow past a bluff body creates an unstable wake in the form of alternating vortices and induces periodic pressure variation [10]. The frequency at which the vortices are shed from the bluff body is given by the Strouhal number, St, $St = \omega \ell / U_\infty$ [11], where ω is the frequency of oscillating flow, ℓ is the characteristic length, and U_∞ is the free-stream velocity. Vortex shedding from a circular cylinder immersed in a steady flow occurs in the range $10 < Re < 10^5$, where Re is the Reynolds number, with an average Strouhal number $\omega d / 2\pi U_\infty \approx 0.2$ [12]. For a trapezoidal bluff

body, the Strouhal number is given as $S = \omega H_1 / U_\infty$ [13], where H_1 is the height of the front side of the trapezoidal cylinder. The front height H_1 and rear height H_2 of the trapezoidal cylinder are denoted in Fig. 2(a).

The piezoelectric film (LDT0-028K/L, Measurement Specialties, Inc., US) is a laminate including a polyvinylidene fluoride (PVDF) film, two silver electrode layers and a polyester (PE) layer. The PDMS flexible diaphragm has a thickness of 200 μm. The electrode layers with a thickness of 28 μm are attached to the top and bottom surfaces of the PVDF film of 24 μm. A 125 μm PE layer is laminated to the top surface of the top electrode layer. The values of d_{31} and d_{33} of the PVDF are 23 and -33 $pm \cdot V^{-1}$, respectively. The capacitance of the PVDF film is 380 $pF \cdot cm^{-2}$. The Young's modulus and Poisson's ratio of the PVDF are 3 GPa and 0.35, respectively. When used in a bending mode, the laminated piezoelectric film develops much higher voltage output when flexed than a non-laminated film. The neutral axis is in the PE layer instead of in the PVDF film so the film is strained more when flexed.

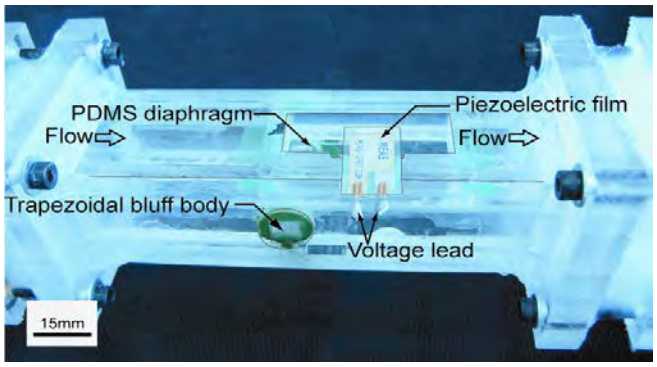

Fig. 3. Assembled energy harvester.

2.2. Fabrication and Experiments

In order to verify the effectiveness of the proposed energy harvesting device, prototypes of the energy harvester were fabricated. Fig. 3 is a photo of an assembled energy harvester. Its dimensions are indicated in Fig. 2(b). Fig. 4 is a photo of the experimental apparatus for testing of the fabricated device. The energy harvester is placed on an optical table for vibration isolation. From the bottom of a storage tank, an inlet pipe is run down to the inlet of the energy harvester. The water level in the storage tank is kept constant for a steady water flow at the inlet of the flow channel. Using gravity, water is forced into the inlet of the energy harvester. Tap water is pumped into the storage tank through a pump located in a recycle tank. An outlet pipe extending between the outlet of the energy harvester and the recycle tank provides a continuous supply of water. The oscillating deflection of the piezoelectric film is measured by a fiberoptic displacement sensor (MTI-2000, MTI Instruments Inc., US). The generated voltage of the piezoelectric film is recorded and analyzed by a data acquisition unit (PCI-5114, National Instruments Co., US). The pressure in the pressure chamber is measured with a subminiature pressure sensor (PS-05KC, Kyowa Electronic Instruments Co. Ltd., Japan) embedded in the bottom plate of the flow channel. The pressure sensor is connected to a data acquisition unit (DBU-120A, Kyowa Electronic Instruments Co. Ltd., Japan).

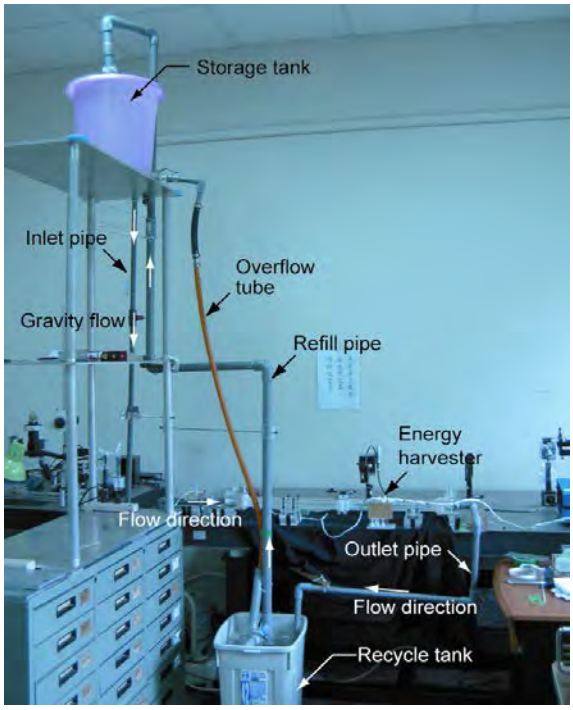

Fig. 4. A photo of the experimental setup.

3. Results

The experimental results are shown in Fig. 5. Fig. 5(a) shows the pressure history in the flow channel behind the bluff body, where the pressure oscillates with an amplitude of nearly 0.3 kPa and a frequency of 52 Hz. The measured deflection history of the free end of the piezoelectric film is shown in Fig. 5(b). The film oscillates with an amplitude of about 20 μm. The measured open circuit voltage generated by the piezoelectric film is shown in Fig. 5(c). The output peak-to-peak voltage is nearly 120 $\mathrm{mV_{pp}}$. The results shown in Figs. 5(a-c) are typical of those obtained over 20 seconds of measurements. Figs. 5(d-f) are the power spectral density corresponding to Figs. 5(a-c), respectively, but are based on all 20 seconds of measurements. Fast Fourier transform is used to compute the power spectral density. It can be seen from Figs. 5(d-f) that there is one obvious peak value of 52 Hz, caused by the pressure fluctuation in the flow channel. The low-frequency noise, below 20 Hz, observed in Figs. 5(d-f) can be attributed to the fact that flows in the experimental setup are always contaminated by ambient noise sources, and the geometry of the bluff body and the walls of the flow channel are not perfectly symmetric and smooth.

The average free-stream velocity U_∞ measured in the experiments is 1.083 m/sec. The Reynolds number Re of the flow can be determined by $\mathrm{Re} = \rho U_\infty D_h / \mu$, where μ is the dynamic viscosity of the water, 1.002×10^{-3} Pa·sec, and D_h is the hydraulic diameter, which is 15.17 mm for the flow channel considered. The calculated Re is 1.64×10^4, which is turbulent. The frequency of the pressure fluctuation is nearly 52 Hz (Fig. 5(d)), which is the rate at which the vortices are shed from the bluff body. Using the equation $\mathrm{St} = \omega H_1 / U_\infty$, the corresponding value of St is estimated as 0.204. White [12] reported an average St about 0.21 for the shedding from a circular cylinder immersed in a steady flow occurring in the range $10^2 < \mathrm{Re} < 10^3$. The estimated value of St for a trapezoidal bluff body of the experiments is reasonable compared with the value 0.21 reported by White [12]. The experimental values of

St for trapezoidal cylinders with the height ratio, H_2/H_1, ranging from 0.3 to 1.0 and the Re values of 100, 150, and 200, have a range from approximately 0.135 to approximately 0.155 [13]. Based on the work of Norberg [14] for a circular cylinder, the variations in St are within the limit 0.1 9 2 0.0 1 for the Re ranging from 250 t o 3×10^5. Ho and Huerre [15] commented that the values of St changes from 0.016 for a laminar flow to 0.022-0.024 for turbulent flow. Based on the reported experimental data [12-15], the estimated value of St, 0.204, based on the experiments carried out in this investigation could be acceptable.

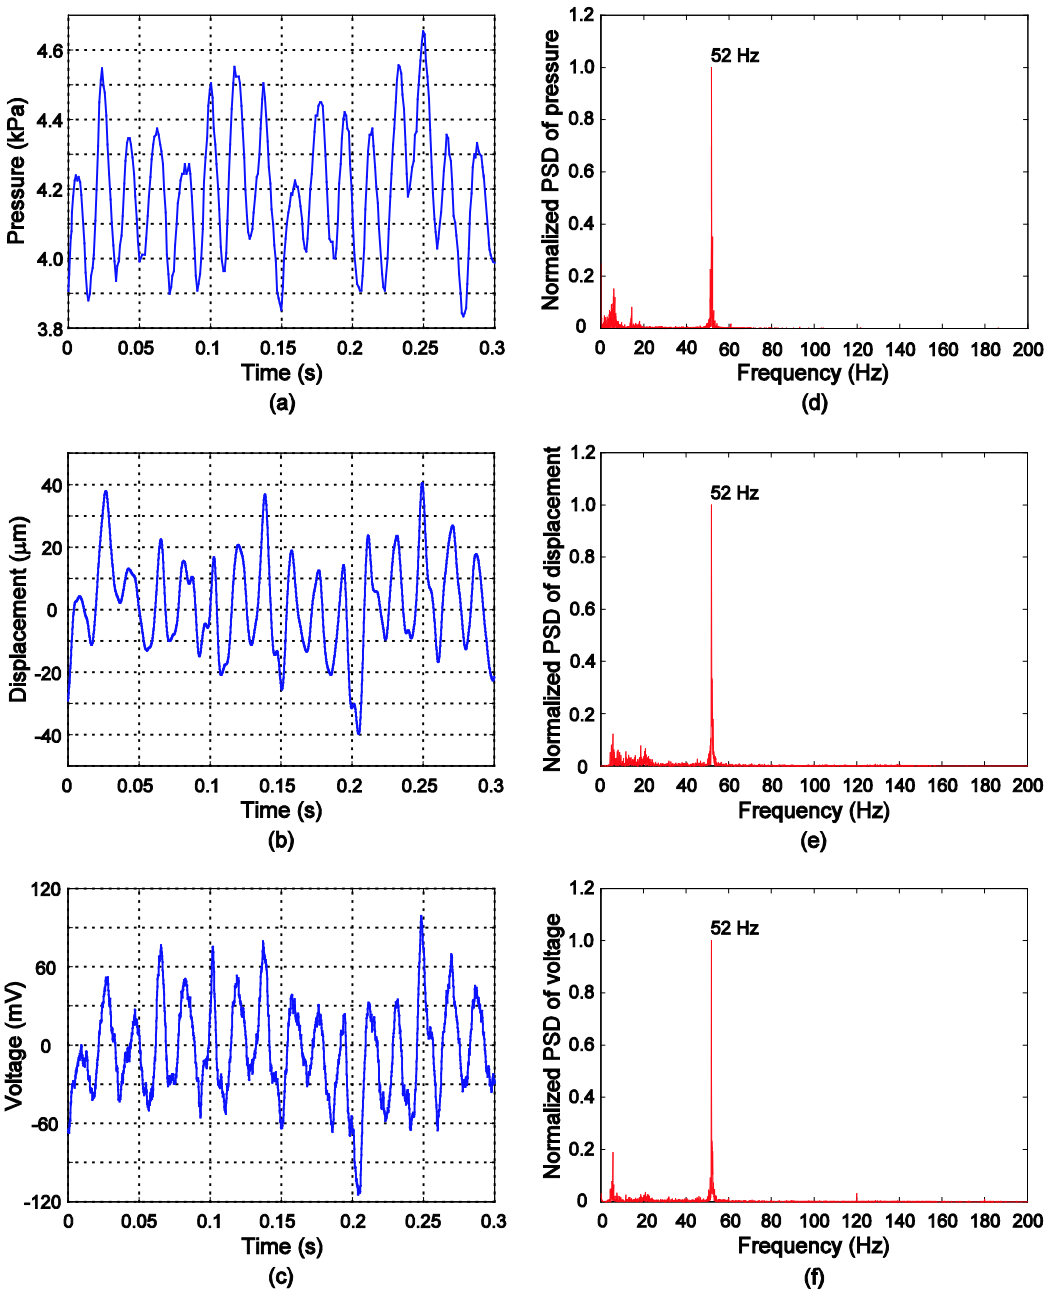

Fig. 5. Experimental results. (a) Pressure variation in the pressure chamber. (b) Deflection of the free end of the cantilever piezoelectric film. (c) Output voltage of the piezoelectric film. (d-f) Power spectral density corresponding to (a-c).

A matched load can be connected to the device to evaluate the power output of the device. The internal electrical resistance of the device is measured by a LCR meter (WK 4235,

Wayne Kerr Electronics, Ltd., UK). The instantaneous power can be expressed as $P = (\sqrt{2}\widetilde{V})^2 / R$, where R is the resistance value of the matched load and $\widetilde{V}$ is the root-mean-square value of the voltage drop across the matched load. By connecting the matched load of 655 kΩ to the device and detecting the voltage drop across the matched load, 14.89 mV_{rms}, the instantaneous power is determined as 0.7 nW.

4. Discussions

The output power of the device is relatively low, given the structure design of the flow channel, the bluff body and the cantilever piezoelectric film. In order to obtain a higher output power of the piezoelectric energy harvester, the dimensions and structure of the device can be optimized, and a piezoelectric material with higher piezoelectric constants can be adopted. In this investigation, the device is not operated at its resonance frequency. Most energy harvesting device based on piezoelectric effects have focused on single-frequency ambient energy, i.e. resonance-based energy harvesting [16]. The resonance frequency of the energy harvesting device can be tailored to the shedding frequency of the Kármán vortex street in order to increase the output power of the device. For random and broadband ambient flow sources, such a device may not be robust. A structure with multiple resonant frequencies may also be considered for energy harvesting from random vibrations with multiple resonant peaks, for example a segmented composite beam with embedded piezoelectric layers [17].

In order to generate the pressure fluctuation of the Kármán vortex street in the channel, a flow source assisted by gravity is used to force tap water into the flow channel in the laboratory environment. Energy can be harvested from pipe flows, blood flow in arteries [18,19], or air flow in tire cavities. The proposed device can be deployed on slopes to provide electricity for wireless sensor networks for detection of landslides. Landslides are usually preceded by heavy rainfalls, and the device can harvest the energy of the water flow along slopes due to rainfall. Energy harvesting from regular, periodic shedding can be integrated into tire pressure monitoring systems to harness the energy of air flow in tire cavities, or self-powering implantable and wireless devices in human bodies to convert the hydraulic energy of flow of body fluid.

Abstract: The large scale model of a Free Stream Energy Converter (FSEC) is built, and can be installed in protected as well as in tidal areas. This is one of the determined objectives of the EU-Project HYLOW, funded by the FP7. First field tests with rope winch and towing boat were done; further, in a protected area near Rostock, and the installation in the River Ems under tidal conditions and ship traffic, are planned for the first half of 2011. Besides, the permanent design control for the FSEC is as necessary as the monitoring of the behaviour of the model positioned in all the sites. If design changes or modifications are necessary, these can be done directly on site, respectively in the Steel Construction Company nearby. Whether it is suited for practice, however, is still dependent on other factors. The investigations are primarily limited on technical and ecological level. It is now necessary to look at the cost-sided development, too. Starting with considerations for the financing and economic efficiencies about expressive cost-benefit analyses up to design and material costs, the European need should be determined in hydropower for low potentials. Realization of hydropower plans takes a long period.

Keywords: *Low head differences, Free Stream Energy Converter, EU-Project, Hylow, Cost-benefit analysis.*

1. Introduction

One reason for the Hylow project is the rising demand for energy. Another one is the necessity to implement renewable energies, because of undeniable importance in view of declining natural resources. Small hydropower is a possible substitute for fossil fuels which are already limited. The European committee has fixed specific targets with a view to initiating change towards renewable energy. In order to achieve these objectives, energy generating systems, which were economically unattractive, are given greater priority.
The Hylow project focuses on the development of a mobile energy converter for low head differences – a topic which is usually neglected, because of missing significant results.

2. Motivation for hydropower

Compared to wind power and photovoltaic, small hydropower is often undervalued - at least in the public perception. In theory the worldwide demand for energy could be covered by hydropower. But it will not be economically practical, because of the uneven distribution of water resources on world territory.

2.1. Strong arguments

The power source “hydropower” offers many advantages.
Minimal emissions occur just in the installation period and in the first running period, when converters have to be stabled. A running energy converter does not need a great number of additional materials or energy. In sum there are low CO_2 emissions during operating time.

Hydropower requires no primary energy – therewith the respective countries relieve their own energy bills as well as they increase the security of energy supply. Furthermore, hydropower depends neither on the natural rhythm of the sun nor on the strength of the wind. This allows a permanent and continuous electricity generation.

There is a significant potential for hydropower in the EU and worldwide. However, the availability of use is limited by specific features of energy supply, such as localization, use of sites, power supply and current collection.

2.2. Background of Hylow

Small hydropower plants are close to nature; their design is often environmentally compatible. This applies to Hylow also. The floating Large Scale Model (LSM) of the FSEC is nearly 7,800 mm in length, 2,400 mm in width, and 3,500 mm in height. The wheel diameter is 3,200 mm and 1,100 mm in width (see Figure 1).

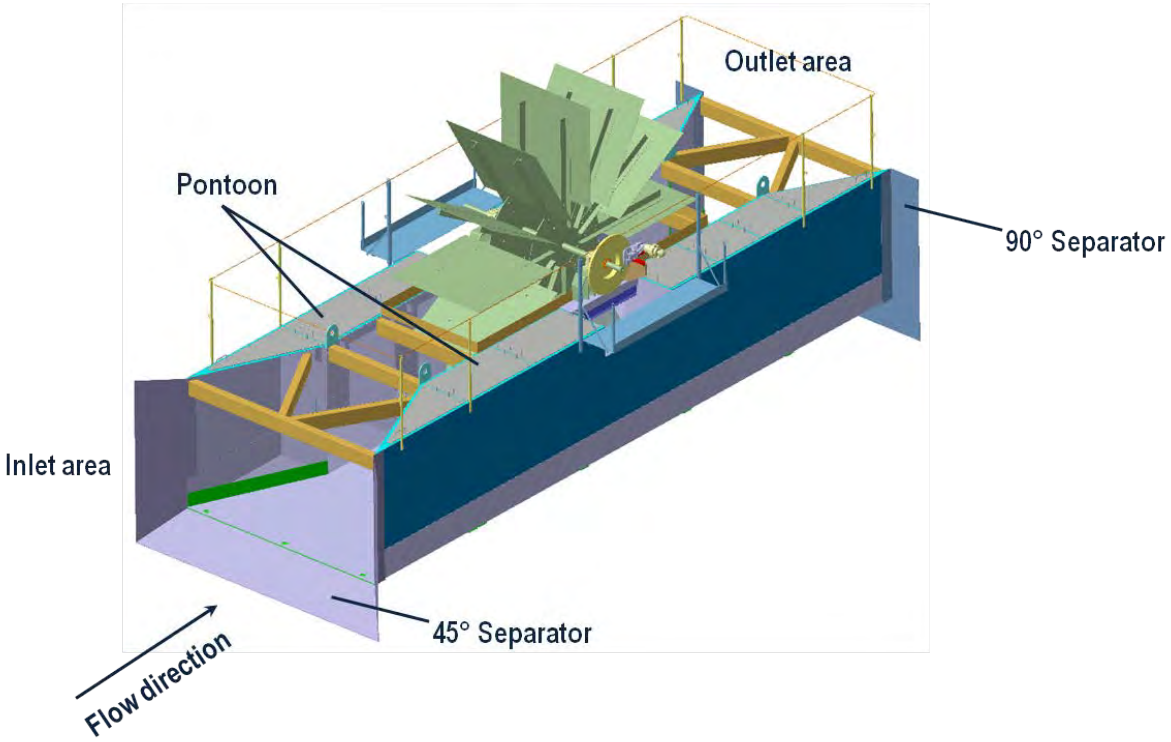

Fig. 1. The CAD model of the LSM, separators included.

The LSM will be placed in running waters with flow velocities of up to 1.5 m/s. The model is dimensioned for exceptional situations, in which the velocity rises, such as floodwaters or strong winds. To realize test runs with the LSM in protected areas no lubricants or other persistent products will be used. The power take-off is envisaged as a friction-type brake, and works without any liquids, so that even in the average case the environment takes no damage. For later applications and for deployment in developing countries to energy production, the brake system will be substituted with a generator solution which is adapted in ecological respects. [1]

3. Product development

Essential for product development activities, besides the idea, are calculations. These start with the power output to be expected. In addition, all forces, which appear, are to be taken into consideration.

3.1. Free Stream Energy Converter

The first geometry of the pontoon was given by calculations and basis tests done with simplified and down scaled configurations. The outline geometry consists of two hulls which

are connected via a base. The hulls in the inlet area are v-shaped, so that the channel will get narrowed, and the flow velocity accelerates. This procedure corresponds to the Venturi principle. [1]

Fig. 2. The LSM on the first deployment – the naval base in Rostock.

During the whole project three field tests with the LSM at different locations (with expected flow velocities between 0.4 and 1.5 m/s) are planned. The first deployment site was envisaged for towing tests; these tests have been successfully completed in autumn, 2010 (see Figure 2). The second and third test sites are in a protected area near Rostock, and in the River Ems in Northern Germany.

Initial towing tests were meant to demonstrate the model behaviour during operational conditions. In addition, the floating behaviour of the model with different velocities and geometries (additional separators) should be tested. The LSM delivered an electric power output up to 500 W.

The towing tests show that something has to be changed concerning the geometry of the LSM. The best results in the first deployment site were achieved with separators at both ends of the LSM. In the inlet area works the separator as a scoop with an angle of 45°, and in the outlet it has 90°. In order to limit the costs several models have to be analysed with the computational fluid dynamics (CFD) software FLOW-3D [3]. See first results in Figure 3.

The FLOW-3D tests are useful for the fine adjustment of length, arrangement and angular size of the separators. Moreover, the trim angle of the FSEC can be adjusted according to the waterline (horizontal alignment in the flow). Figure 3 shows three situations in FLOW-3D with different arrangements of the separators. The set velocity is determined with 1 m/s, and it changes as expected in several areas of the flow pattern – in narrowed parts of the channel are higher velocities than in the widened areas. The simulations are ongoing; final results are expected in spring, 2011.

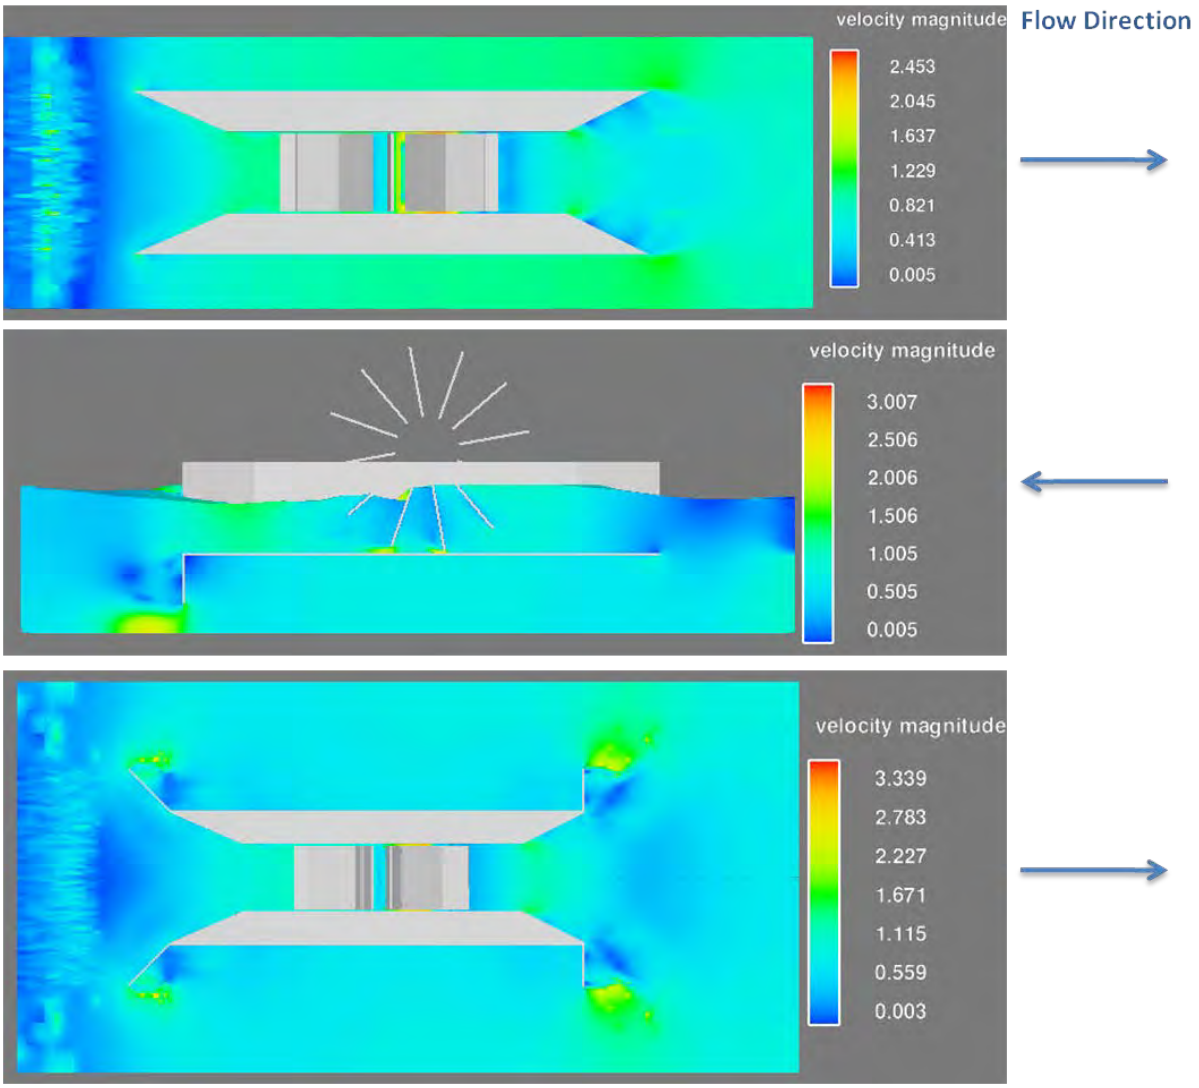

Fig. 3. Geometry tests with FLOW-3D.

3.2. Cost report of the FSEC prototype

To check the efficiency of the FSEC the annual costs are compared with the benefit. The benefit will be calculated from the sale of electricity to the energy companies. Thus, the investment can determine the annual profit, as the difference between the yields and costs. For the considerations, the average values of all costs and yields are used.

The total costs of the energy converter arise from different cost types. A calculation basis of these are the given production costs of the prototype which consist as follows (table 1):

Table 1. Production costs for prototype.

Cost type	**Total** [€]
Personnel costs	30,491.00
Material, standard parts & consumables	24,750.00
Indirect costs (20 % of direct costs)	11,048.20
Manufacturing costs	66,289.20

In these costs no costs for research and development included. Because of the prototype, no values of experience have still integrated into the production procedure. Moreover, detailed

values of wear behaviour are neglected, because there are no empirical values for this special case exist.

4. An FSEC in Europe – where conditions are most favorable

The benefit of the FSEC consists in the production of electrical energy using the potential of flowing water. For the feed in existing electrical grids there are fixed feed-in tariffs which mostly have a limited duration. In addition, a purchase obligation by the energy groups exists in several European countries.

4.1. Feed-in tariffs

Table 2 shows height and duration of the feed-in tariffs for selected European countries. To calculate the annual yield the payment must be multiplied by the energy generated in the year. It is assumed that the FSEC works continually without interruption 8,760 hours per year. The electrical energy is the product of the expected average electric power (assumption = 3 kW) and the annual power consumption in hours.

In case of permanent consumption the electrical energy for 3 kW power output will be 26,280 kWh. The resulting annual yields are given in the right column of table 2 [3]. The countries are sorted according to the amount of feed-in tariffs, starting with the highest.

Table 2. Feed-in tariffs and their time limits in Europe.

European country	**Amount of feed-in tariff**	**Duration of feed-in tariff***	**Annual yield**
	[€/kWh]	[years]	[€]
Great Britain	0.23	-	6044.40
Italy	0.22	15	5781.60
Germany	0.1267	20	3329.68
Netherlands	0.125	15	3285.00
Latvia	0.11	10	2890.80
Slovenia	0.105	15	2759.40
Czechia	0.081	30	2128.68
Denmark	0.0803	10	2110.28
Luxembourg	0.079	15	2076.12
Spain	0.077	25	2023.56
Portugal	0.075	20	1971.00
Ireland	0.072	15	1892.16
Greece	0.07	10	1839.60
Lithuania	0.07	-	1839.60
Slovakia	0.066	15	1734.48
France	0.06	20	1576.80
Estonia	0.051	12	1340.28
Belgium	0.05	-	1314.00
Bulgaria	0.045	15	1182.60
Austria	0.0378	13	993.38
Hungary	0.029	payoff time	762.12

* Some values are not known; duration is unlimited.

The European countries of the first rows have a good chance to invest in the small hydropower market. Therefore the use of the energy converter is determined as a value size. Now as a comparison the costs are considered.

4.2. Overview to cost covering

Thus, the production costs fall with renewed individual manufacture on 70%, because the development is concluded and is possible for a shorter manufacturing time by experience-guided, structured work.

With a small batch production of five energy converters, a cost reduction on 60% (according to the manufacturer) is to be achieved. With these estimates the manufacturing costs change as follows (table 3):

Table 3. Types of production series.

Manufacturing costs for	**Price per unit** [€]
Prototype	66,289.20
Individual production	46,402.44
Batch production (5 pieces)	39,773.52

It is assumed that steady wear behaviour during utilisation exists. The amount of annual depreciation may be calculated according to the linear method. Thereby in every period the same depreciations are created. If the lifespan is 20 years, than the following results can be represented (table 4):

Table 4. Cost structure for all considered production series.

	Prototype **100%**	**Individual production** **70%**	**Small batch production** **60%**
	[€]	[€]	[€]
Personnel costs	30,491.00		
Direct costs	24,750.00		
Indirect costs	11,048.20		
Total manufacturing costs*	***66,289.20***	***46,402.44***	***39,773.52***
Imputed depreciations**	3,314.46	2,320,12	1,988.68
Imputed interests***	1,756.66	1,229.66	1,054.00
Imputed costs of capital	***5,071.12***	***3,549.78***	***3,042.68***
Leasing costs	200.00	200.00	200.00
Maintenance costs	253.56	177.49	152.13
Insurance, taxes, administration	530.31	371.22	318.19
Annual costs	***6,054.99***	***4,298.49***	***3,713.00***

* Total manufacturing costs = A_0
** A_0 / lifespan
*** A_0 / 2 * 5.3% (discount rate of German Central Bank) [4]

The imputed costs of capital are divided into imputed depreciation and imputed interests. The imputed depreciations are the costs for losses in value. Whereas the imputed interests are the interests due on the amount of money lent over the maturity of the operation period.
The amount of the leasing costs depends on the plant size and the location. It varies from country to country, therefore it was assumed that the leasing costs are 200 € per year (average value in Germany). The maintenance costs are 5% of the imputed costs of the capital. The costs for insurance, taxes and administration are 0.8% of the total manufacturing costs.

Concluding, the following table 5 gives an overview to the first five European countries and the profit per annum (annual yield minus costs).

Table 5. Profit per annum for all considered production series.

European country	**Prototype 100%**	**Individual production**	**Small batch production**
	[€]	[€]	[€]
Great Britain	-10.59	1,745.91	2,331.40
Italy	-273.39	1,483.11	2,068.60
Germany	-2,725.31	-968.81	-383.32
Netherlands	-2,769.99	-1,013.49	-428.00
Latvia	-3,164.19	-1,407.69	-822.20

The profit table clearly shows that the prototype is not profitable in the next 20 years. With the other production forms the FSEC under described conditions could be a lucrative business.

5. Summary

The FSEC is able to convert the kinetic energy of flowing waters into electricity. By means of low head differences and by applications of separators power outputs of at least 3 kW are expected. To attain this objective a lot of additional research is needed. Initial results of the ongoing FLOW-3D trials show how the design of the FSEC might essentially change.

The presented cost report demonstrates that only in a few European countries the balance between annual costs and benefit can be achieved. The most important criterion is how long the payback period is. The other item to note is that all the assumptions are defined as cases with ideal conditions. It is still uncertain how long an FSEC in this form will work.

In the manufacture of the FSEC prototype, personnel and material costs is the biggest cost block by far. As a result of batch production and growing experience the personnel costs will be reduced. It is to think about moving the production of further plants in countries which have lower production costs to cover the risk of rising material costs, because of the development in the steel market. It is expected that the steel price and in this connection the material costs for the converter will increase. The saving in materials has direct impacts on the operating earnings, especially when using alternative materials such as wood or glass fibre plastics (GRP) [2].

Abstract: The mapping of the small hydropower (SHP) resource over a given territory is indispensable to identify suitable sites for the development of SHP renewable energy projects. In this study, a straightforward method to map the SHP potential over a large territory is presented. The methodology uses a synthetic hydro network (SHN) created from digital elevation models (DEM) to ensure precise hydro head estimations. From the SHN, hydro heads are calculated by subtracting the minimum from the maximum elevation of synthetic stream segments. Subsequently, stream segments with low hydro heads over a specified maximum distance are removed. Finally, the method uses regional regression models to estimate the annual baseflow for all drainage areas in the study area. The technical SHP potential can then be estimated as a function of the hydro head and maximum penstock length. An application of the method is made to the province of New Brunswick, Canada, where SHP maps have been developed to promote the development of the SHP energy sector in the province. In terms of the SHP opportunity, it is shown that the province of New Brunswick (71,450 km^2) has a good SHP resource. Using a representative hydro head (10 m) and penstock length (3,000 m) for the region, 696 potential sites have been identified over the territory. Results show that the technical SHP potential for New Brunswick is 368 MW for the conventional hydroelectric reservoir SHP configuration.

Keywords: *Small hydropower (SHP), Resource assessment, Hydroelectric power potential, Mapping*

1. Introduction

The definition of small hydropower (SHP) varies according to jurisdictions; in some instances, hydroelectric generating stations having installed capacities of up to 15 MW are generally characterized as SHP [1], while in Canada, hydroelectric generating facilities with installed capacities of up to 50 MW are considered as SHP [2]. Similarly to other renewable energy sources, such as wind power, the mapping of the SHP resource over a given territory is indispensable to identify suitable sites for the development of SHP renewable energy projects.

Large scale SHP assessments for pre-feasibility studies have been done in the United States [3], where data from hydrological regions were used to estimate the annual average streamflow for ungauged drainage areas; the estimated annual average streamflow was then used in conjunction with digital elevation models (DEM) to determine the hydropower potential for sites situated in ungauged natural streams in the corresponding regions. In Canada, even though the province of British Columbia is the only province to have developed an official map of the SHP resource [4], many Canadian SHP sites have been mapped in the International Small-Hydro Atlas [5]. However, the latter was developed with information from ref. [6-10] which are generally based on a combination of historical data and observations from field research; modern mapping techniques have only been implemented in a few of these studies.

In this paper, a methodology for the large scale assessment of small hydroelectric potential is presented along with an application to the province of New Brunswick, Canada. In the first instance, a method is described to find the available hydro head on the hydrographic network of a study area. Secondly, the annual streamflow is calculated, as a function of the hydro head and maximum penstock length, for each available hydro head sites. The technical

hydropower potential is then calculated and the study results are presented in the form of a SHP map.

2. Hydropower Potential Modeling

At a given site, the hydropower potential, P, can be calculated as

$$P = \rho Q g h \eta \quad (1)$$

where ρ is the density of water (kg/m^3), Q is the volumetric fluid flow rate (m^3/s), g is the gravity constant (9.81 m/s^2), h is the height (m) of the drop (gross hydro head), and η is the efficiency coefficient. In this study, the density of water is assumed constant at 1,000 kg/m^3, the efficiency coefficient is set to 0.8 while the hydro head is defined as the height difference between the intake and the generating station. Thus, with these assumptions, only two remaining parameters, Q and h, are needed to determine the hydropower potential for any site in a given study area. A third indirect parameter, the penstock length, can also be used in the determination of the gross hydro head.

2.1. Hydro head modeling

Assuming that a drainage area generates enough streamflow to be considered as a potential site, the first phase of large scale SHP mapping is to locate every potential hydro head on all stream segments of the hydrographic network. To this end, a synthetic hydro network (SHN) using DEM is created to ensure relatively precise hydro head estimations. This is done because spatial entities in the National Hydro Network (NHN) are based on existing data of different agencies [11] and do not perfectly match with the DEM. Since the SHN perfectly matches the DEM, the interoperability between information layers is assured. GIS software tools such as the TauDem tools [12], along with algorithms based on the previous works [13-15] are used to create the SHN from the DEM. The SHN is then validated with the NHN and all stream segments present in the SHN that does not correspond to a NHN stream segment are excluded. From the SHN, hydro heads are calculated by subtracting the minimum from the maximum elevation of the synthetic stream segment. Subsequently, because the penstock length represents an important capital cost of the total civil work costs for SHP projects, a limit is imposed on the Euclidian distance between the highest and lowest node of a SHN stream segment, which is used to represent the penstock length. In this work, the maximum penstock length is established at 3,000 m and all stream segments up to the maximum penstock length having hydro heads of less than 10 m are removed from the model, due to the altitudinal precision of the DEM (± 5 m, 90 % of the time).

2.2. Streamflow modeling

A regional regression model based on the work of Vogel et al. [16] is used to estimate the annual streamflow for all drainage areas in the study area, namely:

$$Q = e^{C_0} X_1^{C_1} X_2^{C_2} \ldots X_n^{C_n} e^{\varepsilon} \quad (2)$$

where Q is the observed annual streamflow or baseflow in a gauged basin (m^3/s), X_i are the various drainage area characteristics (climatic and physical attributes such as average annual temperature, average annual precipitation, elevation and drainage area), C_i are the ordinary least square regression coefficients and ε is the residual of the model.

In order to evaluate the efficiency of the regional regression model between the estimation results and the observation data, a goodness of fit statistical model, known as the Nash and Sutcliff efficiency index [17], E, is used and is given by:

$$E = 1 - \left[\sum_{t=1}^{T} \left(Q_0^t - Q_m^t \right)^2 / \sum_{t=1}^{T} \left(Q_0^t - \overline{Q_0} \right)^2 \right] \quad (3)$$

where Q_o is the observed streamflow at a given time t and Q_m the modeled streamflow. The Nash and Sutcliff efficiency index ranges from -∞ to 1, where 1 represents a perfect match between the model results and the observed data.

2.3. A case study: Province of New Brunswick, Canada

As an application of the methodology proposed, and in order to promote the development of the small hydropower energy sector in the province, the large scale SHP assessment methodology for the conventional hydroelectric reservoir SHP configurations is applied to the province of New Brunswick (NB), Canada. The province of New Brunswick, one of the smallest of the Canadian provinces, both in size (71,450 km^2) and population (748,319), is part of the Maritime provinces on the eastern coast of Canada. The topography of New Brunswick consists in three major geographic regions. The north-west region is characterized by the Appalachian Mountains, which are dominated by Mount Carleton (820 m above sea level). The center of the province is composed of small rounded hills delineated by river valleys. Finally, the southern part of New Brunswick is composed of small hills sloping down to the Bay of Fundy, with the exception of the south-eastern part of the province which is composed of the Caledonia Highlands. In terms of climate, the province of New Brunswick is located within the Atlantic Ecozone, which is characterized by a continental climate due to eastward moving air masses. Although the moist climate provides an annual runoff varying from 600 to 1,000 mm, the annual runoff is more important in the southern region of the province, near the Bay of Fundy, due to higher precipitation events. The province's hydrographic network is composed of three major rivers: the St. John River, which drains the western part of New Brunswick, takes its source in the state of Maine, U.S.A. and discharges into the Bay of Fundy; the Restigouche River, which discharges into the Baie des Chaleurs, drains the northern part of New Brunswick; finally, the Miramichi River, which drains the eastern part of New Brunswick, discharges into the Gulf of Saint Lawrence.

2.3.1. Hydro head modeling input data

The DEM's used to generate the SHN are retrieved from the Canadian Digital Elevation Data (CDED) [11]. The raster dataset, at a 1:50,000 scale, has a minimum cell resolution of 0.75 arc seconds, which represents approximately 32 m^2 for the province of New Brunswick. The altitudinal precision of the dataset is ±5 m, 90% of the time. Furthermore, because some watershed areas are contiguous to the state of Maine, DEM covering corresponding sections of the state are also used. The dataset used to cover the corresponding watersheds are taken from the National Elevation Dataset (NED) 1 Arc Second of the United States Geological Survey (USGS) [18]. The NED dataset has a resolution of approximately 30 m^2 and is resized to match the CDED resolution. Finally, due to computing limitations, the DEM for the entire region is divided into 9 sub-regions, as shown in Fig. 1. These sub-regions are defined by using aggregates of sub-sub-drainage areas as delimited by the Water Survey of Canada (WSC) dataset [19], thus maintaining the topology of the SHN within each sub-region.

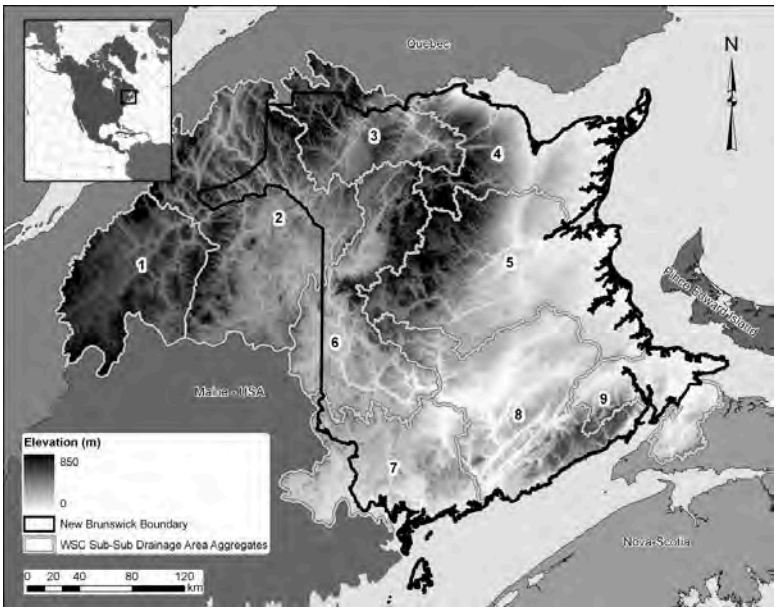

Fig. 1. Study area; sub-regions used for the extraction of the DEM.

2.3.2. Streamflow modeling input data

The climatic attributes such as average annual temperature and average annual precipitation used in several regional regression models tested in this study are taken from ref. [20-21]. In terms of the physical attributes used in the regional regression models, the majority of them, i.e. average slope, average elevation, elevation range, drainage area and eccentricity of the drainage area, are calculated from the DEM.

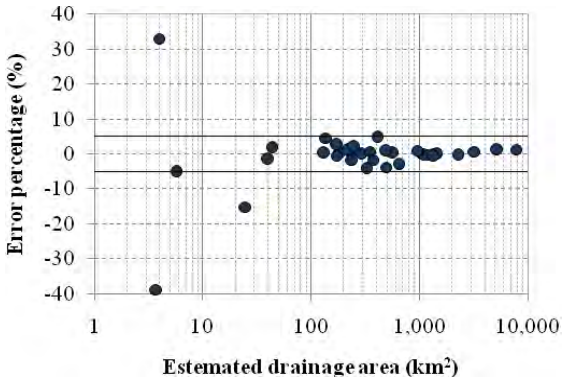

Fig. 2. Relative error between reference basin drainage areas and DEM-based basin drainage area estimation.

Previous research work in regional regression models has shown that the basin drainage areas provide good correlations in such models [16]. As is shown in Fig. 2, by comparing the DEM-based drainage area results for basins having hydrometric stations measuring natural flow to those of the Water Survey Canada as reference, it can be seen that the relative error decreases as the drainage area increases. In this work, a lower limit of 50 km^2 was imposed on drainage basins, such that hydro head having drainage areas with less than the lower limit where not considered. Finally, streamflow data from hydrometric stations [22], located across New Brunswick and having at least 30 years of continuous data, while being situated in basins with drainage areas larger than 50 km^2, are used in the various regional regression models tested.

3. Results

3.1. Hydro head modeling results

Results from the hydro head modeling showed that a total of 696 hydro heads in the province of New Brunswick satisfied the modeling constraints. In general, as in the case of other research in similar topography [23], because the topography is more variable in the upper part of a watershed area, stream segments with high hydro heads were generally located in the upper parts of a watershed area, while sites located in lower parts of a watershed area generally had lower hydro heads. Fig. 3 shows the distributions of hydro head sites by their characteristics.

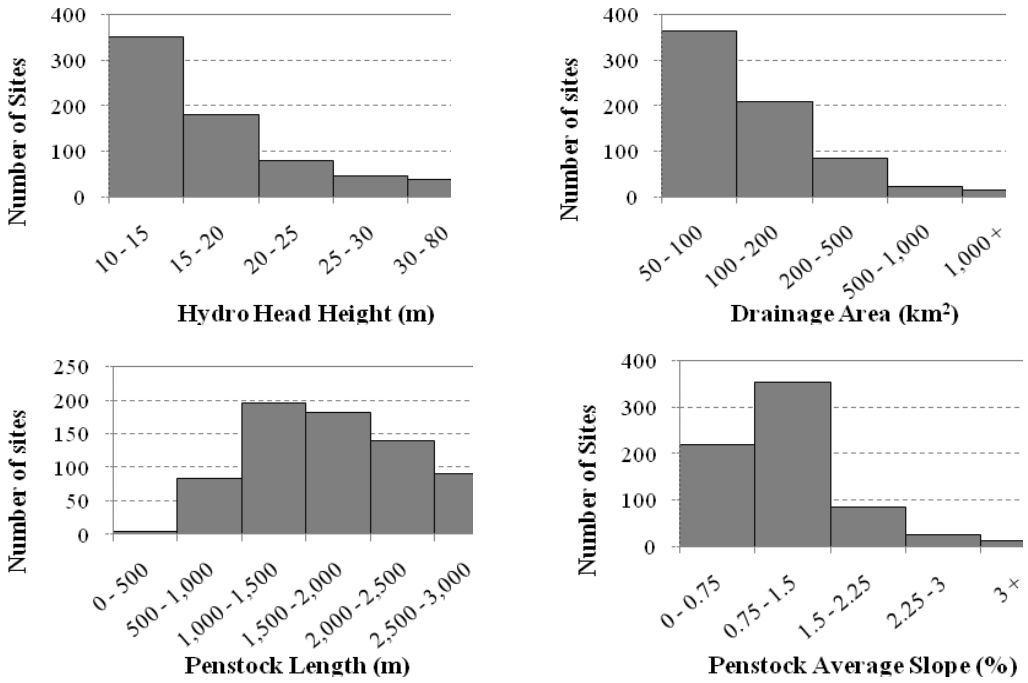

Fig. 3. Distribution of the hydro head sites.

3.2. Streamflow modeling results

In order to estimate the average annual streamflow for all basins in the study region, multiple regional regression models have been attempted in this work; the regional regression model having both the lowest average relative error (6.5%) and the highest Nash and Sutcliffe efficiency index (0.993) was chosen:

$$Q_m = e^{-16.552} A^{0.977} P^{1.733} D^{0.133} \quad (4)$$

where Q_m is the modeled streamflow (m^3/s), A is the drainage area (km^2), P is the average annual precipitation (mm) and D is the average elevation (m) of the drainage area.

3.3. Mapping results

While the methodology described in this paper can be used to estimate the SHP resource potential for both conventional hydroelectric reservoir and run-of-river SHP configurations, only results for the conventional hydroelectric reservoir SHP configuration are presented. Fig. 4 shows the mapping results of the SHP resource potential, for the conventional hydroelectric reservoir SHP configuration, in the province of New Brunswick. For this SHP configuration, the technical SHP potential for New Brunswick is 368 MW. The sites range in

SHP potential from 92 kW to 16.1 MW; the average potential for the 696 sites is 528 kW per site, while the median power potential is 303 kW.

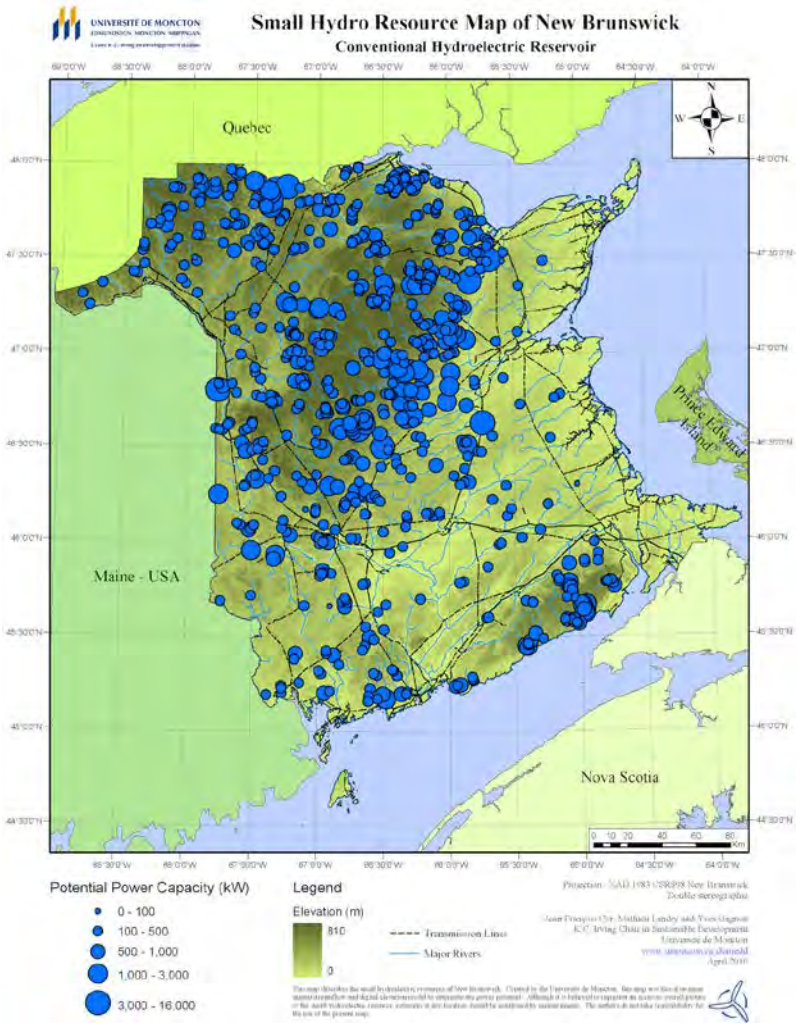

Fig. 4. SHP resource map of New Brunswick for conventional hydroelectric reservoirs.

4. Discussion and Conclusion

In this work, a straightforward method to map the small hydropower (SHP) potential over a large territory was presented. While the methodology presented in this paper is based on previous research work in this field of study, it contains several advantages which are not exclusive to this work but where their combination as a whole represents a significant advancement in this field. First, the methodology is general such that few variables are needed to perform a SHP study. Furthermore, the variables needed in the methodology are readily available at large scale for SHP studies in Canada or in other countries having publicly available GIS data. Secondly, the methodology can simultaneously evaluate and compare the SHP for both conventional and run-of-river configurations over a given area; this point represents a significant advancement in the field of study. Third, the methodology uses the gross hydro head, which significantly reduces the computational efforts of site selection. Fourth, the methodology is extremely fast and cost-effective when implemented using GIS-based software. However, the methodology introduces uncertainties in the estimation of the SHP resource potential which are due to the estimation of the efficiency of the SHP systems, the neglecting of SHP system head losses due to friction, and the use of yearly baseflow data

instead of monthly baseflow data. Finally, field measurements of terrain could be used to increase the accuracy of potential site locations.

An application of the method was made to the province of New Brunswick, Canada, where SHP maps were developed to validate the methodology and to promote the development of the small hydropower energy sector in the province. In terms of the SHP opportunity, it was shown that the province of New Brunswick has a good SHP resource. In comparison to the neighbouring state of Maine[1], a previous study [24] identified that there were over 5,883 sites in the state of Maine having a technical SHP potential capacity of 2,780 MW, thus giving an average SHP of 472 kW/site. In New Brunswick, results from this study have shown that there is a technical SHP potential capacity of 368 MW distributed on 696 sites; thus giving an average SHP of 528 kW/site.

Future work should focus on the elimination of potential sites that are not sustainable economically, environmentally or socially. To this end, potential sites that are located within federal and provincial park boundaries should be notably excluded. In addition, drainage basins having issues such as water supply, tourism, sport fishing, and the presence of species at risk should also be eliminated from the model.

Finally, the New Brunswick SHP map results have shown that the province of New Brunswick has a good small hydropower (SHP) resource which should be developed not only for its environmental benefits and attributes, but also for the social and economic benefits of its residents.

Industrial Energy Efficiency

The effect of long lead times for planning of energy efficiency and biorefinery technologies at a pulp mill

Abstract: The pulp and paper industry has many promising opportunities in the biorefinery field. To reach this potential, investments are required in new, emerging technologies and systems solutions which cannot be quickly implemented. In this paper, an approach to model the necessarily long planning times for this kind of investments is presented. The methodology used is based on stochastic programming, and all investments are optimized under uncertain energy market conditions. The uncertain cost development of the emerging technologies is also considered. It is analyzed using scenario analysis where both the cost levels and the timing for market introduction are considered. The effect of long lead times is studied by assuming that no investments can be decided on now and implemented already today, and only investments planned for today can be implemented in, for example, five years. An example is presented to illustrate the usefulness of the proposed approach. The example includes the possibility of future investment in lignin separation, and shows how the investment planning of industrial energy efficiency investments can be guided by using the proposed systematic approach. The example also illustrates the value of keeping flexibility in the investment planning.

Keywords: *Investment planning, Optimization under uncertainty, Process integration, Lignin separation, Pulp and paper industry*

1. Introduction

As a result of the increased climate concern in society, energy market conditions are bound to change, and energy and products based on renewable feedstock will gradually be valued higher. The pulp and paper industry, which already today is a large user and producer of biomass-based energy and materials, therefore has a large opportunity to increase and diversify its revenues through different biorefinery concepts, see e.g. [1–7]. For mills to become successful in this biorefinery arena, process integration investments are required to ensure energy efficiency of the combined pulp and paper production and biorefinery process. This also calls for investments in new, unproven technologies, with highly uncertain investment costs – for example, carbon capture, black liquor gasification, or lignin extraction.

Investments in these emerging technologies are not quickly implemented. Time is needed for analyzing different options, planning of construction including any shutdowns of the plant, contracting, and so on. This results in long lead times from the first decision to start planning for a certain technology path until the plant is finally run continuously at full load. This is true also for traditional options being evaluated in competition with emerging technologies.

Considering that new decisions cannot be immediately implemented if they have not previously been planned for, decision-makers need guidance – not only regarding what investments to make – but also, and more importantly, to what future investments should be planned for. Better tools to aid decision-makers in this field will hopefully lead to that more of these energy-efficiency and emission-reducing measures are carried out. The purpose of this work is therefore to further develop a methodology for process integration investment planning under uncertainty to consider these aspects of long-term decision-making. Here, we will also use the proposed approach to illustrate the effect of a five-year planning lead time in an example of a pulp mill that considers a future possibility of investing in lignin separation.

2. Methodology

The methodology used in this paper is based on a methodology for optimization of process integration investments under energy market uncertainty [8, 9]. In this work, we have used an approach which in addition allows the influence of the investment cost development for new, emerging technologies to be studied [10]. While investments are optimized under uncertainty in energy market parameters with a stochastic programming approach, the effect of different cost developments on the optimal solution is studied through sensitivity analysis. The solution to the optimization model will be an optimal investment plan with respect to the expected net present value (NPV) based on the information we have about the future today.

We model the investment optimization problem using AMPL [11] and solve it using CPLEX [12]. A strategic view of the analyzed investments is assumed, and the discount rate is therefore set to 9.3% over a 30-year-long planning horizon.

2.1. Long lead times for investment planning

Here, we use the expression 'lead time' to denote the time between the decision to invest and the actual implementation or installation of the technology invested in. This is simply modeled based on the assumption that it takes a few years to analyze, plan and prepare for these extensive process changes. When studying the effect of long lead times it is therefore assumed that it is too late now to decide about investments that should be implemented today, and the first investments will instead be implemented in five years.

Since there are costs associated with evaluation and planning of investments – mainly related to the time committed by engineers, consultants, etc. – a basic assumption is that it is not possible to plan for all investments that might be of interest. In this way, although the planning costs are not explicitly accounted for, they are implicitly considered in the proposed modeling approach. The idea of the proposed approach is then that investments planned for today will constrain what will be possible to implement in five years.

To find different planning alternatives, the approach is to start by optimizing the investment in each cost development scenario assuming that the first investment will be in five years. This will, however, lead to solutions where different investments should be made in five years depending on the cost and price development. Based on the solutions obtained, a matrix can be constructed that shows which investments will be possible to implement depending on what has been planned for. A general illustration of such a matrix is shown in Fig. 1.

The matrix could also contain other investment solutions based on experience from working with the model and the mill. The model will then be run for each of the planning alternatives, with possibilities for implementation as constraints. Thereby the results of different investment plans considering an initial lead time of five years can be analyzed, and the best one possibly identified.

Long lead times should also be modeled for later points in time, but this makes the model and especially the solution of the optimization problem hard. As a first step towards an improved understanding of the effects of lead times we therefore settle for the initial lead time. Experience shows, however, that for a majority of investment plans, very few investments are made at later points in time. Therefore, the modeling of later lead times should not be as important. Furthermore, the optimal solution will obviously result in a plan also for later investments, even though it is not considered that decisions have to be made years before the

actual implementation and hence possibly before future energy prices and cost reductions have been revealed.

3. Input data and assumptions

3.1. The pulp mill

We have applied the proposed approach to a pulp mill example that has previously been presented by the authors [10]. This mill is a computer model representing an average Swedish market pulp mill, producing 1000 tonnes per day of bleached Kraft pulp (see also [1, 13]).

Through process integration and more efficient technology, there is a potential to achieve a steam surplus at the mill of about 25%. The steam could, for example, be used to produce more electricity in a low-pressure turbine, or to produce district heating for a nearby community, or for cogeneration of both heat and electricity. District heating could also be produced from lower-quality excess heat at the mill. Except for these traditional ways of making use of the steam surplus, there are new, emerging technologies that might become promising alternatives. We will here look at the example of lignin extraction.

For energy conversion data and investment costs, the reader is referred to [10]. The cost development scenarios for the lignin separation process are presented in Section 3.3.

3.2. Energy market uncertainty model

The energy market model used in this study is the same as the one used in the previous study on the effect of uncertain investment cost developments for emerging technologies [10]. This uncertainty model was developed using the ENPAC tool [14]. The model consists of 28 scenarios for market electricity and fuel prices, see Fig. 2. The same probability has been assumed for each scenario.

3.3. The investment cost scenarios

For the cost development of the emerging lignin separation technology, six scenarios have been used. For this technology, we have assumed that market introduction might happen in 2015 or 2020. It is assumed that market introduction might happen at the base level (L), corresponding to the estimated cost of the N^{th} plant assumed in previous studies (see [10]), or at a higher cost level (H), here assumed to be 50% higher than the base cost level.

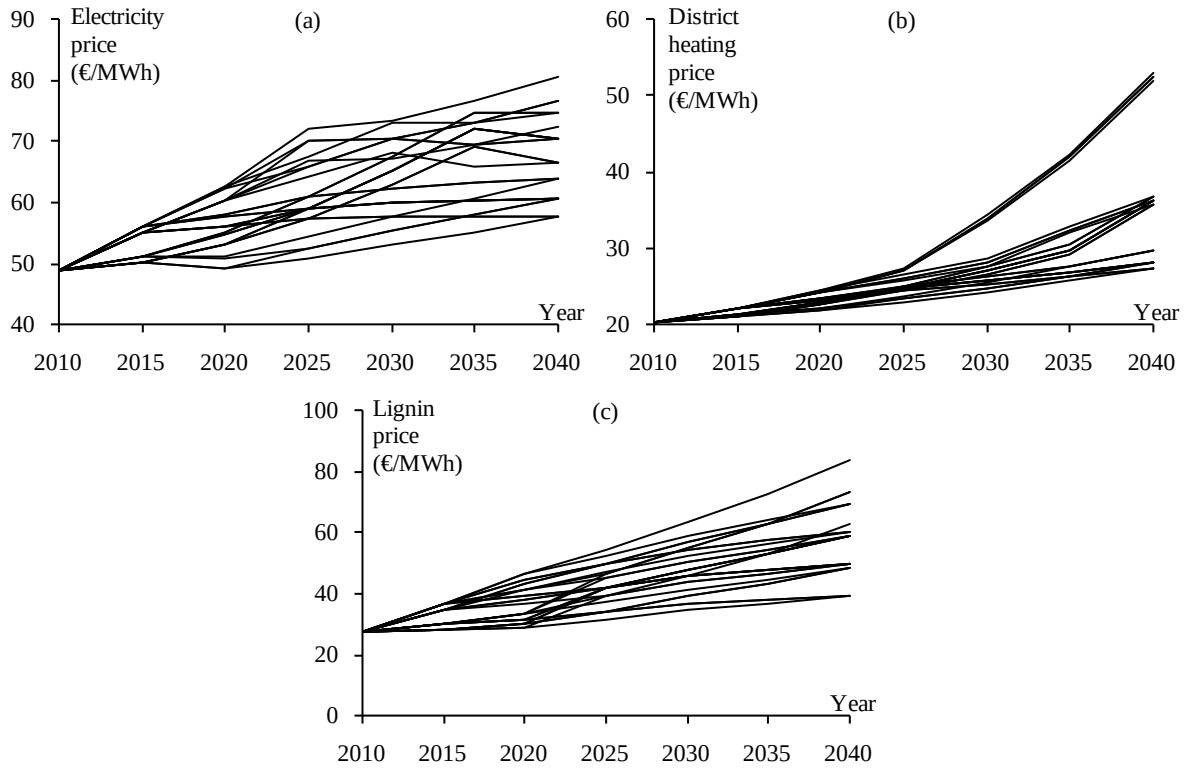

Fig. 2. a) Electricity price scenarios. b) District heating price scenarios. c) Lignin price scenarios.

Table 1 presents the different scenarios for the investment cost of the lignin separation plant. If the market introduction happens at the base cost level, the cost stays permanently at that level (Scenarios A and B). If, instead, market introduction happens at the higher cost level, the cost might stay at the higher level (Scenarios C and D), or it might drop later as a consequence of technological learning (Scenario E) if, for example, not very many plants are sold. There is also a possibility that the technology is never introduced to the market (Scenario F).

Table 1. Investment cost scenarios for the lignin separation plant.

Scenario & Market introduction (year)		2010	2015	2020	2025	2030	2035
A	2015 at base cost level	–	L	L	L	L	L
B	2020 at base cost level	–	–	L	L	L	L
C	2015 at higher cost level where cost is stabilized	–	H	H	H	H	H
D	2020 at higher cost level where cost is stabilized	–	–	H	H	H	H
E	2015 at higher cost level with drop to base cost level 2020	–	H	L	L	L	L
F	Never	–	–	–	–	–	–

–: Unavailability
L: Low cost / base cost level = Estimated cost of N^{th} plant
H: High cost / Higher cost level = 1.5L

4. Results

As described previously, the effect of long lead times is studied by assuming that no investments can be made already today, and that the first investments in five years must be planned for. Furthermore, we assume that the costs and personnel resources associated with planning of investment and implementation make it impossible to plan for every interesting

investment opportunity. To find a number of reasonable investment packages to plan for, the model was solved for one cost development scenario at a time with the constraint that the first investments could be made in five years. The solutions obtained are presented in Table 2.

Table 2. Optimal investments 2015 in different cost development scenarios.

Scenario	Optimal investment	
A, C, E	Lignin:	64 MW lignin
	Heat pump:	32 MW delivered heat
B, D	Cogeneration:	5MW elec. and 26 MW delivered heat
F	Cogeneration:	5MW elec. and 26 MW delivered heat
	Heat pump:	19 MW delivered heat

These three packages obviously differ regarding the lignin extraction investment, but also regarding the amount and means of district heating deliveries. The reason for this difference in district heating production is that the preferred way of generating district heating is by cogeneration from low-pressure steam, but when lignin is extracted as for Scenarios A, C and E, no low-pressure steam is available. In these scenarios, district heating is therefore generated by a heat pump instead. Also in the case of cogeneration, a heat pump might be interesting to further increase district heating deliveries as in Scenario F. By this solution, the mill is, however, locked into a district heating contract of substantial deliveries for which the production based on low-pressure steam is needed to fulfill the delivery requirement. In Scenarios B and D, later opportunities for lignin extraction might make it interesting to use the low-pressure steam for lignin extraction at a later point in time. Therefore, district heating deliveries are more limited, making it possible to replace the production from cogeneration with production from the heat pump.

In some mills, the power boiler and back-pressure turbine might be oversized. Under such conditions, it would probably be more beneficial to increase district heating deliveries by increasing the fuel input to the power boiler than to invest in a new heat pump. Here, however, the boiler is already assumed to be run at maximum capacity.

Fig. 3 is a matrix showing which investments can be made in 2015 depending on what investment package has been planned for. In addition to the alternatives from Table 3, we also added the alternative to plan for a condensing turbine and a heat pump. The alternative not to plan for any investment should obviously never be better than to plan for something, since there is always an option to avoid making an investment that has been planned for. However, the ‘no investment’ planning alternative was included for comparison. It might be interesting if costs and resources for planning are considered explicitly, which they are not here.

The X’s in the matrix represent that an investment is possible, though not required. That means, for example, that if a heat pump has been planned for, this possibility exists in 2015 but there is also always an option to withdraw from the investment. This option to abandon a planned investment is especially important for lignin extraction since this technology might not even be available on the market in 2015. Based on the matrix, the optimization model was solved for different planning alternatives. The expected net present value for the alternatives in the different cost development scenarios is shown in Fig. 4.

		Possible to implement 2015				
		Lignin	Heat pump	District heating from 145 and 100°C heat	Turbine (145-100°C)	Turbine (100-35°C)
Plan 2010	Lignin and heat pump	X	X			
	Cogeneration only			X	X	
	Cogeneration and heat pump		X	X	X	
	Condensing turbine and heat pump		X		X	X
	No investment					

Fig. 3. Matrix of possible technology implementations depending on what has been planned for.

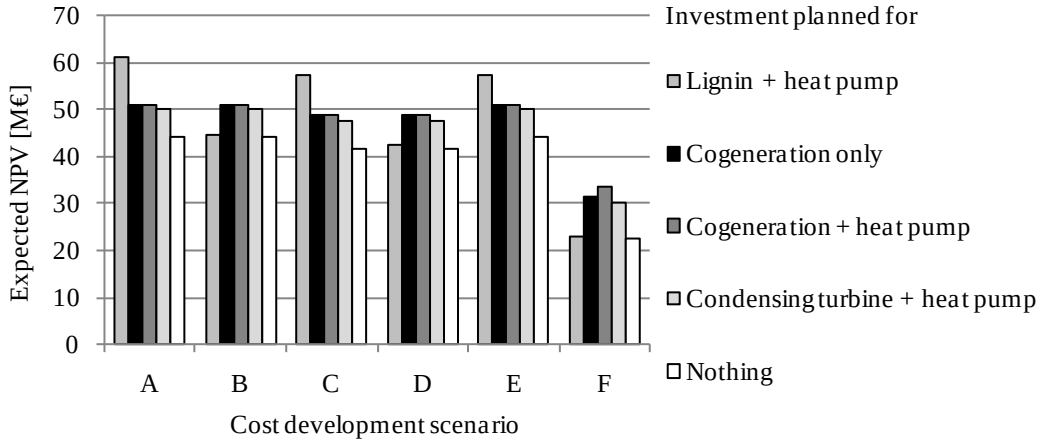

Fig. 4. Expected net present value for different planned investments in 2015.

As can be seen, depending on the cost development scenario, lignin extraction could either be by far the best or by far the worst alternative (at least except planning for nothing). This is explained by the large potential associated with this technology if it becomes a reality, which disappears if the technology has not yet become available for the pulp mill.

The good runner-up is instead cogeneration, which is either the best or the next best alternative in all scenarios. The difference is very small if you include the heat pump or not. Obviously, it is better to include the heat pump in the plan since there is no requirement of going through with the investment. In Scenario F where lignin extraction never becomes available on the market, the heat pump is slightly advantageous. As anticipated, the 'nothing' alternative is the worst one in all scenarios.

5. Discussion

In theory, the optimal planning alternative would include all different technology options, but this would obviously be difficult in practice. Principally, planning for everything means the

same as staying flexible and that should be striven for. However, the underlying assumption in this study was that this is too costly to achieve in reality. Nevertheless, the lack of flexibility obviously has a cost. The results show that if lignin extraction is not planned for, but cogeneration instead, the loss is 19% in expected NPV in Scenario A (17% and 12% in Scenarios C and E respectively). On the other hand, if the plan is for lignin extraction and a heat pump but the lignin separation technology does not become a possibility, the loss is 15%, 15% and even 46% in Scenarios B, D and F respectively. Considering that the use of expected NPV as investment evaluation measure partly hides differences in cash flows because of discounting and weighting of scenarios, these losses in expected NPV are quite important (see for example [10, 15] where differences in expected NPV are related to corresponding differences in annual net profits). These high values of staying flexible by planning for many different investment opportunities imply that, strategically, it should be worth committing more organizational resources to planning of these kinds of investments.

Nevertheless, if we assume that it is not possible to invest in anything else than what has been planned for, and if we further assume that it is not possible to plan for more than a few different new technologies, results like the ones presented in Fig. 4 can be used to evaluate different investment plans. In the example presented here, investment in lignin extraction involves both the highest potential and the highest risk, while cogeneration seems to be a more robust option. The best decision depends on the decision-maker's beliefs about the probabilities of the different cost development scenarios.

5.1. Limitations

The work presented in this paper provides a good starting point for an investment planning methodology where consideration is given to the long lead times that are often involved in these kinds of decisions. There are, however, some limitations which might make it difficult to use the methodology for some applications where these aspects are of importance. Further work with model development should focus on these issues. For example, the costs associated with evaluation, planning and detailed analyses of different investments and their implementation are not explicitly considered in this model. It should also be possible to differentiate these costs and the length of the planning lead time between different kinds of investment alternatives. Further work is needed, too, if not only the initial lead time but also the lead time for subsequent investment stages should be accounted for.

6. Conclusions

The proposed approach for modeling of long lead times for planning of industrial energy efficiency investments gives a more realistic representation of this kind of decision-making. An example illustrates how the planning of future investments can be guided by using this systematic approach considering uncertainties in future energy market conditions as well as in cost development of new technologies. The results clearly show the importance of considering the long lead times involved in the investment planning, since significant values are at stake by making the right or the wrong decision about which investments to plan for.

We have also shown how the proposed approach can be used to value flexibility in the planning of industrial energy efficiency measures. The example demonstrates that the value of this flexibility can be quite high. There is, however, a trade-off between the value of this flexibility and the associated planning costs required to obtain it. It is therefore important to continue the work regarding long lead times to incorporate these planning costs.

Abstract: Electric power, steam and chilled water were consumed in beer brewing process. The process is intensive in energy conversion and utilization. The brewery wastewater can generate biogas of high methane content through anaerobic sludge fermentation. This high concentrated biogas could be an excellent choice employed in energy conversion and utilization. The reclaimed water, after proper treatment, could be employed to scrub CO_2 and H_2S in biogas. Through compression, the purified biogas could be stored as fuel for mechanical operation and further incorporated into the municipal LNG pipe network. According to biogas yield and energy requirements in breweries, energy usage efficiency and configuration of device for biogas Integrated Energy System (IES) were investigated. This paper introduced an Otto cycle internal combustion engine using biogas for power generation. With the biogas yield of 34.84m^3/h (standard state), the power efficiency of 28.45% could be generated with electricity of 70.0kW. Efficiency of combined heating and power (CHP) can reach 61.80% employing the excess heat of the engine exhaust. There are successful examples of combined cooling and power (CCP), combined cooling and heating (CCH) that has efficiency of over 60%.

Keywords: *Biogas produce, Purification process, IES conversion Using efficiency*

1. Introduction

In China, Biogas is not only new energy source, but also an important aspect of sustainable development for the renewable energy. The biogas is generated by industrial wastewater or municipal solid waste through degradation process of anaerobic digestion. Consequently, heat and electricity is generated through the biogas [1]. Adopting the technology of combined cooling, heating, and power (CCHP), this is also known as trigeneration, or integrated energy system (IES). CCHP is the simultaneous production of mechanical power (often converted to electricity), heating and/or cooling from one primary fuel, and is an extension of CHP (combined heat and power, also defined as cogeneration) by coupling with thermally activated cooling technologies that take the waste heat from CHP for producing cooling [2].

Moving parts of internal combustion engines and gas turbine contacts directly with burning gas, there need cleaner fuels, biogas as a biomass energy source by the removal of CO_2 and H_2S and combined with high conversion efficiency, low emission rates, suitable for CHP, CCH and CCP technology. Medium and small-scale units high exhaust temperature, heat recovery of flue gas is conducive to heat (cold) output, and improve unit efficiency.

Because the biogas contains a large share of the inert gas, emissions of oxides of nitrogen (NOx) were reduced relative to natural gas, while unburned hydrocarbons (CH) were increased, and exhibit penalties of performance compared with spark ignition engine of natural gas or gasoline [3].

Kautz et al. [4] studied a 100kW gas turbine recuperative cycle of exhaust to heat air and the influence of low calorific biogas on the combustion air ratio. Kim et al. [5] studied regenerative Brayton cycle using gas turbine recycling exhaust heat. Nwafor [6] examined the impact of advanced injection timing on the emission characteristics of dual-fuel engine.

Ahead of injection timing was intended to compensate for longer ignition delay and slower burning rate of fuelled natural gas engine, and there was a s lightly increase in the oil consumption accompanied with reduced emission of CO and CO_2.

Smith et al. [7] introduced an innovative domestic scale combined heat and power (CHP) plant incorporating a heat pump (HP). HP incorporating enhanced economy efficiency of domestic use of CHP equipment and satisfied flexibility of the family energy requirements.

Biogas was compressed to gather energy density and reduce storage capacity, the best method is biogas purified, then to compress [8]. For example, in New Zealand, both gas compressor and gas scrubber used in conjunction with, in Belgium, biogas produced from the livestock manure is being dried, scrubbed, compressed and stored in a steel tank with pressure of 4 bar in 0.2 m^3, so that is alternative fuels for CNG(compressed natural gas), gasoline, diesel and LPG (liquefied petroleum gas) [9].

2. Biogas process and energy demand in breweries

2.1. Biogas process

Brewery wastewater comes from various procedures, such as the cleaning process of the malt production, brewing, bottling, and the wastewater from cleaning the recycled beer bottle and the packaging sterilization, as well as the overflow, disqualified product, and filter back wash water. This wastewater is rich in carbohydrates, pectin, mineral salts, cellulose etc. Therefore, it is an organic wastewater with high BOD_5 and COD.

Aeration pond m ethod is the application of biological treatment earlier; because of aerobic bacteria have an allergic reaction to load fluctuations, not to deal with high carbohydrate and volatile components of beer wastewater. Use of the up-flow anaerobic sludge blanket (UASB) has a feature that of high organic loading, short hydraulic retention time, no filler in reactor, no sludge return and stirring device, low operation cost, can be inoculated directly with the sludge particles to produce biogas etc., and that is a wastewater treatment technology for sustainable development. It can not meet emission standards used alone. In most cases, the first need to treat beer wastewater by anaerobic digestion, the most of high concentration organic wastewater in UASB was degraded, and then, under the aerobic environment oxidize and decompose low concentration of pollutants in wastewater.

Fig.1 shows the brewery wastewater processing units and biogas generation set. The brewery wastewater discharged from workshop flows to the sump. Most of suspensions in waste water filter through the sieve grid. The pretreatment pool is necessary for wastewater with unqualified temperature and other physical/chemical conditions. Subsequently, the wastewater flows through the balance pool with the pH values adjusted by acid, alkali or $FeCl_3$. The adjusted water is pumped to UASB reactor in the reaction pool to decompose the organic first into acids, then to methane and CO_2. The three phase separator on top of the reactor could separate the biogas, mud and wastewater efficiently. Meanwhile, the methane bacteria could be effectively retained. The biogas is collected in gas tank after adsorption of H_2S through activated carbon. After anaerobic treatment, COD of beer wastewater dropped from about 2500 t o 500 mg / L. The use of air blower aerate for further processing in the aeration tank. Wastewater COD reduced to about 50 m g / L and then flow into the sediment pool. After suspended solid of aerobic fermentation were filtered, the reclaimed water qualified discharged to the sewer.

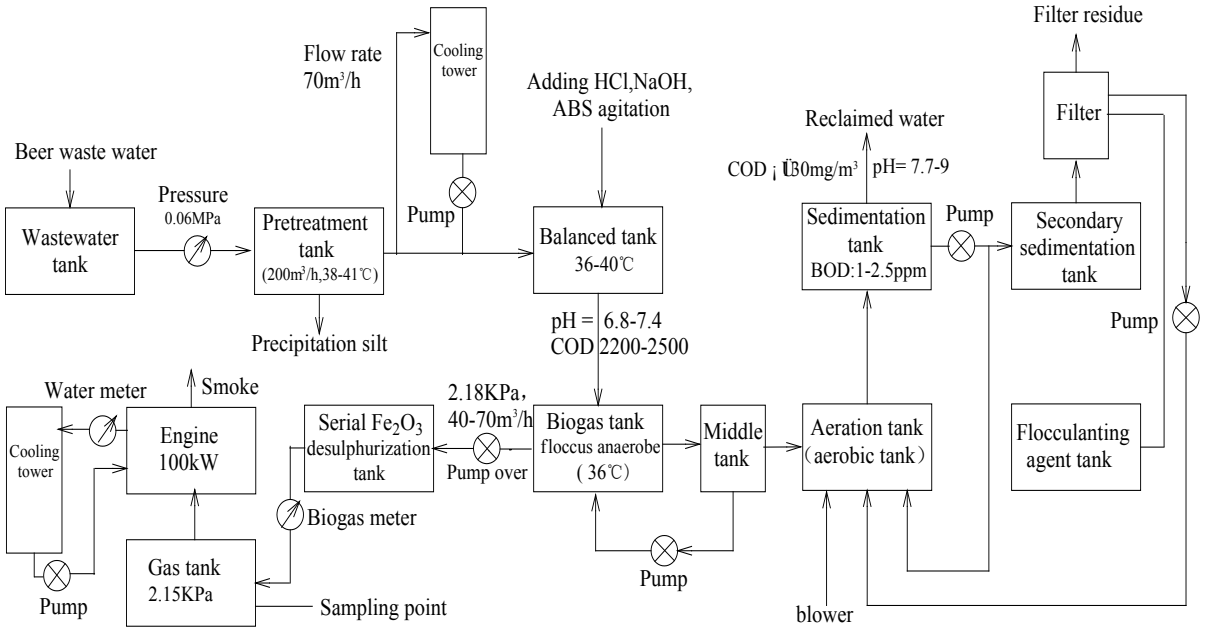

Fig.1. Schematic diagram of processing organic wastewater and generate electricity sets.

2.2. Energy requirement

The brewing process consumes a lot of electricity, steam and chilled water. This process is an intensive process of energy conversion and utilization. Therefore, energy consumption cost accounts for a large proportion of the production cost. Power workshop has 2 sets of 25t steam saturated boiler (burning oil and/or natural gas), steam pressure 7.0-8.0bar. 3 sets of ammonia compression refrigerator, cooling capacity of 496 RT, evaporator pressure of 3.7bar, chilled water supply 4°C, return 9°C. Fig.2 is energy flow diagram of steam and chilled water.

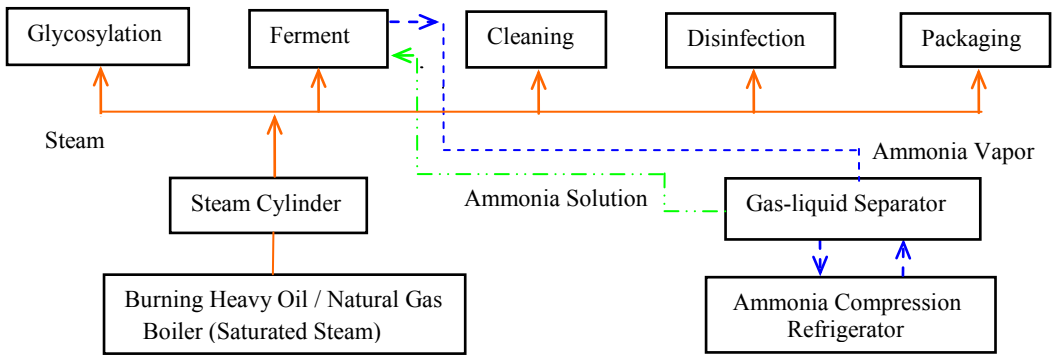

Fig.2. Energy flow diagram of steam and chilled water in breweries.

3. Status of biogas utilization

Shenzhen Kingway brewery (2 plants) and Shenzhen Tsingtao-Asahi brewery could treat beer brewery wastewater of 80-120m^3. The amount of biogas produced is 35-60 m^3 (maximum volume of 80m^3) per hour with the measured methane content of 71.2%. Table 1 shows the biogas composition with low heat value of about 25 426 kJ/Nm^3 and thermal capacity produced as 282.51-423.77kW per hour. Biogas power generation has been running for 1 year period, in order to prevent greenhouse gas emissions before it is used by the torch burning. The heat demand of beer production process provides a choice for biogas CHP and CCHP.

3.1. Engine power generation

Ignition engine was used for power generation in Shenzhen Kingway brewery, Table 2 was the spark ignition engine specifications. Biogas after the removal of H_2S could be generating 70kW (field test) per hour, efficiency of power generation was 28.45%. Table 3 was Composition of engine exhaust for the actual measurement.

Table1. Composition of the biogas

Component	Content (%)	Component	Content (%)
CH_4	71.2	H_2S	＞2500ppm
CO_2	17.1	H_2O,H_2	2.0
O_2	2.39	N_2*	7.31

* Air has leaked into biogas collection cavity over the silt anaerobic digestion pond.

SO_2 (ppm)	32-0		
H_2O (%)	~8.8	3.0-5.5	0.5-4.0
N_2 (%)	~76.6	74-77	76-78

* Reference value from Table 4 of reference [10]

3.2. Heating boiler

There is a biogas fired boiler (model: FBA-080 F) in Shenzhen Tsingtao-Asahi Brewery with the parameters as follows: rated pressure: P = 1.04MPa (saturated steam), the amount of steam produced 1.25 t / h, e xhaust temperature 300°, biogas/ steam ratio = 2:1, boiler efficiency η = 80%. The actual operation pressure was 0. 6MPa.

4. Biogas processing

Because high temperature of biogas fire, slower burning speed, serious ignition delay and higher exhaust temperature, all that resulting in lower efficiency of biogas power generation. biogas purification (removal of CO_2 and H_2S), then compressed and stored as alternative

products of CNG, gasoline, diesel and LPG, showing the goods value of biogas through the transport.

4.1. Gas purification, compression and storage

Removal of H_2S in the biogas can be divided into ① dry and oxidation,② ferric oxide adsorption, ③ activated carbon adsorption, and④ liquid-phase oxidation process. A simple adsorption method using activated carbon was used in 3 breweries.

The amine solution of 10% mono-ethanolamine (MEA) and diethanolamine (DEA) are usually used to absorb CO_2. It takes 5min for the solution regeneration to be completed by boiling. The newer approach is the sulfolane method or the Sulfinol method composed by alcohol amine and sulfolane adding water. Method of reclaimed water which was beer wastewater treated when water pressure increased as the absorbent to remove CO_2 is the most simple and less expensive. Efficiency of the scrubber depends on that scrubber specifications, packing and gas pressure in scrubber, composition of raw biogas, the flow rate and purity of water used and so on.

The critical temperature and pressure required to liquefied biogas were: -82.58 $^{\circ}$C and 47.5 bar respectively. Purification biogas compressed by the compressor, according to different pressure stored in cylinders, which could be transported with long-distance, may be also build a small scale station on side.

4.2. Power fuel

After CO_2, H_2S and water vapor in biogas were removed, the methane (>90%, heat value equivalent to LNG), could be compressed and stored as fuel for car and other power machines.Table 4 is data of LNG imported to Guangdong province of China from Australia, kindly provided by the Shenzhen Gas Group.

Table 4. Data of physical and chemical for LNG.

Composition	(%)	Data (0℃,1atm)	Value
CH_4	87.59	HHV (MJ/Nm^3)	45.08
C_2H_6	8.13	LHV (MJ/Nm^3)	40.71
C_3H_8	3.2	Density (kg/Nm^3)	0.8318
C_4H_{10}	0.99	Specific volume (Nm^3/t)	1202
C_5H_{12}	0.05	LHV (MJ/kg)	48.92

Use of CNG instead of gasoline as a motor fuel, the emissions of CO, CH compounds and NO compounds can be decreased by 97%, 72%, and 39% respectively. Performance of resistance to blast for CNG equivalent to gasoline is about octane number of 130, and CNG does not release lead, benzene and other toxic substances all which can cause cancer. Forklift which using LPG as fuel made by Japan Fuji Co. in Shenzhen Tsingtao-Asahi brewery, may also use purified biogas as a substitute.

4.3. Incorporate into LNG pipe network

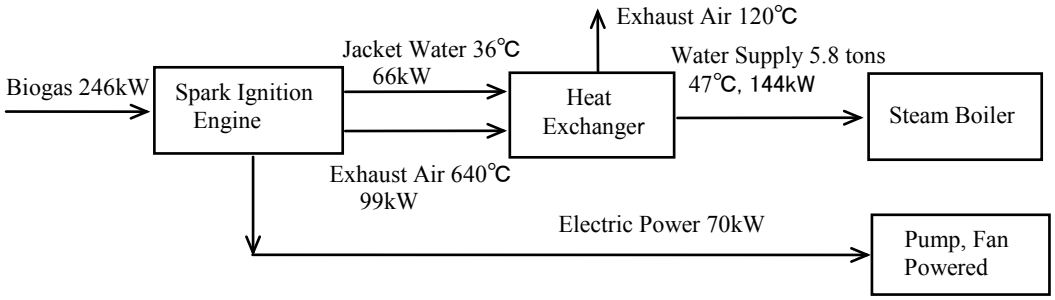
Due to lower productive rate of biogas, gas source instability, lower energy carrier demand load, difficult to manufacture equipment and operation and a long payback time as investment etc., biogas can no effectively use in the IES, so that, it could be considered incorporate into the municipal LNG Network pipe after the quality checked up.

5. Integrated energy system (IES) of biogas

Electricity is the high grade energy. According to the second law of thermodynamics, the electricity generated by biogas is of the highest efficiency, meanwhile, the exhaust gas could be employed for heating or cooling. IES of biogas would adopt the following technologies such as Otto cycle of ignition engine, Brayton cycle of gas turbine, power generation of fuel cells, absorption and adsorption refrigeration, high efficient combustion, high efficiency removal of H_2S and CO_2, as well as recovery and storage for thermal energy.

5.1. CHP project

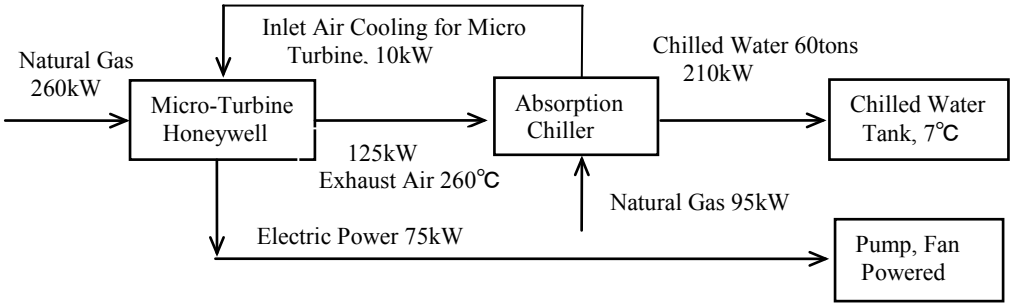
Project 1: Engine + Heat tube exchanger of condensation type
(Shenzhen Kingway brewery)



• Spark Ignition Engine of biogas fueled without removal of CO_2, generate electricity efficiency of 28.45%, discharged heat of 99kW by engine exhaust and of 66kW by jacket cooling water, dispersed heat of 2.8kW by convection and of 4.6kW by radiation.
• If heat of engine exhaust was utilized through heat tube heat exchanger to heat water supply and temperature was reduced to about 120℃, then, overall CHP efficiency may be reached 61.8%, and engine exhaust even could be discharged at the condensation temperature of 57℃.

5.2. CCP project [11]

Project 2: Micro Turbine (Honeywell) + Direct fired double effect chiller



• Turbine efficiency 28.75%. Inlet air cooled to 16℃ to keep constant capacity of turbine.
• Broad absorption chiller using lithium bromide-water, direct fired double effect chiller with COP of 1. Chilled water temperature: supply 7.8-9.4℃, return 12.8-14.4℃.
Performance of MT Honeywell and absorption chiller were shown in Table 5 and Table 6.

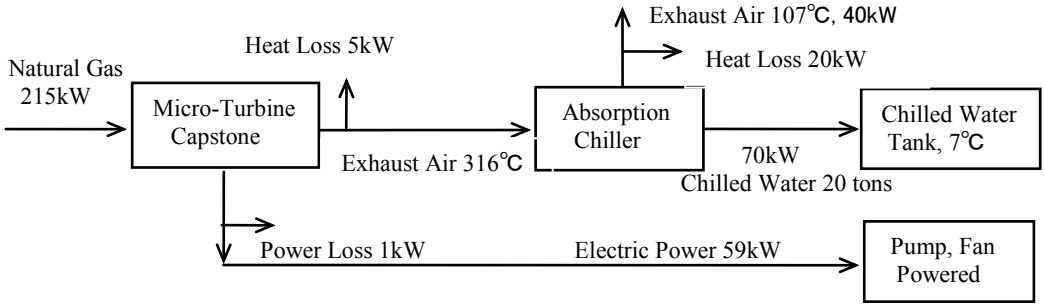
Table 5. Performance parameters of MT (Honeywell).

Item	Parameter	
Rating power (kW)	75	15℃,1atm
NG wastage (m^3 /h)	27	≥0.62MPa(absolute)
Thermoelectricity efficiency (%)	28.5	15℃,1atm
Exhaust temperature (℃)	280	
Exhaust flux (kg/s)	0.67/0.76	
Emission of NO_X (ppm)	<13	15℃,1atm, full load

Table 6. Broad LiBr absorption chillers (Mode: BD7N280-15).

Item	Parameter	Item	Parameter
Capacity of refrigeration (USRT)	23	Produce heat (kW)	114
Chilled water outlet/inlet temp. (℃)	6.7/12.2	Warm water outlet temp.(℃)	50
Chilled water flux (m^3/h)	12.8	Warm water flux (m^3/h)	19.6
Cooling water outlet/inlet temp.(℃)	36/29.4	Inlet temp. of exhaust (℃)	280
Cooling water flux (m^3/h)	24.3	Match electricity (kW)	1.2

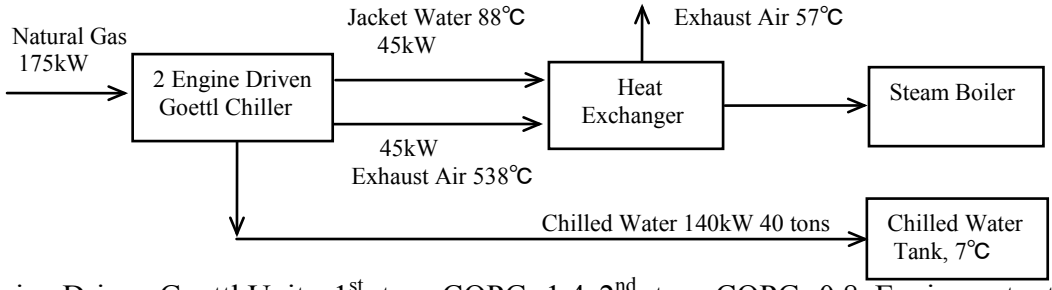
Project 3: Micro Turbines (Capstone) + Single effect chiller



• MT Capstone efficiency 27.9%, with chiller 63.5%. Average exhaust inlet temp.℃271 , outlet temp.113℃.
• Broad absorption chiller driven only by MT exhaust. Single effect chiller with COP of 0.7, nominal capacity of chilled water is 20 tons. Parasitic power is 6.4kW.

5.3. CCH project

Project 4: Engine driven Goettl Units + Heat tube exchanger of condensation type



• Engine Driven Goettl Units. 1st stage COPG=1.4, 2nd stage COPG=0.8, Engine output 52kW, engine efficiency 30%.

6. Conclusion

This paper introduced and analyzed biogas utilization for the three large modern breweries, which is not perfect and irrational for use of biogas energy. Based on the current biogas technology and equipments, accordingly to the biogas yield and energy demand in breweries, analyzed and studied the energy utilization technology, equipment configuration, and conversion efficiency on the integrated energy system (IES) . The biogas purification process employs qualified reclaimed water from wastewater treated of the brewery to scrub CO_2 and H_2S in biogas. This process is simple with low operation cost. The resultant biogas is rich in methane content and efficient to improve the efficiency of IES. Both electricity generation and heating efficiency, as well as the cooling efficiency can reach as high as 60%.

Abstract: In this paper, absorption chillers are modeled as four heat sources: the generator, the evaporator, the condenser, and the absorber and thermoeconomic issues are examined using the available relations. In order to simplify the calculations, all processes are assumed to be reversible. Since heat exchangers are expensive facilities, therefore, reducing the total heat transfer area is taken as the design criterion. In this paper, first the thermoeconomic criterion, taken as the total cost of unit of refrigeration which includes the capital cost and the energy cost, is defined. In the following, the available relationships are used to calculate the maximum value of the thermoeconomic criterion and the maximum refrigeration load. Next, optimal working conditions are specified for absorption chillers and after that, the effect of the thermoeconomic parameter on the maximum thermoeconomic criterion, coefficient of performance and the specific refrigeration load corresponding to the maximum value of the thermoeconomic criterion are investigated.

Keywords: *thermoeconomic performance, absorption chiller, optimization*

1. Introduction

Nowadays, costs of energy consumption and electricity compared to those of fossil fuels have caused engineers in most countries to consider using absorption chillers instead of compression chillers. However, fuel costs need to be controlled in some way and consequently, economical studies are carried out constantly on opt imization of absorption chillers and reducing their economical costs.

A new criterion has been used in the recent years to evaluate the degree of optimality of thermodynamic cycles. The thermoeconomic criterion economically investigates the phenomena. Capital costs and energy costs are considered in these investigations using thermodynamic relationships and working conditions are designed in a way that the operation is economically optimum. Chen and Schouten (1998) evaluated the optimal value of coefficient of performance in irreversible absorption chiller systems [1]. Next, Chen in 1999 evaluated the optimal value of coefficient of performance for the irreversible 4-heat exchange-surface absorption chiller in the maximum specific cooling load [2]. This was followed by other researches with the aim of optimization of absorption chiller processes and other processes similar to those, including thermoeconomic optimization of the reversible sterling heat pump cycle by Tyagi, Chena, and Kaushikb[3].

The largest portion of capital cost of absorption chiller pertains to the heat exchangers used in the generator, condenser, evaporator, and the absorber.

2. Modeling of the cycle and its relationships

In order to simplify the calculations, absorption chiller cycle is assumed to consist of four heat sources including the absorber, the generator, the evaporator, and the condenser, as illustrated in figure 1. We assume that the processes take place reversibly. It is also assumed that the flow is constant in working parts of the cycle and heat transfer between the elements and heat sources during the time of a complete cycle τ, happen at temperatures T_a, T_c, T_e, T_g, respectively. There are thermal resistances between the external components and the

operating elements of the cycle. Temperatures of working components in the generator, evaporator, condenser and the absorber are respectively T_4, T_3, T_2, T_1. Heat transfer coefficients are accordingly U_4, U_3, U_2, U_1. Moreover, heat transfer surfaces are A_4, A_3, A_2, A_1, in the generator, the evaporator, the condenser and the absorber, respectively. The work input for the pump in the cycle Is taken as negligible compared to the heat input to the generator.

It is assumed that the heat transfer between the operating components of the cycle and the external heat sources follows the linear (Newtonian) heat transfer mode and the four processes take place isothermally. Thus, heat transfer equations of all the four processes are written as follows:

$$Q_1 = U_1 A_1 (T_g - T_1)\tau \quad (1)$$
$$Q_2 = U_2 A_2 (T_e - T_2)\tau \quad (2)$$
$$Q_3 = U_3 A_3 (T_3 - T_c)\tau \quad (3)$$
$$Q_4 = U_4 A_4 (T_4 - T_a)\tau \quad (4)$$

Where Q_4, Q_3, Q_2, Q_1 are heat transfers in the generator, the evaporator, the condenser and the absorber, respectively, From the first law of thermodynamic we have:

$$Q_1 + Q_2 - Q_3 - Q_4 = 0 \quad (5)$$

Considering the second law of thermodynamic and the reversibility of the cycle we have:

$$\frac{Q_1}{T_1} + \frac{Q_2}{T_2} - \frac{Q_3}{T_3} - \frac{Q_4}{T_4} = 0 \quad (6)$$

Since the heat exchangers are the expensive component in the cycle, reduction of the heat transfer area (A) is taken as the design criterion. Therefore, by optimizing the total heat transfer area we can obtain optimality.

$$A = A_1 + A_2 + A_3 + A_4 \quad (7)$$

The parameter (a) is defined as the total distribution rate between the condenser and the absorber:

$$a = \frac{Q_3}{Q_4} \quad (8)$$

According to the standard definitions of coefficient of performance (COP) and specific cooling load (r) and equations (1) to (8), coefficient of performance can be obtained as follows:

$$\varepsilon = \frac{Q_2}{Q_1} = \frac{T_4^{-1} + aT_3^{-1} - (1+a)T_1^{-1}}{(1-a)T_2^{-1} - T_4^{-1} - aT_3^{-1}} \quad (9)$$

And the specific cooling load is obtained as follows:

$$r=\frac{Q_2}{A\tau}=\left\{\frac{1}{U_2\left(T_e-T_2\right)}+\frac{T_2^{-1}-T_4^{-1}+a\left(T_2^{-1}-T_3^{-1}\right)}{U_1\left(T_g-T_1\right)\left[T_4^{-1}-T_1^{-1}+a\left(T_3^{-1}-T_1^{-1}\right)\right]}\right.$$
$$\left.+\left[\frac{1}{U_4\left(T_4-T_a\right)}+\frac{a}{U_3\left(T_3-T_c\right)}\right]\frac{T_2^{-1}-T_1^{-1}}{T_4^{-1}-T_1^{-1}+a\left(T_3^{-1}-T_1^{-1}\right)}\right\}^{-1} \quad (10)$$

Equations 9 and 10 are the general relationships for absorption chillers with four reversible heat sources. These relationships can be used to obtain thermoeconomical optimum performance for this type of absorption chillers.According to the studies carried out by Kodal and Shahin as given in [5], the thermoeconomic criterion for absorption chillers with four reversible heat sources is defined as the total price of unit cooling load which includes both capital and energy costs. Therefore, the function which is to be optimized is as follows:

$$F=\frac{\frac{Q_2}{\tau}}{C_i+C_e} \quad (11)$$

Where C_i, C_e are capital and energy costs in the unit of time, respectively. The capital cost of absorption chillers is assumed to be proportional to its total heat transfer area:

$$C_i=k_1 A \quad (12)$$

Where k_1 is the capital recovery factor, the capital cost for the unit heat transfer area. Energy consumption cost is directly proportional to the rate of heat input:

$$C_e=k_2\frac{Q_1}{\tau} \quad (13)$$

Where k_2 is the unit cost of energy. By substituting equations 12 and 13 in 11, we obtain:

$$F=\frac{Q_2/\tau}{(k_1A+k_2Q_1/\tau)}=(k_1r^{-1}+k_2\varepsilon^{-1})^{-1}. \quad (14)$$

By defining $k=\frac{k_1}{k_2}$ as the thermoeconomic parameter having the dimension $\frac{KW}{m^2}$, when the capital cost increases and the cost of energy consumption reduces, the thermoeconomic parameter k goes up. The optimal relationship for the total refrigeration load and the COP of absorption chillers is as follows:

$$r=U_2\left[T_eT_c+aT_eT_a-(T_g\varepsilon+T_e)\frac{T_cT_a(1+a)}{T_g(1+\varepsilon)}\right]$$
$$\times\left\{\left[(1+b_2)^2T_c+a(1+b_3)^2T_a-\frac{a}{1+a}(b_2-b_3)^2T_e\right]-(1-b_1)^2\frac{(1+a)T_aT_c}{(1+\varepsilon)T_g}\right. \quad (15)$$
$$\left.+\frac{T_e}{\varepsilon T_g}\left[(b_1+b_2)^2T_c+a(b_1+b_3)^2T_a-\frac{a}{1+a}(b_2-b_3)^2T_g\right]\right\}^{-1},$$

Where: $b_1 = \sqrt{\frac{U_2}{U_1}}$ (16)

By combining (14) and (15), the ration of the optimal value of the thermoeconomic criterion and the COP of absorption chillers with four reversible heat sources is obtained as follows:

$$k_2F = \left\{ \frac{k}{U_2}\left[T_eT_c + aT_eT_a - (T_g\varepsilon + T_e)\frac{T_cT_a(1+a)}{T_g(1+\varepsilon)}\right]^{-1} \times \left[(1+b_2)^2T_c + a(1+b_3)^2T_a - \frac{a}{1+a}(b_2-b_3)^2T_e\right] - (1-b_1)^2\frac{(1+a)T_aT_c}{(1+\varepsilon)T_g} + \frac{T_e}{\varepsilon T_g}\left[(b_1+b_2)^2T_c + a(b_1+b_3)^2T_a - \frac{a}{1+a}(b_2-b_3)^2T_g\right] + \varepsilon^{-1}\right\}^{-1}. \quad (19)$$

Equation 19 gives the optimum thermoeconomic criterion for a given value of COP and also the optimum coefficient of performance for a given thermoeconomic parameter in reversible absorption chillers. Using equation19, we can evaluate other characteristics of thermoeconomic operation of reversible absorption chillers which obey the linear (Newtonian) heat transfer law.

Equation 19 demonstrates that for the thermoeconomic parameter we have $F = 0$ when $\varepsilon = 0$ or $\varepsilon = \varepsilon_c$, where:

$$\varepsilon_c = \frac{T_a^{-1} + aT_c^{-1} - (1+a)T_g^{-1}}{(1+a)T_e^{-1} - T_a^{-1} - aT_c^{-1}}, \quad (20)$$

is the coefficient of performance for an absorption chiller with four reversible heat sources. When $\varepsilon < \varepsilon_c$, the maximum thermoeconomic criterion is derived. Using (19) and the final condition $\frac{d(k_2F)}{d\varepsilon} = 0$, we can evaluate $COP(\varepsilon_r)$ for the maximum value of the maximum thermoeconomic criteria $(F_{\max})$:

$$\varepsilon_F = \left[1 - \sqrt{1 - \frac{(1+a)T_g^{-1} - T_a^{-1} - aT_c^{-1}}{T_a^{-1} + aT_c^{-1} - (1+a)T_e^{-1}}d_1}\right]d_1^{-1} \quad (21)$$

Where

$$d_1 = \frac{(1+a)(T_g - T_e)d_2}{T_e^2[T_a^{-1} + aT_c^{-1} - (1+a)T_e^{-1}]\{d_3 + [T_cT_g + aT_aT_g - (1+a)T_aT_c]U_2/k\}} + \frac{(1-b_1)^2(1+a)T_aT_c - d_3T_e - [T_eT_c + aT_eT_a - (1+a)T_aT_c]T_gU_2/k}{T_e\{d_3 + [T_cT_g + aT_aT_g - (1+a)T_aT_c]U_2/k\}} \quad (22)$$

$$d_2 = (1+b_2)^2T_c + a(1+b_3)^2T_a - (b_2-b_3)^2T_ea/(1+a) \quad (23)$$

$$d_3 = (b_1+b_3)^2T_c + a(b_1+b_3)^2T_a - (b_2-b_3)^2T_ga/(1+a) \quad (24)$$

Substituting (21) in (19), we can obtain the maximum thermoeconomic limit for a reversible absorption chiller. Substituting (21) in (15), we can obtain the specific refrigeration load (r_F) for the maximum thermoeconomic criterion. Three parameters $F_{\max}, r_F, \varepsilon_F$ are important for the optimum design of reversible absorption chillers. These parameters result in the lowest value of COP and the lowest value of the characteristic refrigeration load and the top limit of the thermoeconomic criterion [5,6,7].

3. Investigation and conclusion

In order to examine the thermoeconomic of the cycle and the impact of its different parameters, a case study was analyzed and the obtained circumstances were compared with each other. The following data were known for the aforementioned case study.

$$T_g = 403K, T_e = 293K, T_c = 313K, T_a = 305K, a = 1, U_1 = U_2 = U_3 = U_4 = 0.5\frac{KW}{K.m^2}$$

By changing any of the following parameters, we take other parameters as constant and equal to the values mentioned above. The characteristic charts of the problem at hand were obtained using the above data. Figure 2 shows the thermoeconomic criteria versus the coefficient of performance of a reversible chiller with $k = 1\frac{KW}{m^2}$. The value of the maximum thermoeconomic criterion $(F_{\max})$ can be obtained from this curve. As you can see, this chart consists of two sections with negative and positive slopes. The part which has a negative slope represents the optimum region for operation of absorption chillers. In figure 3, variations of the thermoeconomic criterion in terms of the characteristic refrigeration load is shown. Here too, we have $k = 1\frac{KW}{m^2}$. From this curve one can easily obtain the maximum value for the thermoeconomic criterion $(F_{\max})$ and the maximum refrigeration load $(r_{\max})$. This curve has three parts. It is obvious that the optimum working conditions for absorption chillers are in the region with negative slope.

Figures 2 and 3 can help one find the optimum region for operation of absorption chillers, which are the regions with negative slopes. This region should abide by the following conditions:

$$F_r \leqslant F \leqslant F_{\max} \quad (25) \qquad \varepsilon_F \leqslant \varepsilon \leqslant \varepsilon_r \quad (26) \qquad r_F \leqslant r \leqslant r_{\max} \quad (27)$$

Where F_r the thermoeconomic criterion for the maximum refrigeration is load $(r_{\max})$ and ε_r is the COP for the maximum value of characteristic refrigeration load for the reversible absorption chiller which can be obtained from the following equation:

$$\varepsilon_r = \left[1 - \sqrt{1 - \frac{(1+a)T_g^{-1} - T_a^{-1} - aT_c^{-1}}{T_a^{-1} + aT_c^{-1} - (1+a)T_e^{-1}} d_4}\right] d_4^{-1} \quad (28)$$

Where:

$$d_4 = \frac{(1+a)\{(1-b_1)^2[T_e T_c + aT_e T_a - (1+a)T_a T_c] + (T_g - T_e)d_2\}}{T_e^2[T_a^{-1} + aT_c^{-1} - (1+a)T_e^{-1}]d_3} - 1 \quad (29)$$

Substituting 28 in 19, we can obtain the maximum value for the characteristic refrigeration load. Moreover, by substituting 28 in (15), we can obtain the value of the thermoeconomic criterion for the maximum characteristic refrigeration load, (F_r). The values of the parameters which influence the operation of the cycle are changed and their effects on the cycle are compared. Figure 4 shows the characteristic curve of the thermoeconomic criterion-coefficient of performance for four different values of the thermoeconomic criterion (k) and figure 5 shows the characteristic curve of the thermoeconomic criterion – refrigeration load for the same four values of the thermoeconomic criterion. We can deduce from these curves that the optimum thermoeconomic criterion for a known value of COP, the thermoeconomic criterion for a specific capacity of refrigeration and optimum coefficient of performance and characteristic refrigeration capacity for a known value of the thermoeconomic criterion, all reduce by increasing the thermoeconomic parameter (k). Figure 6 shows the characteristic thermoeconomic parameter- coefficient of performance curve for four different values of total rate of distribution on heat output (a) and figure 7 shows the characteristic thermoeconomic criterion-refrigeration load curve for the same four values of the total rate of heat output.

It can be deduced from these curve that the optimum thermoeconomic criterion for a known value of COP, the thermoeconomic criterion for a special refrigeration capacity and the optimum coefficient of performance, and the characteristic refrigeration performance for a known value of thermoeconomic criterion all decrease by increasing the total heat output distribution rate (a). As it is evident from figure 7, t he maximum value for the thermoeconomic criterion and its corresponding coefficient of performance, reduce by increasing the thermoeconomic parameter (k) and the specific refrigeration load corresponding to the maximum thermoeconomic criterion increases by increasing the thermoeconomic parameter (k).

4. Conclusion

In this paper, the performance of absorption chillers with four reversible heat sources was analyzed and optimized with the existing relationships. The range of the important parameters for the absorption cooling cycle with four reversible heat sources for its optimum operation was determined. The obtained results can be used as a theoretic guide for further studies on the thermoeconomic optimization and further development of performance of absorption chiller cycles.

Abstract: A mathematical process integration model for the steam generation part (recovery boiler, bark boiler, and turbine) was developed based on a pulp and paper mill in the Northern Sweden. The material and energy balances were calculated theoretically and then the operation data from a pulp and paper mill in the Northern Sweden were used to validate the simulation results. By implementing it into the whole plant, the effect of the operation conditions on the whole plant performance were investigated. The introductory studies were carried out with an objective function to minimize the energy cost. The influence of different parameters was rigorously studied. The correlation between economic and energy optima was discussed.

Keywords: *Pulp and Paper Mill, Steam Generation, Simulation, Optimization*

1. Introduction

The pulp and paper industry is a very energy-intensive industrial sector where it is crucial to improve the material and energy efficiency to the greatest possible extent. Process integration methods represent useful tools for evaluating possible process alternatives. Many process integration studies in the pulp and paper industry have previously been carried out mainly by using Pinch analysis[1,2] and mathematical programming[3,4]. However, the scope of modeling and simulation of the energy and material balances is not as complete as it is in other modern process industries. More detailed work is required especially as large efforts are currently put on turning pulp mills into bio-refineries.

Based on the mixed integer linear programming (MILP) combined with ReMIND[5] and CPLEX[6], mathematical process integration models of steelmaking industries have been developed in our research groups. The developed model has been successfully applied, for example to give suggestions on choosing a new blast furnace, to reduce the CO_2 emission by using alternative production routines, etc[7,8]. Recently, the research work has been extended to mining industries also[9,10].

To extend researches to pulp and paper mill, a complete plant model was developed based on a pulp and paper mill in the Northern Sweden and described briefly in our previous work[11]. In this work, a mathematical process integration model for the steam generation part (recovery boiler, bark boiler, and turbine) was developed in which the material and energy balances were performed theoretically and the operation data (measurements) from the mill were used to validate the model results, which was presented in detail. By implementing it into the complete plant model, the effects of the operation conditions in the steam generation part on the whole plant performance were investigated. Furthermore, introductory studies were carried out with the main objective to minimize the energy cost, and the correlation and differences between economic and energy were also discussed.

2. Process description and model construction

The pulp and paper mill in the Northern Sweden is illustrated in Fig. 1. The lignin is removed to produce the brightness pulp by passing through the digester, O_2 delignification, and

bleaching plant. Paper is produced from pulp in paper making section. The by-product extracted from pulping chips in the digester, i.e. the black liquor, is concentrated in a multi-effect evaporation plant and burned in a recovery boiler (RB) where the combustion of organics provides energy and recovers chemicals which are used to generate the solution of NaOH and Na_2S by passing through the causticizing plant. Bark boiler (BB) provides additional high pressure steam to satisfy the steam demand for the whole plant. The high pressure steam produced in the RB and BB is expanded in a steam turbine producing process steam of 10 and 4 bar. Steam of 30 bar is extracted from the turbine for soot-blowing in the RB and steam 10 bar is used for soot-blowing in the BB. Biomass in form of bark or forest residues and fuel oil are used in the BB. Fuel oil is also used to start up the RB.

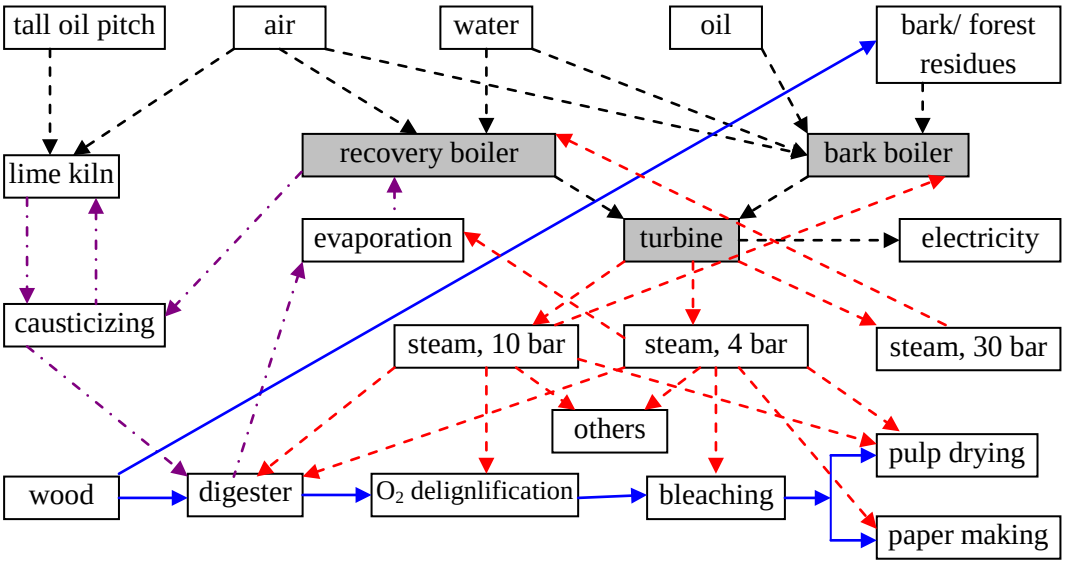

Fig. 1. Schematic representation of the pulp and paper mill.

To perform the process integration, each process unit was modeled as separate modules and thereafter linked. The construction of modules was based on a mathematical programming, i.e. mixed integer linear programming (MILP), and the equation editor used was a Java based programming — ReMIND[5]. In ReMIND, the model structure is represented as a network of nodes and branches, which represent process units and energy/material flows, respectively. The different nodes are connected depending on the input and output to/from each process unit. Each node contains linear equations to express the energy and mass balances required in the process unit. There are two options to express the energy and mass balances for each node, i.e. representing theoretically (option one), or obtaining an equation from the operation measurement under a set of conditions (option two). We chose the option one. The steam generation part including RB, BB, and back pressure turbine is the heart of energy utilization in the plant, and it was studied in the present work.

For RB and BB (boilers), the energy and mass balances were estimated from the chemical compositions of the fuels, the effective heat value of the fuels (H_{eff}) and the corresponding thermodynamic properties of all the related flows. This has been described in detail in literature[12] under operation conditions, such as the temperature of water, air, and flue gas, and the temperature and pressure of steam generated. From the chemical composition of the fuel and the amount of the excess air, the air demand and the amount of flue gas were calculated based on the mass balances. The fuel demand (ton fuel/ ton steam) was calculated from the air demand, the amount of the flue gas, the heat value of fuels together with

conditions for the air, flue gas, water and steam. The principle was briefly summarized in Fig. 2, and the brief description was given in the following text. The properties of the fuels and the related heat capacities were taken from public references and listed in Tables 1 and 2, respectively.

Table 1. Properties of fuels.

	C	H	O	S	Na	K	Slagg	N	H_2O	$H_{eff,dry}$, kJ/kg
black liquor	36.4	3.7	34	5.2	19.9	0.8	0	0	0	12400
fuel oil 5	85.9	11.4	0.9	1	0	0	0.03	0.3	0.5	40700
forest residues	51.9	6.15	40.5	0.02	0.05	0.3	0.86	0.22	0	19300

Table 2.Heat capacity.

substance	heat capacity (kJ/(kgK))		heat capacity (kJ/(Nm^3K))
black liquor	3.74	air	1.29
Na_2CO_3	1.09	flue gas	1.40
Oil	1.92		
bark	2.97		

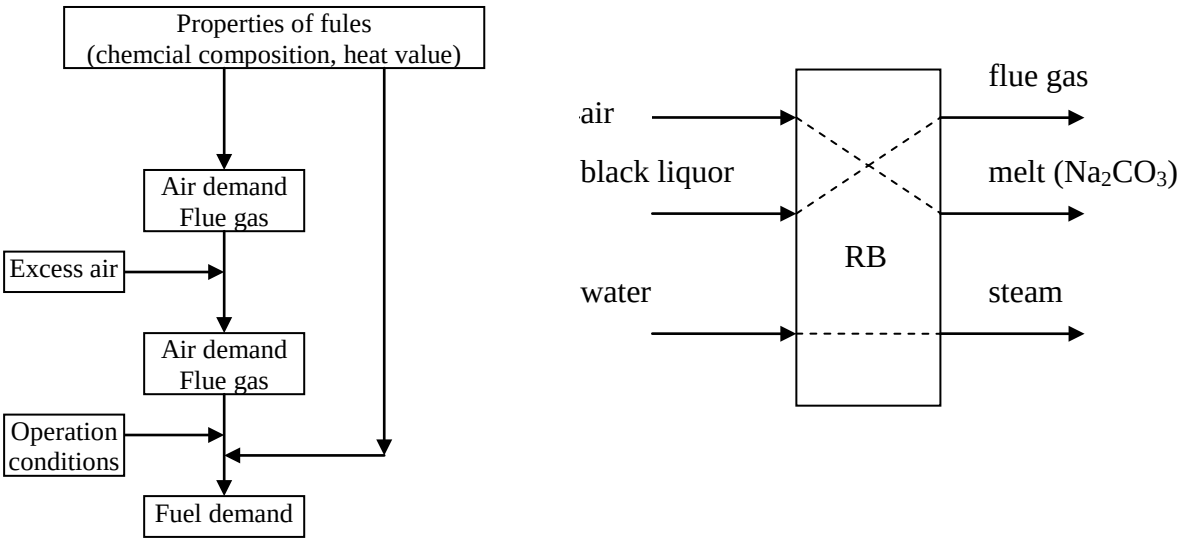

Fig. 2. Schematic representation of mass and energy balance for RB and BB.

$$f_{air,\min} = 22.7 \cdot \left(\frac{w_C}{12} + \frac{w_H}{2} + \frac{w_S}{32} - \frac{w_O}{32} \right) \quad (1)$$

$$f_{air} = f_{air,\min} \cdot (100 + c\%)/100 \qquad \text{m}^3\text{(n)/kg dry fuel} \quad (2)$$

$$f_{flue\ gas} = 22.7 \cdot \left(\frac{w_C}{12} + \frac{w_H}{2} + \frac{w_{H_2O}}{18} + \frac{w_S}{32} + \frac{w_N}{28} \right) + f_{air,\min} \cdot \left(\frac{0.791}{0.209} + c \right) \text{m}^3\text{(n)/kg dry fuel} \quad (3)$$

where f is the flow rate, w is the composition in mass fraction, and c is the excess air in percentage. The flow rate of the flue gas in Eq. (3) is based on the assumption that all the

elements of C, H, S, N will leave the boiler as the flue gas. However, in some case, some elements may leave the boiler more than one form. For example, in the recovery boiler, the elements of C and O leaves boiler as the flue gas and melt in the form of Na_2CO_3. In this case, the following equation was used:

$$f_{flue\ gas} = 22.7 \cdot \left(\frac{w_C}{12} + \frac{w_H}{2} + \frac{w_{H_2O}}{18} + \frac{w_S}{32} + \frac{w_N}{28} \right) + f_{air,\min} \cdot \left(\frac{0.791}{0.209} + c \right) - f_{CO,melt} \qquad (4)$$

where $f_{CO,melt}$ is the consumption part because the element of C and O leaves in the form of Na_2CO_3 (Na+C+O $\rightarrow$ Na_2CO_3). To calculate the flow rate of Na_2CO_3, the totally amount of Na is assumed to be the summation of those for Na and K. Based on the mass balance, we got Eq. (5) in which *TS*% is the dry content of black liquor, and we assumed the same flow rates for water and steam, i.e.: $f_{water} = f_{steam}$.

$$f_{Na2CO3} = 0.53 \frac{\left(w_{Na} + w_K \right)}{\left(1 + \frac{1 - TS\%/100}{TS\%/100} \right)} \qquad \text{(kg/kg wet fuel)} \qquad (5)$$

To represent the energy balance, the reference temperature was chose as 20 °C, and the enthalpy for the components except water and steam at a certain temperature was calculated with the Eq. (6) where *f* is the flow rate, C_p is the heat capacity, and *t* is the temperature in °C:

$$h = fC_p(t - 20) \qquad (6)$$

In ReMIND, the equation representing mass and energy balances should be linear, while the enthalpy of water or steam depends on both temperature and pressure. Therefore, the enthalpies of water/ steam at different temperatures and pressures were calculated firstly from the NIST online database[13] and then the calculated enthalpies were fitted to an equation that is a function of temperature and pressure by assuming the pressure effect is a linear. The fitted equation was input in the equation editor in ReMIND. For water, we obtained:

$$h = (4.2354t + 0.892) + (0.1008 - 2.51 \times 10^{-4} t)(P - 75) \qquad \text{(kJ/kg)} \qquad (7)$$

where *P* is the pressure in bar. For high pressure steam (60 bar), we obtained:

$$h = (2216.2 + 2.4309t) + (7.76 \times 10^{-3} t - 4.94)(P - 55) \qquad \text{(kJ/kg)} \qquad (8)$$

The total energy balance for the RB was:

$$h_{air} + h_{blackliquor} + f_{water} h_{water} + f_{blackliquor} \cdot h_{heatvalue} + h_{heatloss} = h_{fluegas} + h_{melt} + f_{water} h_{steam} \qquad (9)$$

For the BB, we neglected the energy in ash, and the flow rate of the flue gas was calculated with Eq. (3), and total energy balance was:

$$h_{air} + h_{fuel} + f_{water} h_{water} + f_{fuel} \cdot h_{heatvalue} + h_{heatloss} = h_{fluegas} + f_{water} h_{steam} \qquad (10)$$

The mass and energy balances for the turbine are much easier to generate compared to those for the boilers. The enthalpies of steams were obtained with the same method as those in the boilers, and results for medium pressure steam (30bar), low pressure steam at 10 bar, and low pressure steam at 4 bar were shown as Eqs. (11), (12), and (13), respectively.

$$h = (2313.5 + 2.3058t) + (1.395 \times 10^{-2} t - 7.15)(P - 28) \quad \text{(kJ/kg)} \quad (11)$$

$$h = (2400.1 + 2.1856t) + (2.910 \times 10^{-2} t - 11.00)(P - 9) \quad \text{(kJ/kg)} \quad (12)$$

$$h = (2443.9 + 2.1157t) + (8.06 \times 10^{-2} t - 20.5)(P - 3) \quad \text{(kJ/kg)} \quad (13)$$

The material and energy balances for the turbine were:

$$f_{60bar} = f_{30bar} + f_{10bar} + f_{4bar} \quad (14)$$

$$f_{60bar} h_{60bar} \eta = f_{30bar} h_{30bar} + f_{10bar} h_{10bar} + f_{4bar} h_{4bar} + EL + h_{loss} \quad (15)$$

where the flow rate of the 30 bar steam was obtained from the plant, and η is the mechanical efficiency, and h_{loss} is the heat loss, and EL is the electricity generation in MW.

3. Model validation and process integration

The developed model for the steam generation part was implemented into the complete plant model in our previous work[11]. By running the process integration model for the complete plant, the model results were compared with the operation measurements for the model validation. To run the process integration model, an objective function has to be set. In the present work, the objective function was the minimization of the energy cost for the studied pulp and paper mill, and the prices of fuels and electricity used were the same as those we set in our previous work[11].

3.1. Model validation

For the RB, by assuming the heat loss 3.5% and 5% excess air with a certain flow rate of black liquor, the process integration was carried out. The steam generation calculated from model is 220.9 ton/h which is 3.8% higher than the measurement from the mill. For the BB, by assuming the heat loss 3.5%, 5% excess air and 45% dry content of bark, the ratio of the steam generation to bark consumption (dry) calculated from the model is 5.15 ton steam/ ton dry bark, and the corresponding measurements from the mill is 6.07 (ton steam/ ton dry bark). The discrepancy for the BB may be from assumption of the dry content of bark. Generally, the dry content of the bark is from 40 to 50%, and the bark consumption increases with increasing water content of bark. For the turbine, by assuming the mechanical loss 5%, the model calculation agrees well with measurements.

3.2. Process integration

The running of the BB is to satisfy the process steam demand for the whole plant. The operation conditions in the RB will affect the energy consumption for the RB itself, and then affect the performance of the BB. While the operation conditions in the BB will only affect the performance of the BB.

For the RB, the temperature of the flue gas, the temperature of the liquid into the RB, the temperature of the water into the RB, the amount of the access air, the temperature of the air, the water content of the liquor, and the heat loss of the RB will affect the steam generation from the RB. Since the RB is insulated well, the heat loss may be in the range of 1 to 5%. Meanwhile, the amount of the excess air may be from 5% to 15%. The model calculation results show that the variations of these two operation conditions do not affect the performance of the RB a lot, and the discussions were not shown. In addition, the influence the water content of the liquor to the RB has been discussed in our previous work[11].

Fig. 3 illustrates the influence of the temperature of the flue gas on the performance of the RB and the BB. The utilization of the waste heat from the flue gas is very promising. If the temperature of the flue gas decreases from 250 to 125 °C by using heat exchanger to exchange the heat with flows to the RB, the steam generation will increase from 215 to 232 ton/h, and the corresponding bark consumption (wet basis) will decrease from 22.6 to 15.6 to/h. How to utilize the waste heat is a big challenge, and the following text will give the discussion.

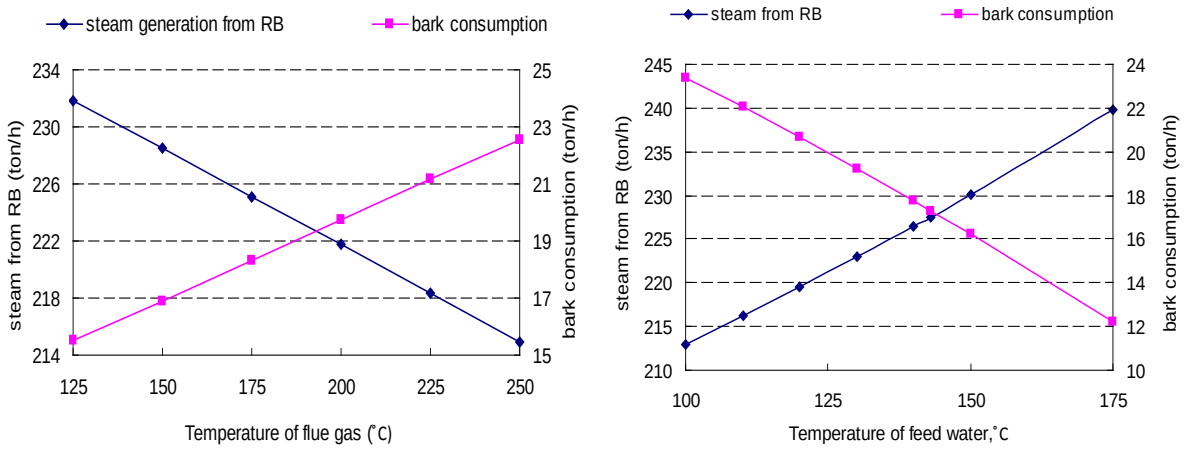

Fig.3. The effects of temperature of flue gas and feed water on the performance of the RB and the BB.

The influence of the temperature of the water on the performance of the RB is also shown in Fig. 3. If the temperature of water increases from 100 to 175 °C, the steam generation from the RB will increase from 213 to 240 ton/h, and the corresponding bark consumption will decrease from 23 to 12 ton/h. This is one possibility to utilize the waste heat in the flue gas. Sometimes, the waste heat from flue gas may not be enough to preheat water, which means that how to reasonably use the waste heat for the whole plant to preheat water is a vital issue to save the energy. On the other hand, the improvement of process performance by adding new heat exchangers and/or changing the existing routines always requires additional investment. It is worth or not? The model results can provide the possibility for the process improvement, and then make the cost estimation to help people to make a decision, which is just the goal of our work.

The temperature of the liquor to the RB will affect the performance of the RB and BB. When the liquor leaves from the evaporation plant, the temperature of the liquor is around 125 °C. From the energy point of view, if the temperature of the liquor can be further increased, the steam generation from the RB will be increased obviously as shown in Fig. 4. However, from the practice point of view, the temperature of the liquor should be lower than the boiling temperature of the liquor which is around 130 °C. Because of this reason, the insulation of the

pipe for the black liquor distribution from the evaporation plant to the RB is very important. For example, if the black liquor is cooled to 100 °C to enter the RB, the steam generation will decrease to 3.5 ton/h and the bark consumption will increase 1.5 ton/h compared to 130°C.

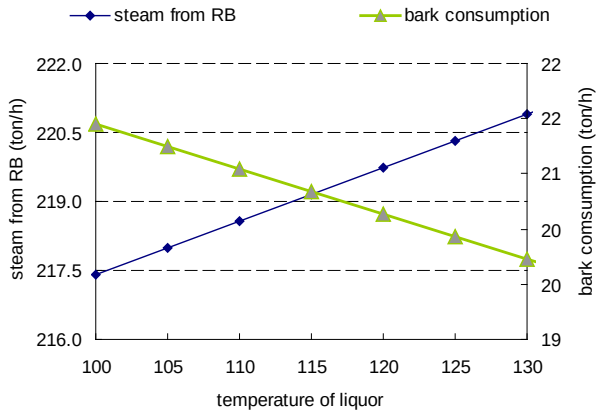

Fig.4. The effect of the temperature of the liquor on the performance of RB and BB.

For the BB, the influences of the temperature of the flue gas, the temperature of the water into the boiler, the amount of the excess air, the temperature of the air, and the heat loss of the boiler on the performance of the BB is the same as those for RB. The effects of the temperature and the water content of the bark are illustrated in Fig. 5, respectively. The increases of temperature of the bark will decrease the bark consumption. Although the energy saving is not so obviously, but it should be very easy to increase the temperature of the bark from 20 to 80 °C. On the contrary, the effect of water content on the bark consumption is considerable, and this explains the possible reason for the discrepancies of the model results from the measurement in model validation part.

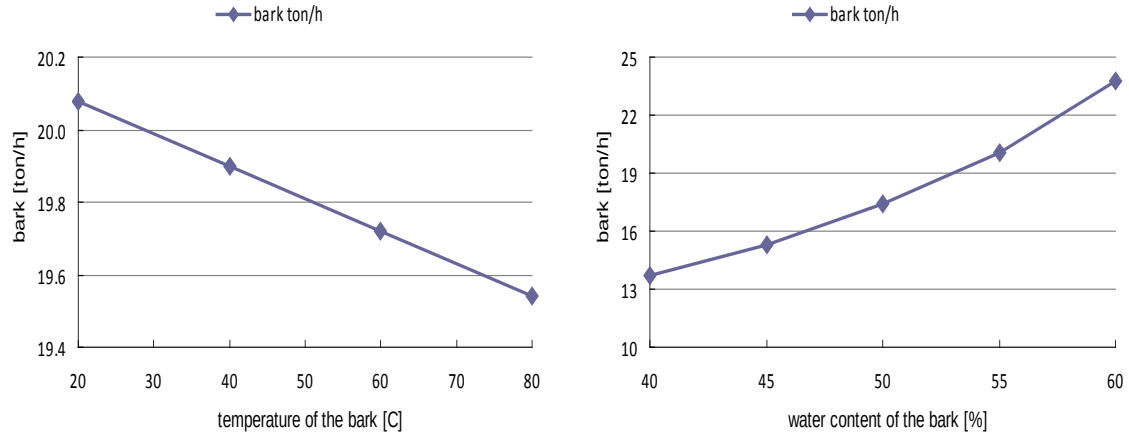

Fig.5. The effect of the temperature and water content of the bark on the performance of BB.

4. Conclusions

A mathematical process integration model for the steam generation part was developed. The material and energy balances were obtained theoretically. The model of the steam generation part was implemented into the previous developed whole plant model, and the model results of the steam generation part were validated with the operation data by running the process integration model with the low energy cost as the objective function. The effects of the operation conditions in the steam generation part on the whole plant performance were investigated. It shows that the utilization of the waste heat from the flue gas to increase the

temperature of the feed water into the boiler is an option to decrease the bark consumption, and the insulation of the pipes for the black liquor distribution from the evaporation plant to the RB is very important. For the BB, the water content of the bark affects the bark consumption considerably.

Abstract: Swedish companies have since 2003 been able to get certified by an energy management system (EEMS) and companies that have been certified, can now show savings in energy use. The downside of today's EEMs is that too few small and medium-sized enterprises (SMEs) have chosen to certify such a system in the organization. To increase awareness and interest among SMEs, a simplified version of the EEMS would be desirable. This article presents a simplified EEMs for SMEs developed from the original European standard (SS-EN 16 001). The article describes how the simple EEMS was developed and how the system was validated, i.e. how different companies responded to test-runs of the developed simplified EEMS. By testing the simplified EEMS in practice among various SMEs, different needs from the industry have been documented. The requests that were of greatest importance was how different incentives can be designed to increase the certification level, e.g. tax exemptions etc. The Swedish LTA for energy-intensive industries includes tax exemptions, as well as the certification of the European EEMS standard, and has shown to lead to large energy savings. An examples of a future energy policy could thus be a Long-Term Agreement (LTA)s program for SMEs including the simplified EEMS.

Keywords: *Energy management, SME, Industrial energy efficiency, PFE*

1. Introduction

Increased global warming is posing a major threat to global environment. The industry is a large emitter of carbon dioxide emissions, the major green house gas, and accounting for about 78 percent of the world's annual coal consumption, 41 percent of the world's electricity use, 35 percent of the world's natural gas consumption, and nine percent of global oil consumption [1]. Industrial energy efficiency is one of the most significant means of reducing the threat of increased global warming [2]. During the last decade, energy prices rose significantly for the Swedish industry. Between 2000 and 2006, electricity prices in Swedish industry almost doubled and oil prices rose by about 70 percent [3]. Even more price increases are to be expected, not least as a consequence of planned tax increases in the nation. The electricity price increase has partly been due to the liberalization of the European electricity markets. The liberalization caused the domestic markets to converge and Sweden has for a long time enjoyed one of the lowest electricity prices in Europe, see, e.g. [4]. Oil price increases may not create competitive disadvantages solely for Swedish industry. Electricity price increases on the contrary most likely will. This is particularly related to the Swedish industries and the fact that the historically low electricity prices have resulted in a higher use of electricity than for their European competitors in many Swedish industrial sectors, see [4] for a comparison in the European foundry industry.

Two main means exist of overcoming the threat of rising energy prices for the Swedish industry. One is to focus on managing the energy supply side with diversified portfolios etc. and, the other means is energy management focusing on a reducing energy end-use at the company. In regard to the latter, an EnErgy Management System (EEMS) may be a tool supporting companies in this important work. However, for most companies, not the least small- and medium-sized enterprises (SMEs), the certification of an EEMS is far too costly. The cost for an EEMS certification in Sweden is approximately 8 000 EUR. The need for

developing an EEMS for SMEs can thus not be understated. The aim of this study has been to develop an EEMS for SMEs. The conducted research has been inspired by the European standard for EEMS but is a stand-alone product with a graphical interface. The paper is outlined as follows. Initially, the background to the paper (introduction) is presented, followed by a presentation of energy efficiency in SMEs, and a presentation of the methodology. After that, the developed EEMS is presented, and finally, results and major conclusions are presented.

2. Energy efficiency in SMEs

Even though energy management is stated to be an important means for reducing industrial energy costs and reducing negative environmental impact [5-6], with some exceptions, e.g. [5-10], energy management in industry may be considered a scarcely researched subject. In regard to SMEs having limited resources to work with energy efficiency and energy management, a full-scale, in-house energy management program may not be justifiable [11]. For example, the cost of an energy management program, e.g. certification of an EEMS etc., may be in parity with the annual energy cost at an SME. A simplified EEMS for SMEs could thus be a means for increased energy management practices.

In Sweden, a few studies on barriers to energy efficiency among SMEs have been conducted [4,12-13]. Major barriers include: lack of time or other priorities/other priorities for capital investments, lack of access to capital/lack of budget funding, cost of production disruption/hassle/inconvenience, technical risk such as risk of production disruptions, difficulty/cost of obtaining information on the energy use of purchased equipment [9,22-23]. High-ranked barriers to energy efficiency among SMEs such as lack of time and other priorities, outlines the need for support, support which should not be too costly due to the barriers lack of access to capital, and moreover should involve information (difficulty/cost of obtaining information) [9,22-23]. A simplified EEMS developed for SMEs may overcome many of the barriers to energy efficiency and facilitate the adoption and governance of energy management in the sector.

3. Methodology

Swerea SWECAST conducts a research project named ENIG (Energy Efficiency In Group) together with Swerea IVF and FSEK (Association of Swedish Regional Energy Agencies). Project ENIG includes a number of research and development tasks to promote energy efficiency in Swedish industry [14].

A task in the project ENIG is "To develop a simplified EEMS for SMEs ", which means that a system promoting industry for energy efficiency will be developed based on the existing European standard for energy management systems, EN 16001. The new EEMS will serve as guidance for companies in their work with management systems. Most companies that have adopted energy management are outside the definition of SMEs. The reason for this is that many companies lack the resources to establish management systems, but also the lack of incentives that could increase the level of certification within the SMEs.

At a later stage, there are expectations that the simple EEMS in turn could help SMEs with the introduction of the real European standard, EN 16001, or the coming international standard ISO 50001 [15] .

SIS Publishing Co. owns the copyright to SS-EN 16 001 and because of legal reasons, an interconnection with the original standard had to be excluded. The application has been developed considering that it could be upgraded meaning that SMEs could get certified according to SS-EN 16 001. The management system is based on the PDCA-method (Plan-Do-Check-Act-method). Figure 1 shows an illustration on the PDCA-method and how it leads to continuous improvement.

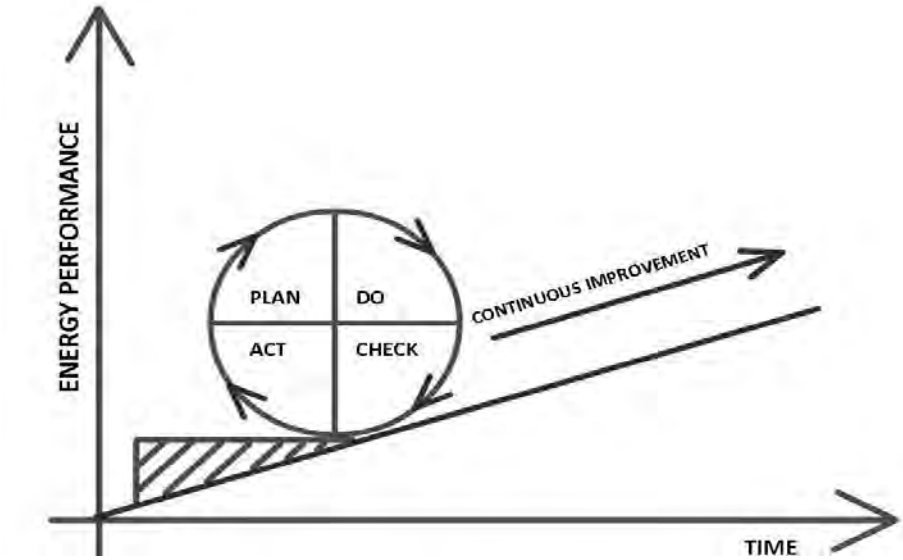

Figure 1: Continuous improvement with the PDCA-method. [16]

The simplified EEMS is built using lean production as a way of thinking when introducing energy use in EEMS [17] and its graphical interface is developed using Adobe Flash and Adobe Acrobat. It is developed as a presentation of the EEMS, and the SMEs should by working through the presentation; learn how to start working with EEMS. The simplified EEMS is more or less a self-learning system. To make the program more interesting and user-friendly, focus on how to build the interface resulted in the use of Adobe Acrobat. The EEMS program takes the user through the EEMS step by step by linking the slides with each other. The linking is made following the PDCA-method, see figure 2.

To improve the simplified EEMS even more, different companies in different sectors were visited and were asked to test-run the program. Interviews were held concerning how the SMEs would like to work with a management system and why they didn't certify in accordance with the original standard. During the test-run, the EEMS was demonstrated and a review on how it differed from the real standard was explained. The results were documented and from the testing results, changes were made in the EEMS. The testing of the simplified EEMS was divided into two phases, the first one with companies that have worked with EEMS for a while and have experience on how to organize their work with energy improvements. The second phase included SMEs, mainly without any experience with management systems. With results from the site visits and test runs, the EEMS could be developed even further and included a validation of the developed program, i.e. how compatible it was in practice for SMEs.

4. Results – simple EEMS program

SMEs can benefit from a simplified EEMS, because they usually have lack of resources and time to look for the best practices that are relevant to their sector [18]. Figure 2 shows how the system is built and how every part of the system is linked together.

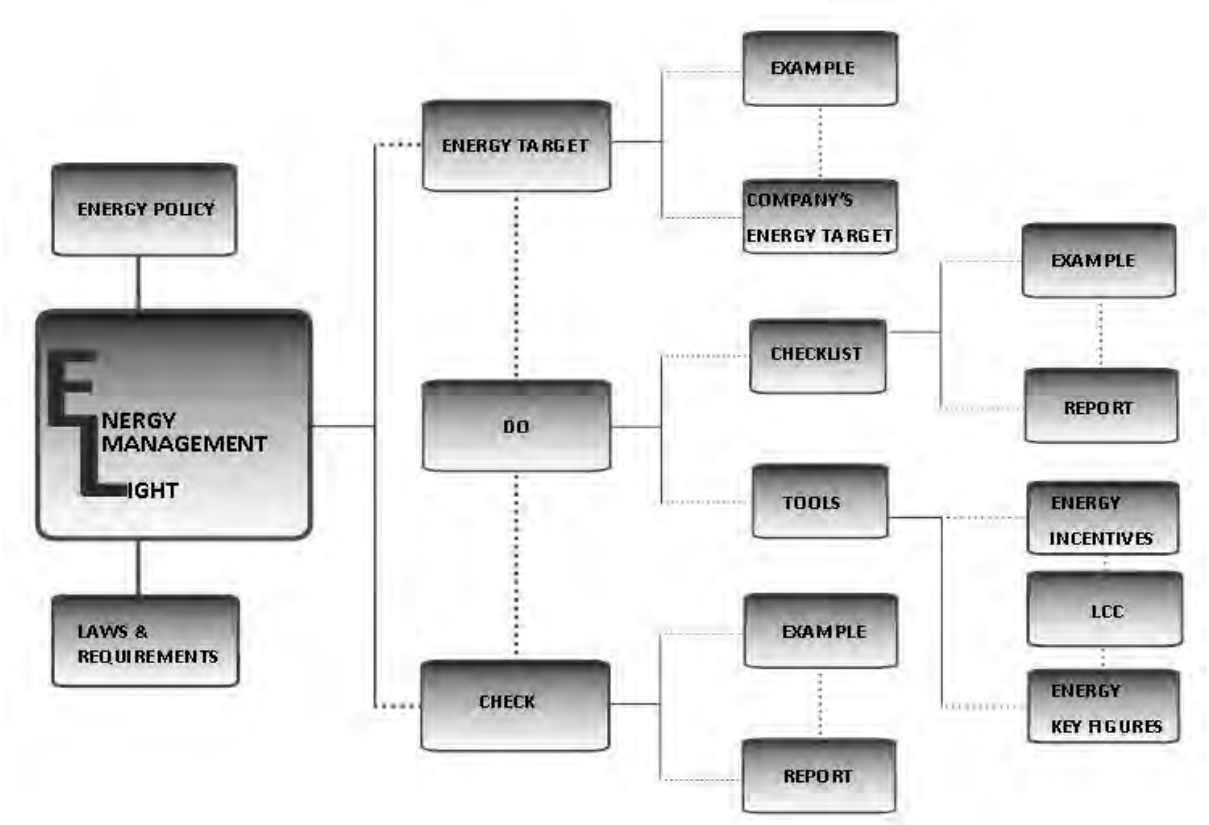

Figure 2: How the different parts from the simple EEMS are linked together.

To implement the simplified EEMS, companies should go through the management system in the following order:

1st. Energy Policy: The company should define an energy policy. Some requirements for an energy policy are that, it should be simple, easy and possible to communicate to everyone in the company. The Energy Policy will be the document that is published and it shows how the company plans to work with energy efficiency. It is important to write an easily understandable to understand policy and it is desirable that all the staff from the company agrees on what is expressed in the policy.

2nd. Laws and standards: Update the laws and requirements that could affect the company's work. Documenting a record of national, but also international laws and standards is a way to identify what rules the company should adjust its energy use for. The laws and requirements that concern the company will be documented and saved for future monitoring.

3rd. Implementation: The implementation part of the EEMS consists of two parts, checklist and energy tools. Introducing a checklist could be used as guidance for companies in their energy use, see figure 3. By introducing different energy tools in the company, they will have more alternatives to improve the work with energy efficiency. The energy tools that the company could use in their energy work are energy incentives, LCC and key energy figures etc.

4th. Follow up: In the follow-up, companies should review their results, through a review of the energy management practices conducted. The review should address the energy policy and work with energy efficiency at the company. In order to facilitate the revision an example

paper was developed to show which parts that are the most important to review. A proper follow up of the management system should find different discrepancies that exist in the energy targets. By eliminating the discrepancies, companies could improve their level of energy efficiency.

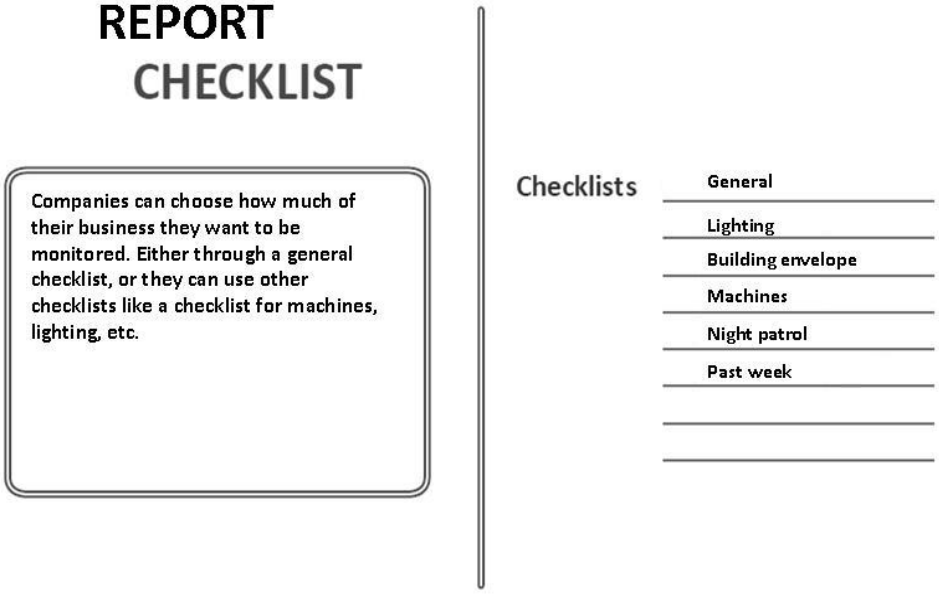

Figure 3: How EEMS presents the different checklists.

5th. Continuous improvement: The companies should always work with continuous improvement of the simple EEMS, see figure 4.

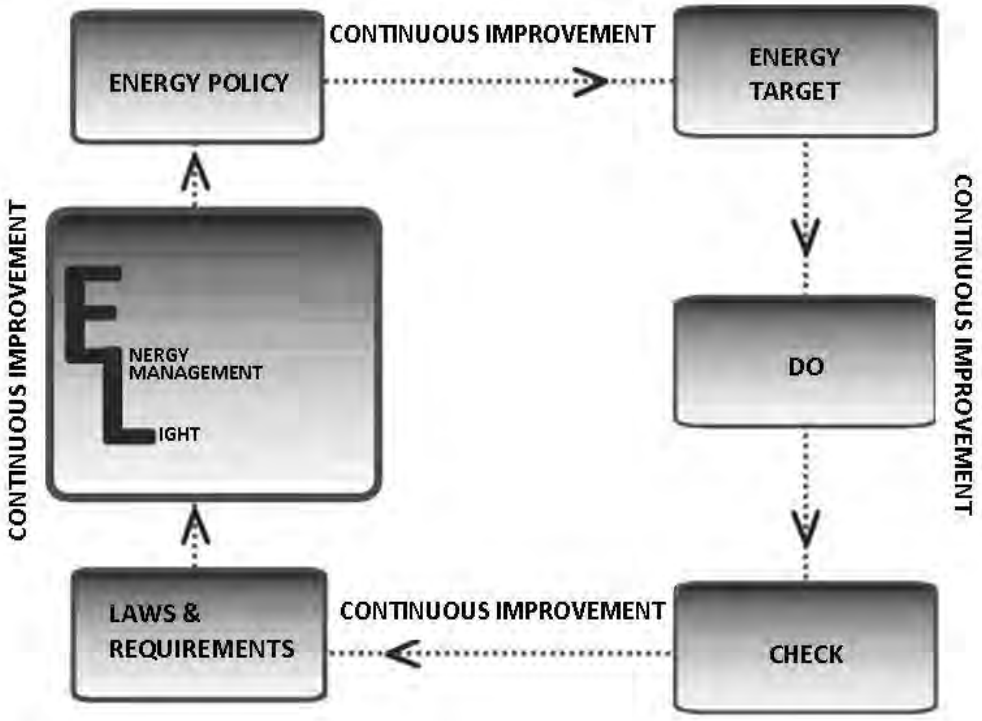

Figure 4: Continuous improvement of the simple EEMS.

If the company wants to do an effective work with their management system they have to dare to act and improve. In order to improve the simplified EEMS, anomalies in the system could be reduced and the the energy efficiency could be increased.

4.1. Validation of the developed EEMS program

Test runs of the simple EEMS have contributed to a continuous improvement of the program on how they would like to use an energy management system.

In early development of the simple EEMS, people with a greater insight on how to work with management functions were visited. The people who attended the first testing may be seen as either energy experts at the Swedish Energy Agency or staff from large industries with a well-known reputation from decades of successful energy management practices.

The improvements that were made during the test runs in the first phase were how the simplified EEMS could be more easily understood and user friendly. An idea from one of the industrial respondents was that if companies were trying to work according to the lean-production philosophy, they would automatically understand how EEMS is supposed to work. By implementing a presentation on how lean production and EEMS are linked together a more user friendly approach could thus be achieved.

During the meeting with respondents from the Swedish Energy Agency, ideas resulted in adapting checklists in the simplified EEMS, arguing that a checklist is an easy way to do an energy audit of the energy use in a SME. The meeting with another industry respondent helped to develop an EEMS towards a more user-friendly interface. The respondent working full time with certified environmental and energy management systems could contribute with thoughts and ideas about how the workflow should be improved.

After the site visits and meetings with respondents at the Swedish Energy Agency, the EEMS was now ready to go into phase two, which was testing the EEMS among SMEs. Four companies were visited during the test phase.

Feedback from the test runs in phase two was solely positive. The test-runs gave a useful view on how the SMEs would like to work with an EEMS. All of the four companies thought that the simplified EEMS was easier to use, smoother, based on common sense and required less resources to implement than the original SS-EN 16 001.

The Swedish LTA for energy-intensive industries includes tax exemptions, as well as the certification of the European EEMS standard (SS-EN 16 001), and has shown to lead to large energy savings (about 1.4 TWh electricity annually). A request from one of the company respondents test runs was to use the simplified EEMS in an LTA (Long-Term Agreements) specially tailored for SMEs in the future. The main reason why the company participating in the test-run did not participate in the current LTA was due to too high certification EEMS costs.

5. Conclusion

This work together with previous research by Thollander and Dotzauer (2010) [11], indicates that a simple and less costly version of an EEMS is desirable among SMEs. By developing an EEMS suited for smaller organizations, it could help companies to increase their level of knowledge on how to organize their business in regard to energy management, and thus enabling increasing levels of energy efficiency in the company. Increased understanding of

energy management could contribute to more companies seeing the potential for energy efficiency and energy management.

Even if companies do not consider that they need an EEMS, a shorter training or insight into the simplified EEMS would help companies to realize the importance of organizing their energy management work. By trying to reduce inventories, increase productivity, improve quality, they can become more competitive and (energy) efficient in their business. Moreover, by increasing awareness on how production is managed, this may contribute to a reduction of energy use.

One incentive could be an LTA with tax exemption if companies used the simplified EEMS, like the Swedish PFE for energy-intensive industries.
PFE was found to show large energy savings among the participating companies and the project showed that companies succeed in saving energy through certification of an EEMS. However, PFE for SMEs should have greater demands for education and training in management systems and a required implementation of an energy audit. By informing companies how to use an EEMS, they could implement routines on how to use the data they receive through an energy audit.

According to the company-visits, the simplified EEMS program proved easy to use, none of the visited SMEs who made test-runs of the program thought it was inconceivable. However, more test-runs are needed to further shape the program into a final form. The estimation is that about 20 test runs would be needed to get an insight into how well the simplified EEMS performs among SMEs. Another interesting test-run, which was not performed, is to let a few companies use the simple EEMS for a longer period. This test run could be a good feedback on how well a simple EEMS actually works for a longer period and if the companies can achieve savings in their energy use.

A final conclusion is that a simplified EEMS can help companies to start implementing the measures that are deduced from an energy audit. An obstacle for energy audits to become useful is that they may end up in a "desk drawer", i.e. the company has not been able to use the new information. The main reason is that companies lack tools for how to deal with all of the new data obtained from an energy audit. By using a simplified EEMS, companies have now a tool that creates routines that measure and document their use of energy and their work to increase energy efficiency. Thus, companies can, through the developed program, achieve a support to spot inefficiencies in their energy use and realize that they can increase profits by reducing their energy use.

Abstract: The pulp and paper industry, with its wood biomass feedstock, has promising opportunities to become a key player in the biorefinery arena. A successful implementation of biorefinery pathways requires optimization of the energy system through process integration, and can lead to both increased and diversified revenues as well as a reduction of global CO_2 emissions. This paper presents the results from a pinch analysis of a partly integrated Kraft pulp and paper mill. The objective was to identify the potential for energy efficiency improvements, focusing on possibilities to save steam. Another objective was to identify practical retrofit solutions for the mill heat exchanger network and to estimate the costs for the required investments. The potential for energy savings at the mill is estimated at 18.5 MW, i.e. 12% of the current steam demand. Two alternative retrofit options are presented in the paper. A straightforward retrofit that is easy to implement enables 5.8 MW of steam to be saved at a cost of €0.13 million per MW of saved steam. A second more extensive retrofit option is also presented which could achieve steam savings of 11 MW at a cost of €0.14 million per MW of saved steam. Assuming that the steam savings lead to a reduced use of bark fuel in the power boiler, the pay-back period of both energy saving retrofit investments is estimated to be less than about 16 months.

Keywords: *Pinch analysis, Pulp and paper industry, Retrofit, Steam savings.*

1. Introduction

Extensive research aiming at improving energy efficiency and heat integration of pulp and paper plants has been conducted during the past decades. The pulping industry, with its wood biomass feedstock, has clear opportunities to become a key player in the biorefinery arena. Successful implementation of biorefinery concepts requires maximized heat integration, and can lead to increased and diversified revenues as well as reduced global CO_2 emissions.

There are many possible biomass conversion paths in biorefineries, including thermo-chemical, biochemical, mechanical and chemical processes. Thermo-chemical conversion usually involves gasification, pyrolysis or direct combustion, with significant excess heat flows at different temperature levels. Pinch analysis is an essential tool for investigating opportunities for heat integration both within the thermo-chemical biorefinery plant, and between the thermo-chemical biorefinery plant and other nearby industrial process plants with significant heat flows, such as a Kraft pulp mill.

Integration of biorefinery operations within a pulp and paper plant is a typical application of heat cascading, whereby heat for one plant is supplied by excess heat from another. Opportunities for biorefinery-related heat-cascading in the pulping industry have been widely discussed in the literature. A review report published in 2008 [1] discusses general issues for process-integrated biorefineries and also discusses the following specific examples:
Drying of biomass (e.g. forest residues, bark)
Pelletizing in connection with drying and forest residues leaching
Energy combine with ethanol production
Energy combines with other industries
A chemical market pulp mill with optimized energy consumption could achieve a surplus of energy which can be utilized to produce electricity, enable decreased firing of bark fuel in the mill's power boiler which can be dried and sold on the biomass fuel market, or enable

integration of appropriate biomass energy combine process concepts. An integrated chemical pulp and paper mill, on the other hand, needs to import energy, since the paper machine is a large consumer of heating steam. However, energy savings within an integrated mill also lead to economical savings and decreased environmental impact since they provide a way to reduce the fuel import demand. The mill studied here is a partly integrated pulp and paper mill which means that part of the produced pulp is sold as market pulp and the rest is used to produce paper. One objective of this study was therefore to contribute to the knowledge base about the energy situation in such a partly integrated pulp and paper mill. It is important to note that very few published studies in the literature address energy efficiency at partly integrated pulp and paper mills based on the Kraft process. Therefore, it is important to contribute to further development of the knowledge about the energy situation in this type of mill. The main objective of this work was to identify potential energy savings through pinch analysis at a partly integrated pulp and paper mill. The aim was also to suggest practical retrofit solutions for how to achieve a reduced energy demand, or alternatively, how to release excess heat at higher temperatures. The costs of the proposed measures were also estimated.

The results presented in this paper are based on the results of an MSc thesis project conducted by two students at Chalmers University of Technology in close co-operation with mill personnel at the Billerud Karlsborg mill. The thesis report by Eriksson and Hermansson, *Pinch analysis of Billerud Karlsborg, a partly integrated pulp and paper mill* [2] provides a detailed description of the work and results of the energy systems analysis.

The pinch study was part of a larger project conducted in co-operation between research groups at several Swedish universities[1], the Swerea MEFOS Research Institute and the pulp and paper mill Billerud Karlsborg. The aim of the project, hereafter called the Billerud project, was to establish a framework for process integration studies with a regional perspective in the pulp and paper industry. One of the objectives of the project was to improve co-operation between different institutions and actors who use and develop process integration tools such as pinch technology and reMIND (see for example reference [9]). The results of the pinch analysis presented in this paper are therefore planned to be used in connection with other models developed within the project. The opportunities for this model interaction are discussed in Section 5.2.

2. Methodology

This study was conducted using pinch technology, and it is assumed that the reader is familiar with the basic concepts. For a comprehensive description of the theory, the reader is referred to references [3] and [4]. The principal steps of the methodology are described below [5]:
Define the process stream system to be investigated with respect to opportunities for improved energy efficiency.

Extract stream data and establish energy saving targets using pinch analysis.
Analyze the existing heat exchanger network in order to identify pinch rule violations.
Make changes to the existing network so as to solve some of the pinch violations.
Evaluate the profitability of the proposed changes to the heat exchanger network.
Process data representing typical average winter operation was retained for the study. Most of the data required was available directly in the plant's process data-log, but some additional

[1] Energy Engineering at Luleå University of Technology, Business Administration and Social Sciences at Luleå University of Technology, Energy Systems at Linköping University, School of Natural Sciences, Linnæus University and Heat and Power Technology, Chalmers University of Technology.

measurements were needed. Manufacturer specifications, engineer estimations, and mass and energy balances were also used to complete the data set required. Stream-specific minimum temperature differences for heat exchanging and heat transfer coefficients were used in accordance with previous studies [5].

The costs of the proposed heat exchanger network retrofits were calculated based on area requirements, with surface area costs taken from recent pinch studies of similar mills [6]. The cost of piping was estimated at 50% of the installed heat exchanger cost based on typical cost estimation factors presented in [4], since the distances between streams were not investigated. Additional costs for e.g. instrumentation, control and pumping costs were also neglected.

3. Mill description

The studied mill is a partly integrated Kraft pulp and paper mill situated in northern Sweden, producing 300 000 tonnes/year of pulp and paper (40% pulp and 60% paper). Electricity is cogenerated in a back-pressure steam turbine unit. The mill was built over 80 years ago, but the main parts still in use were built in the early 1980's. Continuous energy improvements have been made during the lifetime of the plant. However, given the availability of new research results and the continuous changes of energy market conditions, it is of interest to re-investigate the potential for process integration and energy savings on a regular basis. Pinch analysis provides a good tool for this type of investigation and has now been used at the Billerud Karlsborg mill for the first time.

4. Results

4.1 *Theoretic potential for energy savings*

A large number of heat exchangers supplying heating or cooling to mill process streams were identified (27 cold and 35 hot streams). Adopting stream-specific values of $\frac{1}{2}\Delta T_{min}$ for different stream types, ranging from 0.5 K for utility steam to 8 K for air, the process pinch temperature is 148˚C. This means that the mill has a net deficit of heat above 148˚C and a net surplus below. The theoretical minimum external heating requirement is 135.4 MW.
The composite curves for the mill are shown in Fig. 1. The potential internal heat exchange is illustrated by the overlap of the hot and cold curves. In a theoretical case with maximum heat exchange between the curves, the hot streams should be able to provide all heat to the process except for the actual steam demand. Achieving this for a retrofit design would, however, require far too many new heat exchangers to be profitable.

In the grand composite curve (Fig. 2), the composite curves are merged. The horizontal line below the pinch represents the surface condensers, which provide about 41 MW of heat at 60˚C. This heat is currently used for warm water production from raw water. This heat could be released by making use of the hot streams in the heat pocket below the surface condensers' temperature. These streams are hot effluents from the evaporation and bleaching plant and outgoing air from the pulp dryer and the paper machine. There is also a heat pocket at around 70˚C which could enable heat integration for several streams in this region.

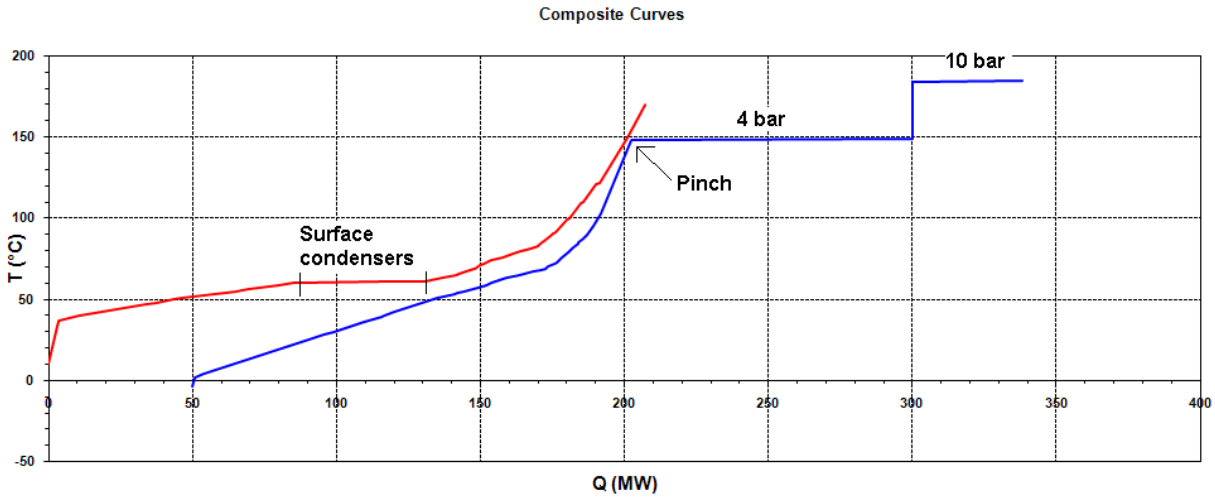

Fig. 1. Composite curves for the process.

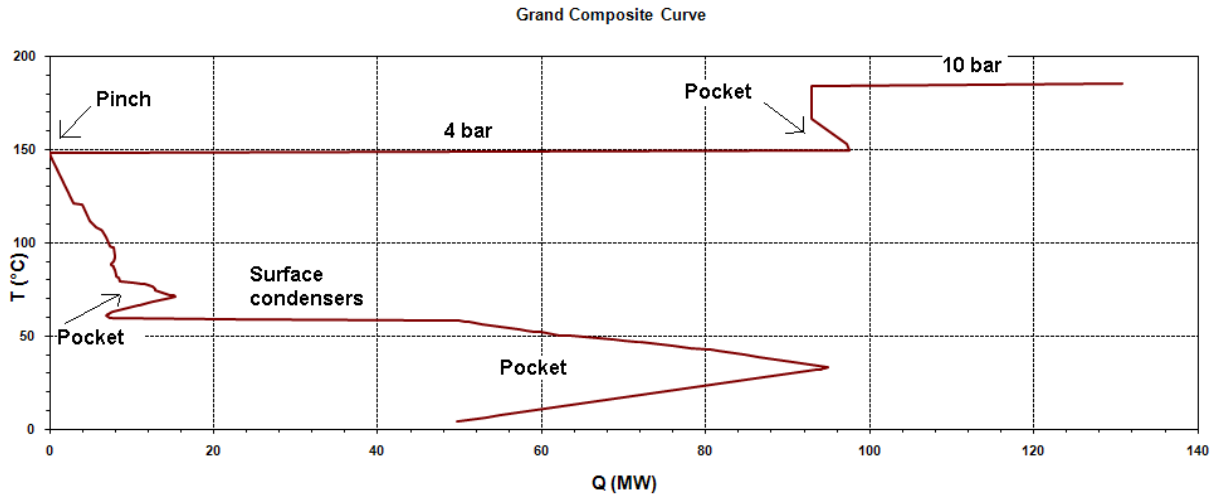

Fig. 2. Grand composite curve for the process.

4.2 *Pinch violations*

The difference between the actual steam demand and the minimum demand for hot utility is due to pinch violations i.e. non-optimal heat exchange. With a minimum hot utility of 135.4 MW and a current steam demand of 153.9 MW, the resulting pinch violations for the plant are 18.5 MW. This corresponds to a theoretical steam-saving potential of 12% of the current steam demand. All violations are due to heating below the pinch.

4.3 *Retrofit suggestions*

In this section, two retrofit options are presented: Retrofit I involves relatively straightforward changes whereas Retrofit II is more extensive. The focus of both retrofit options is on eliminating steam users below the pinch temperature. This could be achieved by improved heat recovery from high temperature water effluent streams in drains or by heat exchanging streams differently in the network. The major difference between the proposals is that in Retrofit I only changes that do not affect the hot and warm water system (HWWS) are considered, whereas in Retrofit II this process section is included.

4.3.1 *Retrofit I*

In Retrofit I, the main focus has been to save as much steam as possible without interfering with the HWWS. This retrofit could achieve steam savings of 5.8 MW of low-pressure (LP) steam, which corresponds to 4% of the present steam demand and 32% of the pinch violations. In Table 1, the cold streams are presented together with the hot stream that, according to the proposal, should replace the LP steam that is currently used. The resulting steam savings are also indicated. In this proposal, steam is replaced by condensate streams and hot effluents from the evaporation plant. Costs for new heat exchangers include costs for new heat exchanger area and piping. The total cost for the Retrofit I proposal is estimated at €759 000 and the resulting specific cost is €130 000 per MW.

Table 1. Steam savings resulting from retrofit measures in Retrofit I.

Cold stream	**New hot stream**	**Steam saved (MW)**
E2 filtrate	Condensate from stripper	1.0
E2 filtrate	Condensate from stripper	1.3
White water for pulp dryer and paper machine	B-condensate	2.1
White water for paper machine	Condensate cooling pulp dryer	1.5
Total		**5.8**

4.3.2 *Retrofit II*

The more extensive heat exchanger network retrofit results in larger energy savings than Retrofit I. In addition to the steam savings of Retrofit I, changes that affect the HWWS are also included in Retrofit II. The replaced steam users are shown in Table 2. In total it is possible to save approx. twice as much steam as in Retrofit I, i.e. about 11 MW of LP steam. This corresponds to 7% of the present steam demand and 60% of the pinch violations. The total cost of the Retrofit II proposal is estimated at €1 580 000, or €143 000 per MW.

Table 2. Steam savings resulting from retrofit measures in Retrofit II.

Cold stream	**New hot stream**	**Steam saved (MW)**
E1 filtrate	Liquor cooling	1.6
E2 filtrate	Condensate from stripper	1.0
E2 filtrate	Condensate from stripper	1.3
D0 filtrate	Hot water	2.6
White water for pulp dryer and paper machine	B-condensate	2.1
Local heating	Digester liquor	1.0
White water for paper machine	Condensate cooling pulp dryer	1.5
Total		**11.0**

In addition to the changes made in Retrofit I, it is necessary to modify or build seven additional heat exchangers. When replacing a heat exchanger in the HWWS it is important that the new network still can achieve the same temperatures in the hot and warm water tanks.

4.4 *Other findings from the pinch study*

4.4.1 *The paper machine*

There is a lack of information regarding how the heat recovery in the paper machine is currently implemented. A thorough investigation of the heat recovery system would most

probably identify further opportunities for improvement. Using a system similar to the one used in the pulp dryer, with a fluid transferring heat from the outgoing air to the incoming air, could improve efficiency and provide operational flexibility with respect to outdoor temperature. At present, there are large amounts of energy released to the surrounding with the outgoing air effluent stream due to its high humidity content.

4.4.2 *Bleaching plant*

The bleaching plant is the largest user of hot water in the mill. A comparison with other mills indicates that there is a potential for energy savings at the studied mill and that there are reasons to investigate the bleaching plant more thoroughly. Using presses instead of filters when washing the pulp and keeping the temperature at a more even level between the bleaching steps are two ways of lowering the demand for steam and hot water and thus improving the energy efficiency.

4.4.3 *Hot and Warm Water System (HWWS)*

It would be possible to reach a higher temperature in the hot water tank with some changes in the heat exchanger network. This would lead to lowered steam demand in the subsequent hot water users. This option was not included in the study, since traditional pinch analysis is not the best approach to such tank temperature optimization. It would, however, be interesting to further analyze this opportunity.

4.5 *Economic evaluation*

There are several ways for the mill to benefit from potential energy savings. The most obvious and straightforward is to simply reduce the amounts of oil and bark fired in the power boiler. Due to large seasonal variations it is, however, not possible to reduce the boiler load during all parts of the year, since during summer, it already runs at minimum load. Other options include investing in a condensing turbine, delivering district heating or integrating a biorefinery process.

To make an initial assessment of the profitability of the proposed energy-efficiency measures, a simple calculation was performed for the option of bark savings. Assuming bark savings can be achieved during two thirds of the year, the economic savings will be €107 000 per MW and year and hence the payback period will be less than 16 months for both proposals. Considering that the fuel reduction is likely to be oil rather than bark during parts of the year, the payback period could well be even lower.

5. Discussion

5.1 *Seasonal variations*

The study was carried out for winter operating data. The summer steam demand is lower because of increased ambient temperatures. Therefore this study is not representative for the whole year.

No detailed investigation of possible economic benefits through, for example, reduced burning of bark or district heating delivery were made. To analyze these options, more information regarding yearly variations in bark boiler firing, steam system and demand of heating and cooling in general are required. The effect of these seasonal variations on the steam-saving potential could, however, be estimated using the results of previous studies [6]. The effect on the overall energy balance of the mill could, for example, be studied using the

reMIND tool, thereby connecting the results from this pinch analysis to other studies within the Billerud project.

5.2 *Pinch-reMIND interaction*

It is possible to use the results of the pinch analysis presented in this paper in an energy system model developed using the reMIND simulation and optimization tool (see e.g. [7]). This model interaction is based on what has previously been shown to be a good way to use the results from pinch analysis in optimization studies using reMIND, see for example [8] and [9]. For a more general discussion of the role of optimization for efficient implementation of process integration measures in industry, see [10].

In reMIND, optimization is carried out by using mixed integer linear programming in order to minimize the system cost. The system cost includes amongst others, the investment costs of different measures that can be taken to change the system. The structure of the energy system is represented as a network of nodes and branches where branches represent energy or material flows. One node may represent, for example, a process line or a single equipment unit. It may also represent a possible steam-saving investment which will be the case when representing the results from the pinch analysis. Multi-period optimization can be modelled in reMIND which makes it possible to consider seasonal variations in the overall energy system studied.

The two retrofit alternatives identified in the pinch analysis could, for example, be modelled as two different investment options in the reMIND model, each resulting in a certain steam saving2 which can be achieved for a specified investment cost.

6. Conclusions

The theoretical potential for energy savings at the studied mill was estimated at 18.5 MW, corresponding to 12% of the current steam demand. Two retrofit proposals to accomplish parts of this theoretical potential were suggested. Assuming that the steam savings lead to a reduced use of bark in the power boiler, the pay-back period of the energy savings investment is estimated to be less than about 16 months.

Acknowledgements

The excellent work of Lina Eriksson and Simon Hermansson who conducted the pinch study during their MSc thesis work is gratefully acknowledged. We would also like to thank Monika Resin, process engineer at Billerud Karlsborg, who co-supervised their work and of course also the rest of the staff at the mill who contributed to the study. Professor Thore Berntsson (examiner of the MSc thesis and supervisor to the first author of this paper) is also acknowledged for his contributions to this work.
This research project was led by the Energy Engineering group at Luleå University of Technology with funding provided by the Swedish Energy Agency, Billerud Karlsborg AB and Billerud Skog.

Abstract: Classical thermodynamics is capable of determining limits on energy production or consumption in terms of the exergy change. However, they are often too distant from reality. Yet, by introducing rate dependent factors, irreversible thermodynamics offers enhanced limits that are closer to reality. Thermodynamic analyses lead to important formulas for imperfect efficiencies. In this paper power limits for generation or consumption of thermal, solar, chemical energy are obtained by application of the optimal control theory.

Power limits define maximum power released from energy generators and minimum work supplied to separators or heat pumps. In this research we consider power limits for both devices of energy generator type (engines and fuel cells) and of energy consumer type (heat pumps, separators and electrolysers). Each process is driven either by a simple heat exchange or by the simultaneous exchange of energy and mass fluxes. We stress the link of these problems with the classical problem of maximum work. Particular attention is devoted to fuel cells as electrochemical flow engines. Amongst a number of new results, notion of certain special controls (Carnot variables) plays an important role. In particular, we demonstrate their role in the analysis of heat and radiation engines, chemical power generators and fuel cells.

Keywords: *efficiency, power generation, entropy, thermal machines, fuel cells.*

Nomenclature

A_v *generalized exergy per unit volume*.....Jm^{-3}
a_0 *constant related to the Stefan-Boltzmann constant*.....$Jm^{-3}K^{-4}$
a_v *total area of energy exchange per unit volume*..... m^{-1}
$\dot{G}$ *resource flux*.....gs^{-1}, $mols^{-1}$
g *conductance*.....$Js^{-1}K^{-a}$
h *numerical value of Hamiltonian*.....$Jm^{-3}K^{-1}$
n *flux of fuel reagents*.....gs^{-1}, $mols^{-1}$

σ_s *entropy production of the system*..... $JK^{-1}s^{-1}$
ζ *chemical efficiency*..... -

1. Introduction

In a previous work (Sieniutycz 2003 [1]) we discussed basic rules for modeling power production and energy limits in purely thermal systems with finite rates. In particular, radiation engines were analyzed. In the present work we treat generalized systems in which temperatures T and chemical potentials μ^k are essential. This is associated with engines propelled by fluxes of both energy and substance. When one, say, upper, reservoir is finite, its thermal potential decreases along the stream path, which is the consequence of the energy balance. Any finite reservoir is thus a resource reservoir. It is the resource property or the finiteness of amount or flow of a valuable substance or energy which changes the upper fluid properties along its path. Then, in the engine mode of the system, one observes fluid's

relaxation to the equilibrium with an infinite lower reservoir, usually the environment. This is a cumulative effect obtained for a resource fluid at flow, a set of sequentially arranged engines, and an infinite bath Downgrading or upgrading of resources may occur also in electrochemical systems of fuel cell type. Fuel cells working in the power production mode are electrochemical flow engines propelled by chemical reactions.

In a process of power production shown in Fig. 1 two media differing in values of T and μ interact through an energy generator (engine), and the process is propelled by diffusive and/or convective fluxes of heat and mass transferred through 'conductance' or boundary layers. The energy flux (power) is created in the generator between the resource fluid ('upper' fluid 1) and, say, an environment fluid ('lower' fluid, 2). In principle, both transfer mechanisms and values of conductance of boundary layers influence the rate of power production (Curzon and Ahlborn 1975[2]; De Vos 1994 [3], Sieniutycz and Kuran 2005 [4], 2006 [5]).

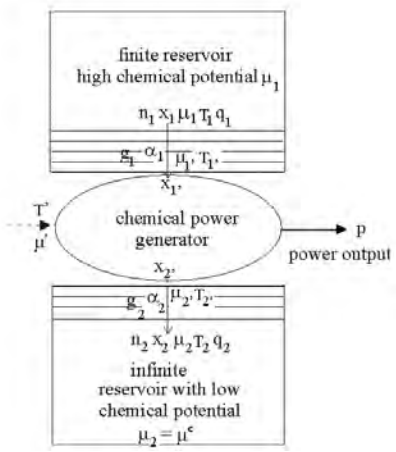

Fig. 1. A scheme of chemical and/or thermal engine.

2. Carnot Control Variables in Power Systems

Diverse controls can be applied in power systems to represent the propelling fluxes of heat and mass transfer. Here we shall recall and then use definitions of Carnot control variables (Carnot temperature and chemical potential) whose derivations and applications were originated in our previous work (Sieniutycz 2003 [8]). We begin with the simplest case of no mass transfer, i.e. we shall consider a steady, internally reversible ('endoreversible') heat engine with a perfect internal power generator characterized by temperatures of circulating fluid $T_{1'}$ and $T_{2'}$, Fig.1. The stream temperatures, attributed to the bulk o each fluid are T_1 and T_2. The inequalities $T_1 > T_{1'} > T_{2'} > T_2$ are valid for the engine mode of the system. With an effective temperature called Carnot temperature

$$T' \equiv T_2 \frac{T_{1'}}{T_{2'}} \tag{1}$$

entropy production of the endoreversible process, takes the following simple form

$$\sigma_s = q_1 \left(\frac{1}{T'} - \frac{1}{T_1} \right) \tag{2}$$

This form is identical with the familiar expression obtained for processes of purely dissipative heat exchange between two bodies with temperatures T_1 and T'. In terms of temperature T' of Eq. (1) thermal efficiency assumes the classical Carnot form containing the temperature in the bulk of the second reservoir and temperature T':

$$\eta = 1 - \frac{T_2}{T'} \tag{3}$$

This property substantiates the name "Carnot temperature" for control variable T'. In terms of T' description of thermal endoreversible cycles is broken down to formally "classical" equations which contain T' in place of T_1. In irreversible situations Carnot temperature T' efficiently represents temperature of the upper reservoir, T_1. Yet, at the reversible Carnot point, where $T_{1'} = T_1$ and $T_{2'} = T_2$, Eq. (1) yields $T' = T_1$, thus returning to the classical reversible theory. These properties of Carnot temperature render descriptions of endoreversible and reversible cycles similar. They also make the variable T' a suitable control in both static and dynamic cases (Sieniutycz 2003 [8]).The notion of Carnot temperature can be extended to chemical systems, where also the Carnot chemical potential emerges (Sieniutycz 2003 [8]), where instead of pure heat flux q the so called total heat flux (mass transfer involving heat flux) Q is introduced. The heat flux equals the difference between total energy flux ε and flux of enthalpies of transferred components, $q = \varepsilon - h$, satisfying an equation

$$Q \equiv \varepsilon - \mu_1 n_1 ... \mu_k n_k ... - \mu_m n_m . \equiv \varepsilon - G \tag{4}$$

where G is the flux of Gibbs thermodynamic function (Gibbs flux). The equality $\varepsilon = Q + G$ is fundamental in the theory of chemical engines; it indicates that power can be generated by two propelling fluxes: heat flux Q and Gibbs flux G, each generation having its own efficiency. The related driving forces are the temperature difference and chemical affinity. Assuming a complete conversion we restrict to power yield by a simple reaction $A_1 + A_2 = 0$ (isomerisation or phase change of A_1 into A_2). We have a chemical control variable

$$\mu' = \mu_2 + \mu_{1'} - \mu_{2'} \tag{5}$$

which has been used earlier to study an isothermal engine (Sieniutycz 2008 [9]). After introducing the Carnot temperature in accordance with Eq. (1), total entropy production of the endoreversible power generation by the simple reaction $A_1 + A_2 = 0$ takes the following form

$$\sigma_s = Q_1 \left(\frac{1}{T'} - \frac{1}{T_1} \right) + n_1 \frac{\mu_1 - \mu'}{T'} \tag{6}$$

where $Q_1 = q_1 + T_1 s_1 n_1$ is the total heat flux propelling the power generation in the system. The resulting equation is formally equivalent with a formula obtained for the purely dissipative exchange of energy and matter between two bodies with temperatures T_1 and T' and chemical potentials μ_1 and μ'.

3. Energy Systems with Internal Imperfections

Carnot variables T' and μ' are two free, independent control variables applied in power maximization of steady and dynamical generators. Ideas referring to endoreversible systems may be generalized to those with internal dissipation. In such cases a single irreversible unit can be characterized by two loops shown in Fig. 2 which presents the temperature–entropy

diagram of an arbitrary irreversible stage. Each stage can work either in the heat-pump mode (larger, external loop in Fig. 2) or in the engine mode (smaller, internal loop in Fig. 2).

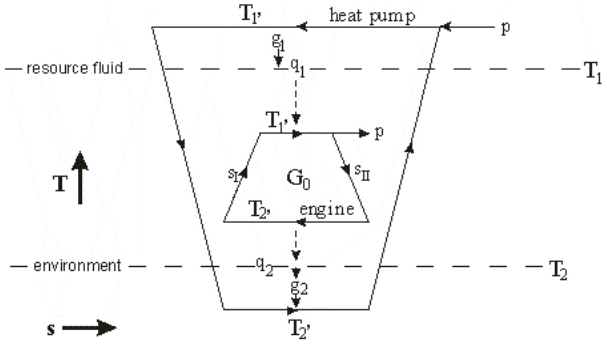

Fig. 2. Two basic modes with internal and external dissipation: power yield in an engine and power consumption in a heat pump. Primed temperatures characterize the circulating fluid.

The related analysis follows the earlier analyses of the problem which take into account internal irreversibility by applying the factor of internal irreversibility, Φ. By definition, $\Phi = \Delta S_{2'}/\Delta S_{1'}$ (where $\Delta S_{1'}$ and $\Delta S_{2'}$ are respectively the entropy changes of the circulating fluid along the two isotherms $T_{1'}$ and $T_{2'}$ in Fig. 2) equals the ratio of the entropy fluxes across the thermal machine, $\Phi = J_{s2'}/ J_{s1'}$. Due to the second law inequality at the steady state the following inequalities are valid: $J_{s2'}/J_{s1} > 1$ for engines and $J_{s2'}/J_{s1} < 1$ for heat pumps; thus the considered ratio Φ measures the internal irreversibility. In fact, Φ is a synthetic measure of the machine's imperfection. Φ satisfies inequality $\Phi > 1$ for engine mode and $\Phi < 1$ for heat pump mode of the system. A typical goal is to derive efficiency, entropy production and power limits in terms of Φ.

3.1. Power yield and entropy production in systems with internal imperfections

The thermal efficiency component of any endoreversible thermal or chemical engine can always by written in the form $\eta = 1 - Q_2/Q_1$. After defining the coefficient $\Phi = 1 + T_{1'}\sigma_S^{int}/Q_1$ called the internal irreversibility factor the internal entropy balance takes the form usually applied for thermal machines

$$\Phi \frac{Q_1}{T_{1'}} = \frac{Q_2}{T_{2'}} \qquad (7)$$

One can evaluate Φ from averaged value of the internal entropy production that describes the effect of irreversible processes within the thermal machine. Clearly, in many cases Φ is a complicated function of the machine's operating variables. In those complex cases one applies the data of $\sigma_s^{int} = dS_\sigma^{int}/dt$ to calculate averaged values of the coefficient Φ. In our analysis the quantity Φ is treated as the process constant. This corresponds with the observation that it is an average value of Φ, evaluated within the boundaries of operative parameters of interest which is used in most of analyses of thermal machines. In terms of the Carnot temperature T' and factor Φ the efficiency η , Eq. (7), assumes the simple, pseudo-Carnot form which is quite useful and general enough to describe thermal, radiative and chemical engines:

$$\eta = 1 - \Phi \frac{T_2}{T'} \qquad (8)$$

A particularly interesting role of the above formulas is observed for radiation engines which are energy systems driven by black radiation. In these systems Gibbs flux $G = 0$, whereas total heat flux Q is identical with the energy flux ε, i.e. $Q = \varepsilon$. The majority of research papers on power limits published to date deals with systems in which there are two infinite reservoirs. To this case refer steady-state analyses of the Chambadal-Novikov-Curzon-Ahlborn engine (CNCA engine) in which energy exchange is described by Newtonian law of cooling, Curzon and Ahlborn 1975 [2], or of the Stefan-Boltzmann engine, a system with the radiation fluids and energy exchange governed by the Stefan-Boltzmann law (De Vos 1994 [3]). In a CNCA engine the maximum power point may be related to the optimum value of a free (unconstrained) control variable which may be efficiency η, heat flux q_1, or Carnot temperature T'. When internal irreversibility within the power generator play a role, the pseudo-Carnot formula (8) applies in place of Eq. (3), where Φ is the internal irreversibility factor (Sieniutycz and Kuran 2006 [5]). In terms of bulk temperatures T_1, T_2 and Φ one finds at the maximum power point

$$T'_{opt} = \left(T_1 \Phi T_2\right)^{1/2} \qquad (9)$$

For the Stefan-Boltzmann engine exact expression for the optimal point cannot be determined analytically, yet, this temperature can be found graphically from the chart $p = f(T')$. A pseudo-Newtonian model, Sieniutycz and Kuran 2006 [5], Kuran 2006 [6], which treats the state dependent energy exchange with coefficient $\alpha(T^3)$, omits to a considerable extent analytical difficulties associated with the use of the Stefan-Boltzmann equation.

4. Dynamical Energy Yield

4.1. General Issues

When resources are finite and/or the propelling fluid flows at a finite rate, the Carnot and resource temperatures decrease along the process path. The previous (steady) analysis is replaced by a dynamic one, and the mathematical formalism is transferred from the realm of functions to the realm of functionals. Here the optimization task is to find an optimal profile of the Carnot temperature T' along the resource fluid path that assures an extremum of the work consumed or delivered and – simultaneously – the minimum of the integral entropy production. Dynamical energy yield requires the knowledge of an extremal curve rather than an extremum point. This leads us to variational methods (to handle extrema of functionals) in place of static optimization methods (to handle extrema of functions). For example, the use of a pseudo-Newtonian model to quantify the dynamic power yield from radiation, gives rise to a non-exponential optimal curve describing the radiation relaxation to the equilibrium. The non-exponential shape of the relaxation curve is the consequence of nonlinear properties of the radiation fluid. Non-exponential are also other curves describing the radiation relaxation, e.g. those following from exact models involving the Stefan-Boltzmann equation (Kuran 2006 [6], Sieniutycz and Kuran 2005 [4], 2006 [5]). Optimal (e.g. power-maximizing) state $T(t)$ is accompanied by optimal control $T'(t)$; they both are components of the dynamic optimization solution.

Energy limits of dynamical processes are inherently connected with exergies, the classical exergy and its rate-dependent extensions. To obtain the classical exergy from work functionals it suffices to assume that the thermal efficiency of the system is identical with the

Carnot efficiency. On the other hand, non-Carnot efficiencies, influenced by rates, lead to 'generalized exergies'. The benefit from generalized exergies is that they define stronger energy limits than those predicted by classical exergies (Berry *at al* 2000 [7]).

4.2. Radiation Systems

Radiation engines are thermal machines driven by the radiation fluid, a medium exhibiting nonlinear properties. Energy transfer rates in reservoirs containing nonlinear media can be described by various models. Usually one assumes that the energy transfer in a reservoir is proportional to the difference of absolute temperatures in certain power, a. The case of $a = 4$ refers to the radiation, $a = -1$ to the Onsagerian kinetics and $a = 1$ to the Fourier law of heat exchange. As the first case of the radiation engine modeling we consider a "symmetric nonlinear case" in which the energy exchange process in the energy exchange in each reservoir satisfies the Stefan-Boltzmann equation. Next we consider "hybrid nonlinear case" in which the upper-temperature fluid is still governed by the kinetics proportional to the difference of $(T^4)_i$ whereas the kinetics in the lower reservoir is Newtonian.

Here are equations of *symmetric nonlinear case*. For the "symmetric" kinetics governed by the differences in T^a, the Carnot representation of the total entropy production has the form

$$\sigma_s = g_1 g_2 \frac{T_1^a - T'^a}{\Phi g_1 \left(T'/T_2\right)^{a-1} + g_2} \left(\frac{(\Phi - 1)}{T'} + \left(\frac{1}{T'} - \frac{1}{T_1} \right) \right) \qquad (10)$$

Superiority of Carnot control T' over the energy flux control ε_1 may be noted. Analytical expressions for the energy-flux representation of the entropy production or the associated mechanical power p cannot generally be found in an analytical form. The work expression to be minimized is

$$W = \int_{t^i}^{t^f} \varepsilon_1 \eta dt = \int_{t^i}^{t^f} g_1 g_2 \frac{T_1^a - T'^a}{\Phi g_1 \left(T'/T_2\right)^{a-1} + g_2} \left(1 - \Phi \frac{T_2}{T'} \right) dt \qquad (11)$$

In the case of analytical difficulties which occur for a different from the unity the maximization can be performed numerically by dynamic programming using Carnot T' as the free control.

We consider now *hybrid nonlinear case*. It involves the radiative heat transfer ($a = 4$) in the upper reservoir and a convective one in the lower one. To obtain an optimal path associated with the limiting production or consumption of mechanical energy the sum of the above functionals i.e. the overall entropy production

$$S_\sigma = -\int_{\tau^i}^{\tau^f} c(T_1) \left(\frac{\Phi}{\left(T_1^a + \dot{T}_1^a\right)^{\frac{1}{a}} + \dot{T}_1 \Phi g_1 / g_2} - \frac{1}{T_1} \right) \dot{T}_1 d\tau_1 \qquad (12)$$

has to be minimized for a fixed duration and defined end states of the radiation fluid. The most typical way to do accomplish the minimization is to write down and then solve the Euler-Lagrange equation of the variational problem. Analytical solution is very difficult to obtain, thus one has to rest on numerical approaches.

5. Finite Rate Exergies and Finite Resources

We are now in position to formulate the Hamilton Jacobi Bellman theory for systems propelled by energy flux ε. Two different kinds of work: first associated with the resource downgrading during its relaxation to the equilibrium and the second – with the reverse process of resource upgrading, are essential. Total power obtained from an infinite number of infinitesimal stages representing the resource relaxation is determined as the Lagrange functional.

5.1. Some Hamilton Jacobi Bellman Equations for Energy Systems

We shall display some Hamilton Jacobi Bellman (HJB) equations for radiation power systems. A suitable example is a radiation engine whose power integral is approximated by a pseudo-Newtonian model of radiative energy exchange. For the *symmetric* model of radiation conversion (both reservoirs composed of radiation), where $\Phi' \equiv \Phi g_1/g_2$ and coefficient $\beta = \sigma a_v c_h^{-1}(p_m^0)^{-1}$ is related to molar constant of photons density p_m^0 and Stefan-Boltzmann constant σ, we obtain a HJB equation

$$\frac{\partial V}{\partial t} = \max_{T'(t)}\left\{\left(\dot{G}_c\left(1-\Phi\frac{T^e}{T'}\right)+\partial V/\partial T\right)\beta\frac{T^a - T'^a}{\left(\Phi'(T'/T_2)^{a-1}+1\right)T^{a-1}}\right\} \qquad (13)$$

For *a hybrid model* of the radiation conversion (upper reservoir composed of the radiation and lower reservoir of a Newtonian fluid the related Hamilton-Jacobi-Bellman (HJB) equation is

$$-\frac{\partial V}{\partial t^f}+\max_{T'(t)}\left\{-\left(\dot{G}_c(T)(1-\frac{\Phi T^e}{T'})+\frac{\partial V}{\partial T^f}\right)u\right\}=0 \qquad (14)$$

5.2. Chemical Power Systems

The developed approach can be extended to chemical and electrochemical engines. Here we shall make only a few basic remarks. Yet, as opposed to thermal machines, in chemical ones generalized streams or reservoirs are present, capable of providing both heat and substance. Large streams or infinite reservoirs assure constancy of chemical potentials. Problems of extremum power (maximum of power produced and minimum of power consumed) are static optimization problems. For a finite "upper stream", however, amount and chemical potential of an active reactant decrease in time, and considered problems are those of dynamic optimization and variational calculus. Application of chemical Carnot control μ' in terms of fuel flux n_1 and its mole fraction x to the Lagrangian relaxation path leads to a work functional

$$W = -\int_{\tau_1^i}^{\tau_1^f}\left\{\zeta_0 + RT\ln\left(\frac{X/(1+X)+dX/d\tau_1}{x_2 - jdX/d\tau_1}\right)\right\}\frac{dX}{d\tau_1}d\tau_1 \qquad (15)$$

whose maximum describes the dynamical limit of the system. Here X = x/(1-x) and j equals the ratio of upper to lower mass conductance, g_1/g_2. The path optimality condition may be expressed in terms of the constancy of the following Hamiltonian

$$H(X,\dot{X}) = RT\dot{X}^2\left(\frac{1+X}{X}+\frac{j}{x_2}\right) \qquad (16)$$

For low rates and large concentrations X (mole fractions x_1 close to the unity) optimal relaxation rate of the fuel resource is approximately constant. Yet, in an arbitrary situation optimal rates are state dependent so as to preserve the constancy of H in Eq. (16).

6. Concluding Remarks

This research provides data for power production bounds (limits) which are enhanced in comparison with those predicted by the classical thermodynamics. As opposed to the classical thermodynamics, these bounds depend not only on changes of the thermodynamic state of participating resources but also on process irreversibility, ratios of stream flows, stream directions, and mechanism of heat and mass transfer. The methodology familiar for thermal machines has been extended to chemical and electrochemical engines. Extensions are also available for multicomponent, multireaction units (Sieniutycz 2009 [10]).

The generalized bounds, obtained here by solving Hamilton Jacobi Bellman equations, are stronger than those predicted by thermostatic. They do not coincide for processes of work production and work consumption; they are 'thermokinetic' rather than 'thermostatic' bounds. Only for infinitely long durations or for processes with excellent transfer (an infinite number of transfer units) the thermokinetic bounds reduce to the classical thermostatic bounds. A real process which does not apply the optimal protocol but has the same boundary states and duration as the optimal path, requires a real work supply that can only be larger than the finite-rate bound obtained by the optimization. Similarly, the real work delivered from a nonequilibrium work-producing system (with the same boundary states and duration but with a suboptimal control) can only be lower than the corresponding finite-rate bound. This is a direction with many open opportunities, especially for separation and chemical systems.

Abstract: The purpose of the presented paper is to investigate oxygen enrichment in hot stoves for an integrated steel plant. The application of oxygen enrichment in hot stoves will lead to lower coke or PCI rate by increased blast temperature. With oxygen enrichment, the high calorific value COG, could be saved while keeping the same blast temperature. Several alternatives of using the saved COG are presented. Furthermore, an analysis of how oxygen enrichment into hot stoves will have influence on the whole energy system has been carried out by means of an optimization model. Different strategies have been suggested to minimize the total energy consumption at the studied steel plant and the nearby CHP plant.

Keywords: *Oxygen enrichment, Hot stoves, Blast furnace, Energy system*

1. Introduction

In the process of iron-making, hot stoves (HS) are used to preheat air used in the blast furnace (BF). The preheated air is called hot blast. A higher blast temperature will lead to lower coke consumption in BF operation, hence, the energy consumption and CO_2 emission from BF will be reduced. Hot stoves work as counter-current regenerative heat exchangers. Hot stoves typically use low calorific blast furnace gas (BFG) combined with higher calorific value coke oven gas (COG). BFG is generated from BF when producing hot metal. COG is a valuable fuel being high in hydrogen (H_2) and methane (CH_4). At an integrated steel plant, COG is often delivered from the coking plant.

Basically, using oxygen enrichment in the air for combustion in the hot stoves offers three advantages. First, the hot blast temperature may be increased due to higher flame temperature which reduces the blast furnace reductant consumption. Secondly, the lower volume of flue gas reduces the loss of sensible heat via the flue gas. Thirdly, COG or other higher value fuels could be used more effectively elsewhere.

The purpose of this paper is to investigate the application of oxygen enrichment in hot stoves and its potential influences to the total energy system at an integrated steel plant. This is done by performing calculations of mass and heat balance for the HS-BF system, and also by means of an optimization model.

In next section, the HS-BF system is described followed by the description of BF performance with oxygen enrichment in hot stoves. In section 4, an optimization model has been applied to present the potential influences on the total energy system of the studied steel plant and a nearby combined heat and power plant (CHP). Finally, in section 5 concluding remarks are made based on the presented work including some recommendations.

2. Description of hot stove – blast furnace system

The hot stove often includes two separate parts, a combustion chamber and a check chamber. They work as a counter-current regenerative heat exchanger. The fuel gas is first combusted

in the combustion chamber. The flue gas passes through the check chamber and heats it up, then leaves the stack to the ambient. This progress is often called on-gas time. When the check chamber is fully heated up during on-gas time, the blast time is started. During the blast time, the cold blast is blown into the system in opposite cycle and is heated by the check chamber. It then passes through the combustion chamber. Before blowing into the blast furnace, it is often mixed with cold blast to get the required and stable hot blast temperature. BFG is a process gas with low calorific value. It has to be blended with COG to get a higher calorific value before entering the combustion chamber. After blending, the average heating value is around 4.3 MJ/Nm^3.

Traditionally the combustion air is used in hot stoves for fuel combustion. For the studied plant, the hot blast produced is 254 kNm^3 per hour with a temperature of 1104 °C, which is required by the blast furnace to produce hot metal with a production rate of 275 tonnes per hour during the reference period.

The combustion air can be enriched with gaseous oxygen, oxygen enrichment. Compared to traditional combustion, less N_2 will be generated which will absorb less reaction heat from combustion. This will lead to a higher adiabatic flame temperature (AFT) with the same amount of fuel gas. As for the hot stove, therefore, a higher blast temperature can be achieved. On the other hand, the low caloric value fuel gas can also be combusted alone without mixing with any enrichment gas to get the same flame temperature with the use of oxygen enrichment instead. The common enrichment gases used at hot stoves are, for example COG, LPG or NG.

3. BF performance with oxygen enrichment in hot stoves

In the studied steel plant, the hot stoves are fuelled with BFG together with some amounts of COG. The calculations for oxygen enrichment in HS-BF system were carried out by using a spreadsheet model [1].

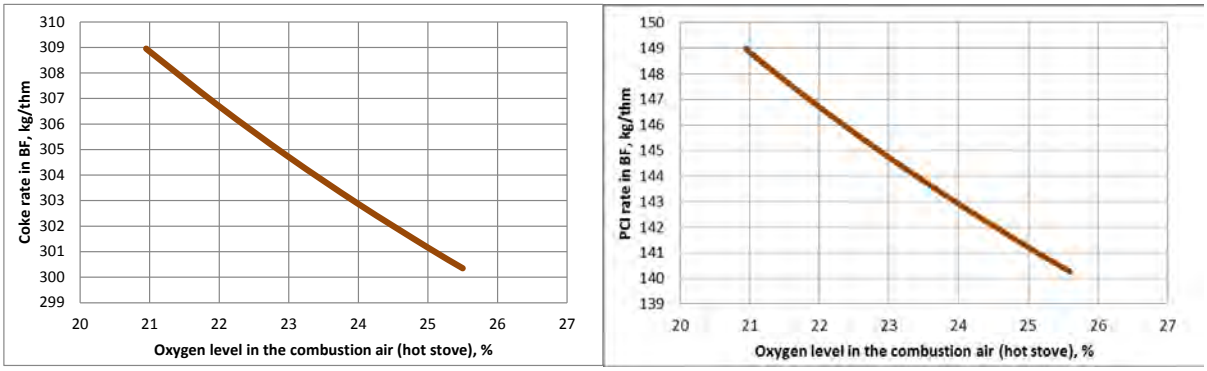

Fig. 1. The correlation between oxygen level in the air and coke rate (left) and PCI rate (right) in BF.

3.1. Increased blast temperature with oxygen enrichment

For the studied hot stoves, the hot blast temperature is assumed to increase to 1200 °C with the enriched oxygen in the combustion air. A higher hot blast temperature will lead to a lower reductant in the blast furnace. In the studied BF blast furnace, coke is used as reductant and charged from the top with other burden materials such as iron ore pellet and fluxes. Besides coke, pulverized coal (PCI) is also injection into BF via tuyers as fuel and reductant. Therefore, it's interesting to study the potential coke and PCI saving due to a higher hot blast temperature. Fig. 1 presents potential coke and PCI saving with enriched oxygen in the

combustion air, which corresponds to 9.01 kg coke or 9.15 kg PCI with per ton hot metal per increased 100 °C blast temperature, respectively.

3.2. COG saved with oxygen enrichment

At a fixed blast temperature, increased oxygen level in the combustion air will lead to decreased COG flow in hot stoves, while BFG flow rate has to increase to provide enough energy, as shown in Fig.2. The high caloric value COG can be saved and used for other purpose.

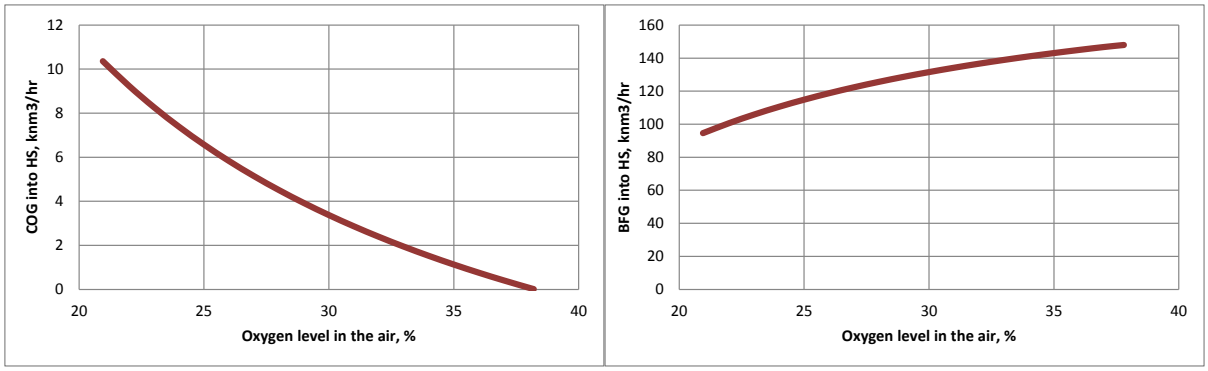

Fig.2. The correlation between oxygen level in the combustion air and COG (left) and BFG (right) flow in the hot stoves.

Previous studies showed that a lower reducant in BF could be achieved by injecting COG through tuyers [1-3]. Fig.3 shows the potential coke or PCI saving if saved COG in hot stoves instead is injected into BF via tuyers.

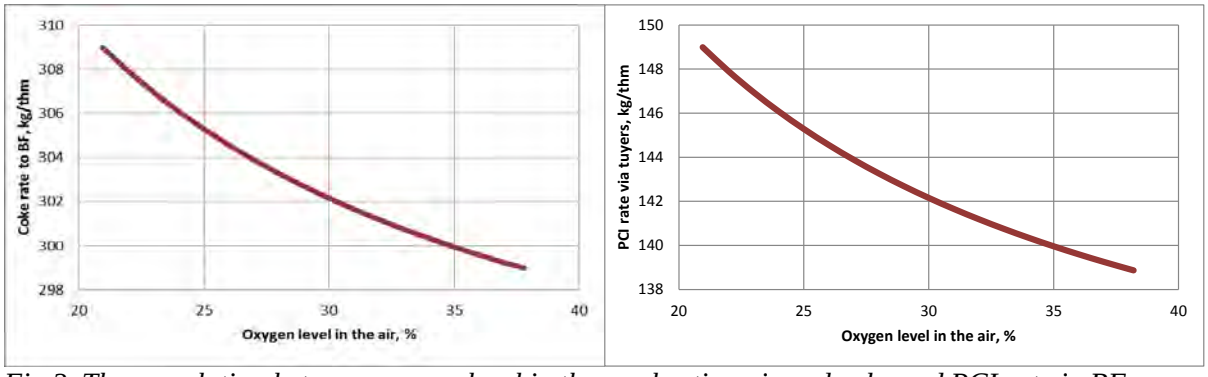

Fig.3. The correlation between oxygen level in the combustion air and coke and PCI rate in BF.

Table 1 gives a summary of key parameters for all scenarios discussed above. It's been noticed that a higher amount of BFG could be generated when COG is injected into BF via tuyers. At the same time, this will also lead to a higher heating value of BFG.

For the studied steel plant, there is another scenario to utilize the saved COG from the hot stove. That is to use it at the nearby combined heat and power (CHP) plant, which corresponds to Scenario 4 in Table 1. This will be presented in Section 4.

Table 1. Key parameters in hot stove – blast furnace system for different scenarios.

	Unit	Ref. case	Fixed COG_coke saving	Fixed COG_PCI saving	Fixed BLT_to PP	Fixed BLT_coke saving	Fixed BLT_PCI saving
	Scenarios	Scenario 1	Scenario 2	Scenario 3	Scenario 4	Scenario 5	Scenario 6

4. System analysis of the energy system in the studied steel plant

The studied integrated steel plant consists of the following main process units: coking plant (CP) → blast furnace (BF) → basic oxygen plant (BOF) → secondary metallurgy (SM) → continuous casting (CC). The final product is slab from CC. In addition, there are also some other process units, a lime kiln for lime production, an oxygen plant and a combined heat and power plant (CHP). All these process units are connected through material flows and a process gases network. Besides COG and BFG, there is also recovered process gas from the BOF, called basic oxygen furnace gas (BOFG). Fig. 4 shows the structure of the process gas network

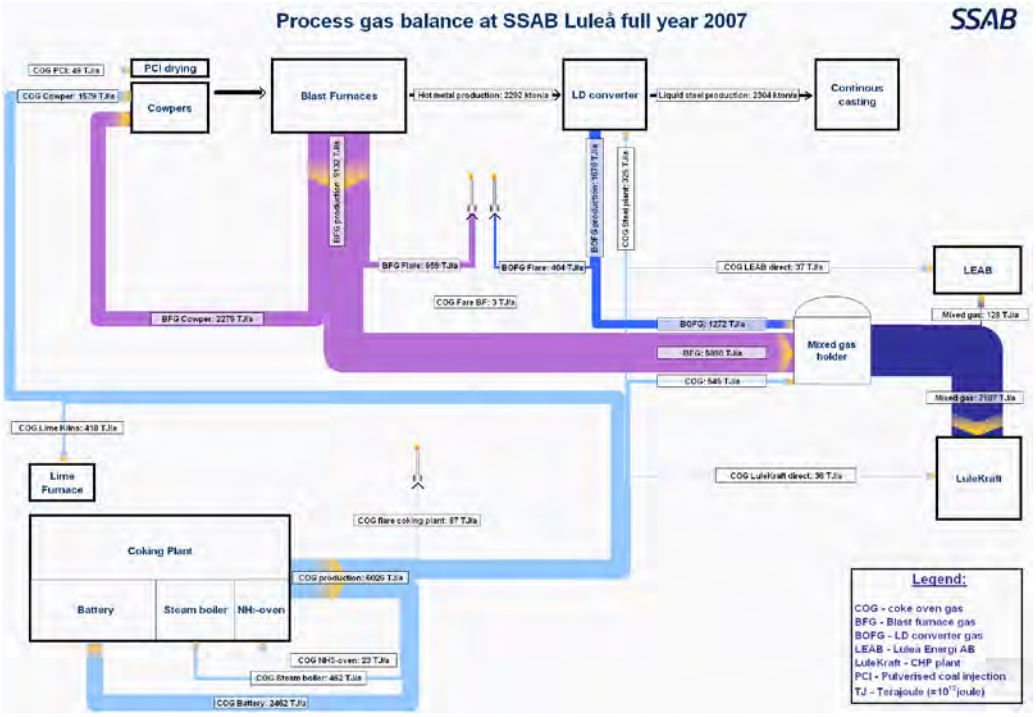

Fig. 4. The structure of process gas network at the studied plant

An optimization model has been applied to analyze the energy system in the studied steel plant. More details about the model can be read in previous publications [4-5]. The objective function set in the model is to minimize energy consumption for the total steel plant. There are two driving forces to run the model. The first is to produce the final product slabs, at 263 ton/hour as a year average. The second is to produce hot water at the CHP plant to the district heat network used by the nearby city. The CHP plant also produces electricity which is used at different process units within the plant. Therefore, it also provides electricity for oxygen

production at the oxygen plant. When there is excess electricity generated from the CHP plant, the extra electricity is sold externally to the grid.

Before entering the CHP plant, the process gases of BFG, COG and BOFG are blended in the mix gas holder to get the required heating value and a stable gas flow before entering the boiler. Oil is used when heat load is higher or when there is lack of mixed gases. The electricity can be generated from the steam turbine by two different modules, a back pressure module and a condenser module, mainly depending on the heat demand from the district heat network. The alpha value of the back pressure module is 0.44 ($\alpha = P_{el}/P_{heat)}$), and the electricity efficiency of the condenser module is 0.32. The boiler efficiency, η, is 0.9. In the model, the maximum fuel limitation for the boiler is 350MW, which is set by the regulation to control emissions, e.g. NO_x, SO_x and CO_2. The other limitation set for the boiler is the maximum flow rate of process gas, 90 Nm^3/s.

Fig. 5 illustrates the heat demand curve versus the out-door temperature. As shown in the figure, the maximum heat supply from the CHP plant is 220 MW, and the minimum heat supply is 20 MW. When the out-door temperature varies in the internal of [-18;16] °C, the heat demand curve can be linearized.

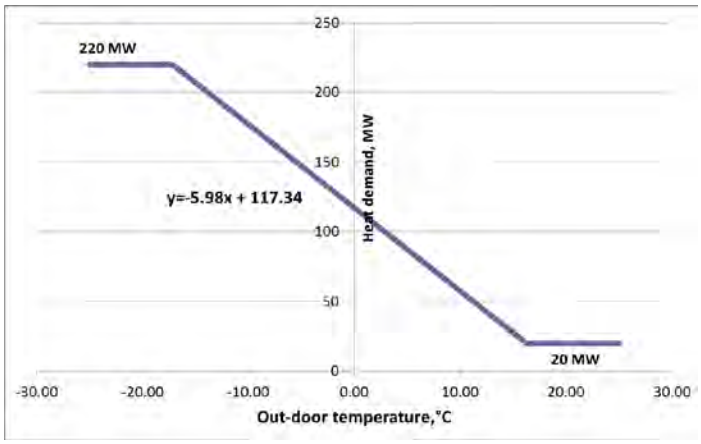

Fig.5.The correlation between out-door temperature and heat demand in the district heat network.

The optimization model is based on hourly data with a time span of one full year for the reference period. For example, the average heat demand is 85.7 MW, corresponding to an average out-door temperature of 5.3 °C. However, to illustrate how heat demand changes will have influence on the process gas network, the average value cannot be used because it varies with the seasonal out-door temperature especially in the Nordic region. Therefore, in this presented work 5 different values of heat demand are chosen: 20, 70, 120, 170 and 220MW respectively.

The model is set to run for the reference case and the optimized case to minimize the energy use for the total energy system. The energy content of the used energy carriers are presented in Table 2.

For the reference case, the model is run based on the operational data during the reference period to simulate for different heat demand levels. For the optimized case, the model will choose one scenario and combined scenarios listed in Table 1 (Scenario 1-6). Compared to the reference case, more freedoms are given in coal blending in the coke plant in the

optimized case. Stable production is assumed, meaning there are no variations in each process unit, except for the CHP plant.

Table 2. Key parameters in hot stoves, GJ/ton.

Energy carrier	Value	Energy carrier	Value
TCMT petcoke coal	35.9	Bachatsky PCI coal	28.7
Peak downs coal	29.6	El Cerrejon PCI coal	27.0
Riverside coal	29.3	External coke	40.9
Massey powellton coal	30.2	PCI	28.2
Rocklick Eagle coal	30.4	Oil, GJ/MWh	3.6
Gonyella coal	29.2	Electricity, GJ/MWh	3.6
Gusare PCI coal	28.2	Flaring, GJ/unit	1.0

Fig. 6 shows the specific energy consumption (SEC) both for the reference and the optimized case. It indicates that a lower SEC will always be achieved in the optimized case. It's been found that BF behaviors in the optimized case are changing when heat demand is increasing at the CHP plant. The model prefers oxygen enrichment for COG saving to get the fixed BLT the same as the reference into BF. However, the way to use the saved COG varies between the scenarios of injecting into BF for coke saving (Scenario 5) and delivering to the CHP plant (Scenario 4) to avoid oil consumption in boiler. As indicated in Fig. 8 (right), before the heat demand is increased to 153.3 MW which corresponds to an out-door temperature of -6°C, BF will always be operated as Scenario 5. Scenario 4 starts when heat demand is greater than 153.3 MW. The percentage of Scenario 4 operation increases to 100% when the heat demand rises to 183.8 MW, meanwhile, operating of Scenario 5 decrease from 100% to 0%. The model will keep running Scenario 4 when heat demand is higher than 183.8 MW to get the minimum energy consumption.

The comparison between reference case and optimized case at a same level of heat demand may explain why minimum energy consumption could be achieved for the model. The following factors contribute for this. First in the coke plant, the coal blending is changed. In principle, the types of coal chosen are with lower volatile energy content. Lower volatile content coal will lead to a higher coke production rate, which will also lead to a lower amount of coking coal required in the coke batteries to produce the same amount of coke as the reference case. Thus, the energy consumption from the coke plant could keep as low as possible. Lower volatile type coal will generate less COG, consequently there will less COG to the CHP plant. However, this will compensate when saved COG from hot stoves instead is injected into BF to have a lower coke rate in BF. This has been proved when comparing the purchased coke amount between reference case and optimized case for example at the heat demand level of 20 MW. This solution will be kept the same until the heat demand is up to 153.3 MW at which point the model has to adopt a strategy of mixing Scenario 5 and Scenario 4 with a varying weighting ratio in order to keep the minimum energy consumption for the total energy system. At the point of 183.8 MW, the solution is completely switched to 100% of Scenario 4 because at such a high level heat demand it is more energy effective to use the saved COG in the CHP plant instead of injecting into BF and by that avoiding use of oil at the CHP plant. However, some amount of oil has to be used even in the optimized case when the heat demand is over 185.7 MW.

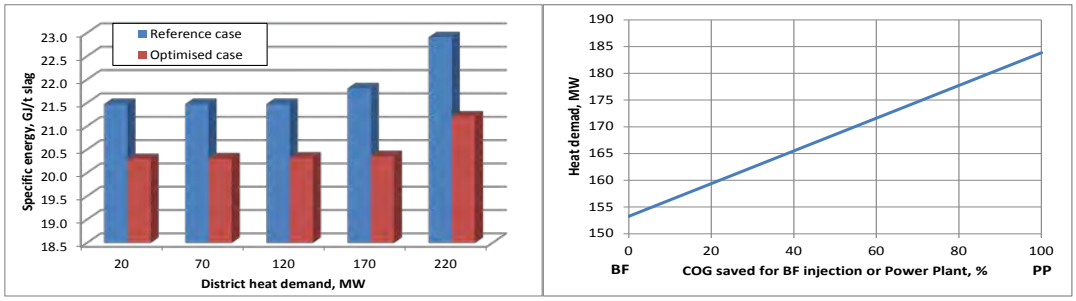

Fig.6. Left: Comparison of SEC between reference case and optimized case;
Right: BF behavior in the optimized case.

Fig. 7 illustrates the comparison of heat supply from the CHP between the reference case and the optimized case. It is found that oil will be replaced by COG in the optimized case at a high levels of heat demand. However, some amount of oil is still needed when the out-door temperature is lower than -11 °C.

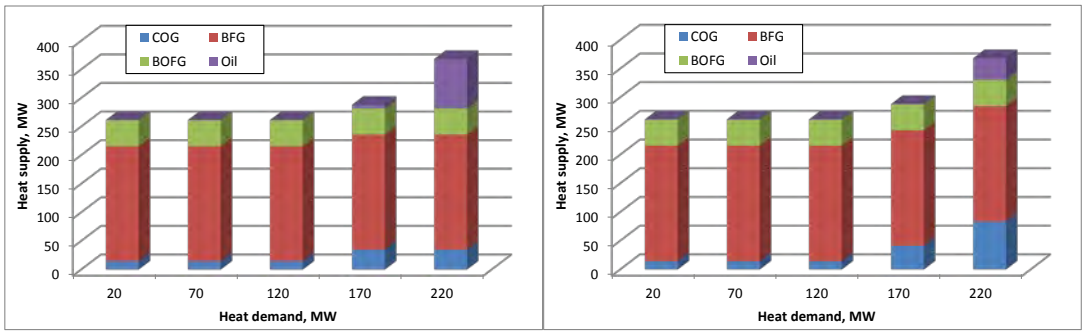

Fig.7. Left: Heat supply in the reference case; Right: Heat supply in the optimized case.

5. Concluding remarks

The presented work shows that the application of oxygen enrichment into hot stoves could lead to a lower coke or PCI rate in BF if the blast temperature is allowed to increase. High calorific value COG can also be saved by use of oxygen enrichment. Therefore, it is possible to use the saved COG in other process units. For the studied steel plant, the alternatives are, for example, inject COG into BF via tuyers or deliver it to the nearby CHP plant for district heat and electricity production. There are also other alternatives to use COG, such as at the reheating furnace in the rolling mill, or in the electric arc furnaces (EAF) to replace other fuels such as natural gas, LPG or oil. However, this depends on the site specific and is not applicable on the studied site.

An analysis of how oxygen enrichment into hot stoves will influence the total energy system has been carried out by means of an optimization model. Different strategies have been suggested from the model to achieve the minimum energy consumption for the studied steel plant and the nearby CHP plant.

The optimization made for the studied plant is to minimize the energy consumption for the total energy system. However, it does not mean that optimal solutions also are cost effective, which in fact is interesting to study.

In the current model, the availability of process gases and their flaring are set at a fixed value, based on hourly average value with a yearly time span. In addition, each process unit is assumed operating continuously and steadily. However, in reality there is normal varations.

Therefore, it might be of importance to take these factors into account for energy system optimization.

As for the CHP plant, only a few heat demand corresponding to a few out-door temperatures, are included in this optimization work. The performance of CHP plant, such as heat loads curve, is therefore limited. Solution space based optimization can provide a better resolution for the studied energy system [6].

The HS-BF system is a very important part in the optimization model, and it's also the most complicated process unit in an integrated steel plant with the BF-BOF route. The mass and energy balance for HS-BF system are first carried out in a spreadsheet, key operating parameters generated from the spreadsheet then put into the HS-BF sub-model of the optimization model. Different operating conditions generate a list of key operating parameters as input to the model. Thus, the optimal solution from this sub-model can either be one case or a mixed case. This, however, may lead to less dynamic. For instance, the model only shows the oxygen amount into hot stoves at which COG will be fully substituted by BFG. What happen in between oxygen enrichment starting and maximum level cannot be predicted in model. Therefore, it could not show the results if the optimum level of oxygen enrichment is in between when modeling the total energy system although it may not be the case. Further model improvement in HS-BF system is needed towards a dynamic response.

Abstract: Industrial chemical heat pumps (ICHPs) provide an ability to capture low - grade heat rejected from industrial sources and to reuse the heat increased temperature in industrial processes. Also it can be used for residential heating, cooling, water heating and energy storage. Several temperature boost levels can be obtained according to chemical reaction couple chosen. It can be either single source system or dual source system connected with available reject heat source. Dual source system is more effective than single source system and higher output temperature levels can be obtained. Reject heat source temperature and desired temperature boost are important in chemical reaction couple selection. Chemical reaction couple must be chosen carefully to provide the highest efficiency in all candidate systems. Economical feasibility of industrial chemical heat pump can be determined after calculations according to heat pump capacity. In this study, economical analysis of an industrial chemical heat pump system was accomplished compared with a steam boiler. Economical calculations was carried out and curves that show the relations between investment cost and capacity of chemical heat pump, investment cost and capacity of steam boiler, reject heat capacity and net savings were obtained for waste heat capacities below 2000 kW. It is determined that the chemical system is feasible if the waste heat capacity is higher than a certain value according to economical parameters and lifetime. Also, net gain increases almost linearly with increasing waste heat capacity.

Keywords: *Chemical heat pump, Economical analysis, Waste heat*

1. Introduction

Industrial chemical heat pumps can utilize waste heat at lower temperatures and use it at increased temperatures for industrial processes. An extensive literature study was performed by Wongsuwan et. al. [1]. Industrial chemical heat pumps requires up to one-fifteenth of electrical power input when compared to conventional vapor compression cycle heat pumps [2]. Chemical heat pumps consist of two different reactions which run at two different temperature levels [3]. For this aim, dehydrogenation of alcohols and hydrogenation of acetone can be used in chemical heat pumps [4]. The feasibility of the isopropanol/acetone/hydrogen chemical heat pump system was investigated theoretically by Gastauer and Kameyama [5]. Reverse reaction for isopropanol/acetone/hydrogen chemical heat pump system is

$$CH_3\text{-}CHOH\text{-}CH_3 \leftrightarrow CH_3\text{-}CO\text{-}CH_3 + H_2 \quad (1)$$

Dehydrogenation of isopropanol is endothermic reaction which occurs at 55-85 ^oC in liquid phase and hydrogenation is exothermic reaction and occurs at maximum 202 ^oC in gas phase. A typical isopropanol/acetone/hydrogen heat pump is given in Figure 1. In this study a comparative economical analysis was performed. Maximum $COP_t=Q_{out}/Q_{in}$ of the isopropanol/acetone/hydrogen heat pump is 18.2% depending on isopropanol concentration [6].

In this study, an economical analysis was conducted as a function of waste heat flux. Total costs including investment and operational and maintenance costs of the chemical heat pump system and the steam boiler is obtained. Net gain is defined as the difference between the total costs of the chemical heat pump system and the steam boiler.

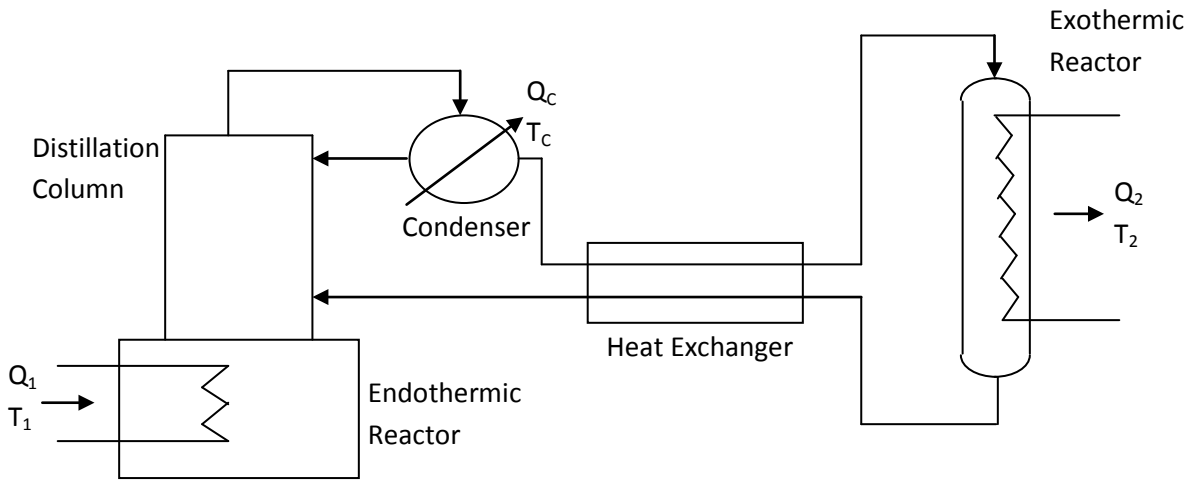

Figure 1 Isopropanol/acetone/hydrogen chemical heat pump flow diagram [5]

2. Economical Analysis of Chemical Heat Pump System

2.1. Investment Cost

Figure 2 derived from [7] can be used for determination of the investment cost of the chemical heat pump system.

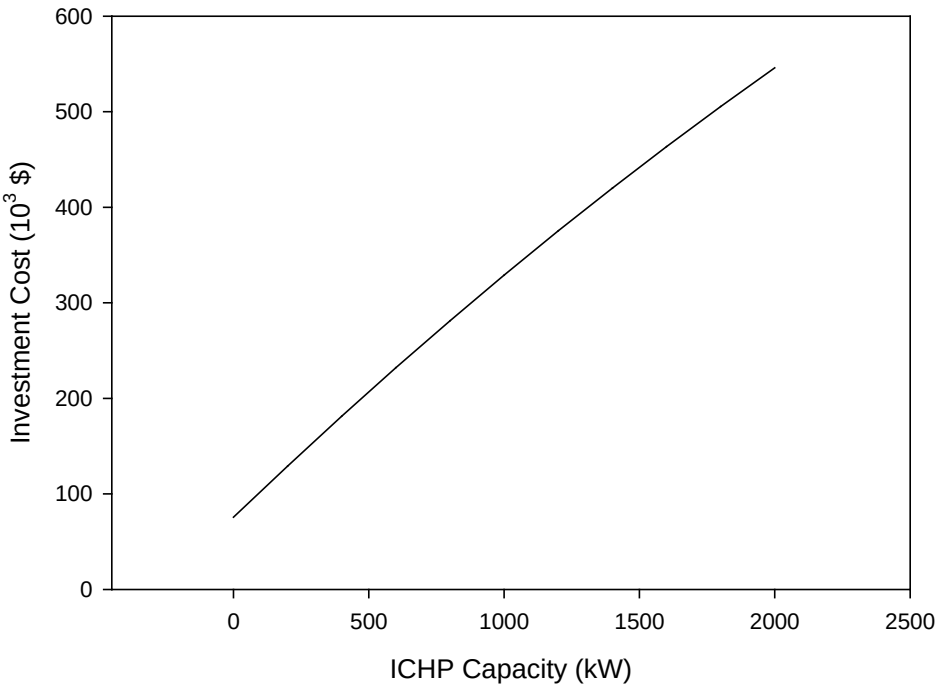

Figure 2 Relationship between industrial chemical heat pump capacity and investment cost

The equation that gives the function in Figure 2 is of the form

$$I_{CO} = -0.01832Q^2 + 271.77Q + 75567.3 \quad (2)$$

where ICO is the investment cost ($) and Q is the capacity (kW).

Figure 2 was obtained using economical values for 1988. In order to use it for the present calculations, it is required to make some modifications. For this aim a correction factor was defined as below:

$$f = (1 + i_1)(1 + i_2)(1 + i_3) \ldots\ldots (1 + i_n) \quad (3)$$

where i represents the inflation rate in corresponding year after 1988.
If the inflation rate is constant for all years from 1988 to the present, in that case;

$$f = (1 + i)^n \quad (4)$$

n is the number of the years from 1988 to present. Then, the investment cost of the chemical heat pump system in the present year, I_C ($), is calculated from

$$I_C = f.I_{CO} \quad (5)$$

2.2. Equivalent Annual Cost

Equivalent annual cost is obtained as a function of interest rate, i and lifetime of investment, n (year) from

$$EAC = I_C \frac{i(1+i)^n}{(1+i)^n - 1} \quad (6)$$

2.3. Operating and Maintenance Cost

Operating and maintenance cost of the chemical heat pump is calculated from [7]

$$OM = \frac{ES.CE.OT}{16} + 0.05 I_C \quad (7)$$

Here, ES, CE and OT are equipment size (kW), cost of electricity ($/kWh) and operating time (h) respectively. The number 16 is used for industrial chemical heat pump which uses a fan to operate a cooling tower. If groundwater is used for cooling then a value of 20 should be used [7]. Maintenance cost is assumed 5% of investment cost.

2.4. Total Cost

Total cost is the sum of the equivalent annual cost and operating and maintenance cost.

$$TC = EAC + OM \quad (8)$$

3. Economical Analysis of Boiler

3.1. Investment Cost

Investment cost is the price of a boiler which has the same thermal capacity as the chemical heat pump system. The investment cost of boiler was derived from present steam boiler prices available in the market. The variation of the boiler price ($) with thermal capacity (kW) is given in Figure 3 and can be calculated from the Eq. 9 as a function of boiler capacity Q (kW) for the capacities up to 2000 kW.

$$I_C = -0.00453216Q^2 + 21.9991Q + 3367.2 \quad (9)$$

3.2. Equivalent Annual Cost

Equivalent annual cost is obtained as a function of interest rate, i and lifetime of investment, n (year) from

$$EAC = I_C \frac{i(1+i)^n}{(1+i)^n - 1} \tag{10}$$

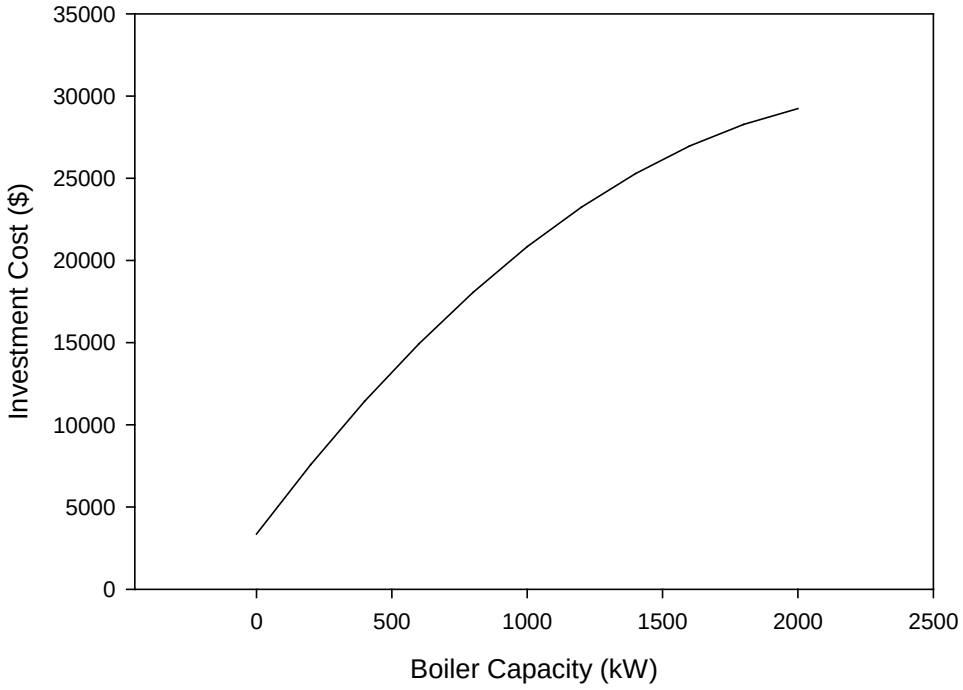

Figure 3 Relationship between boiler capacity and investment cost

3.3. Annual Energy Consumption

Annual energy consumption is the amount of fuel which is consumed during the operation of boiler and can be calculated from

$$AEC = \frac{Q.OT}{\eta_B.LHV} \tag{11}$$

where η_B is the boiler efficiency and LHV is the lower heating value of fuel (kJ/kg). The cost of the annual energy consumption is

$$AC = AEC.CF \tag{12}$$

and CF is the cost of the fuel ($/kg).

3.4. Operating and Maintenance Cost

Operating and maintenance cost of the boiler is calculated from

$$OM = AC + 0.05I_C \tag{13}$$

Maintenance cost is assumed 5% of investment cost.

3.5. Total Cost

Total cost is the sum of the equivalent annual cost and operating and maintenance cost.

$$TC = EAC + OM \tag{14}$$

4. Results

Net gain is calculated from the difference between total costs of the chemical heat pump system and the boiler.

$$NG = TC_{CHP} - TC_B \tag{15}$$

where TC_{CHP} and TC_B are total annual costs of chemical heat pump and boiler respectively. The parameters used in the analysis are as below:

Waste heat flux, 550 – 11200 kW
Effectiveness of chemical heat pump, 18% [6]
ICHP capacity, 100 – 2000 kW
Boiler efficiency, 90%
Fuel, Fuel-Oil
Lower heating value of fuel, 39774.6 kJ/kg
Fuel price, 0.87 $/kg
Electricity price, 0.125 $/kWh
Inflation rate, 8%
Operating time, 5475 h/year
Lifetime, 6 – 15 years

Figure 4 represents the relation between ICHP capacity and net gain. It is seen that net gain increase almost linearly with increasing ICHP capacity.

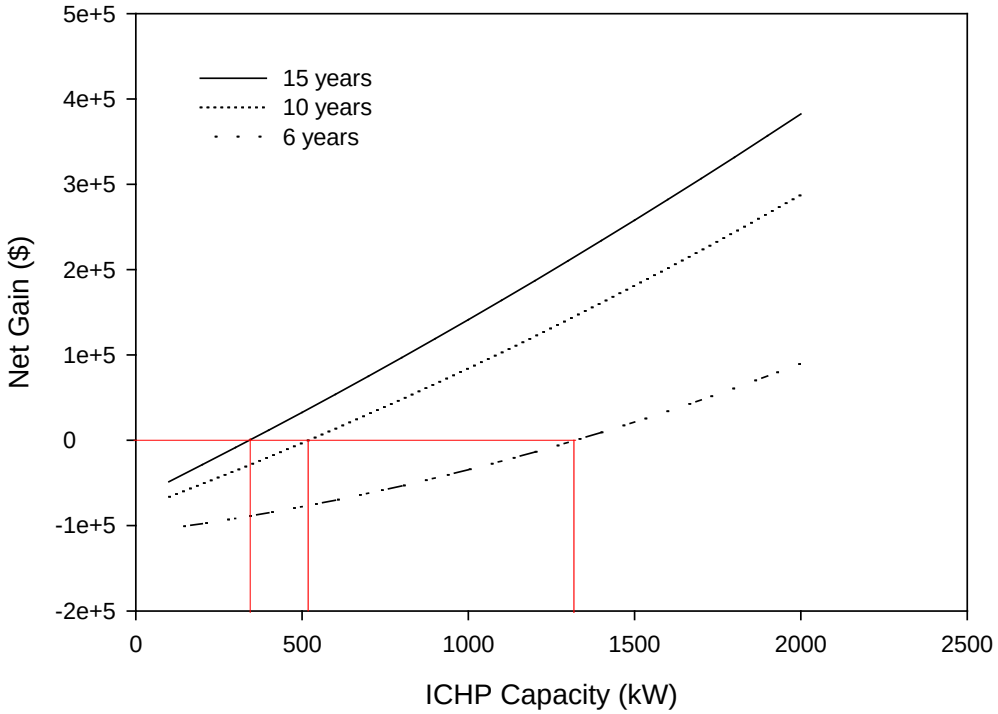

Figure 4 Relationship between ICHP capacity and net gain for lifetime 6, 10 and 15 years

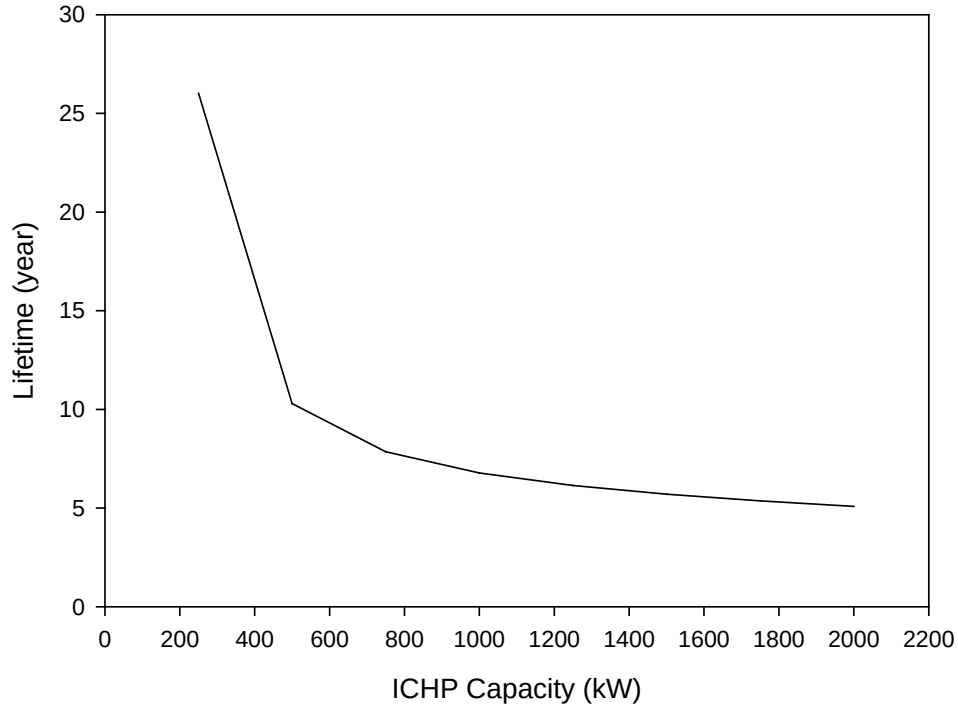

Figure 5 Relationship between ICHP capacity and lifetime where the net gain is zero

Figure 5 shows the relation between ICHP capacity and lifetime for zero net gain. It is seen that if the ICHP capacity is higher than 1000 kW, lifetime is asymptotically approaches 5 years.

5. Conclusion

Economical feasibility of industrial chemical heat pumps can be determined after calculations according to heat pump capacity. Economical calculations were carried out and curves show the relations between investment cost and capacity of chemical heat pump, capital cost and capacity of steam boiler, ICHP capacity and net savings were obtained. It is determined that the chemical system is feasible if the waste heat capacity is higher than a certain value according to lifetime of investment. Also, net gain increases linearly with increasing waste heat capacity. In Figure 5, the upper region of the net gain zero curve shows the feasible zone and it is seen that the payback period is almost constant for the capacities higher than 1000 kW.

Abstract: The challenge of economic and environmental sustainability demands a better way to manage production in the industry when treating energy consumption and emission of greenhouse gases. The reduction of greenhouse gases promoters are using: renewable energy matrix that can capture the CO_2, renewable energy resources and, production activities with better efficiency in thermal systems. The industry segment contributes over 33% for CO_2 emissions and it can be reduced through: energy integration in designs, intensifying the process and, better efficiency of utilities in the routine. The objective is demonstrates that, if global industry reduce at least 25% of thermal energy losses, 20% of losses of steam, and if change combustible oil to renewable in 33,8% proportion, the greenhouse effect reduce in 33%. The methodology to achieve reduction of CO_2 emission includes: Preliminary assessment, Strategies, Specific Programs, Restrictions analyzes and measurement of results. Between strategies are actions on operation, design and business chain. Between programs there are: evaluations about utility control and management; biomass economic chain viability; and, actions to recover steam losses on design. The restrictions are to implement politic programs in society and industry segment to change patterns becoming possible thermal energy reduction and renewable combustible substitution. The projected results on reduction of CO_2 in industry emissions are summed and almost overcome target of 21,6 (20,4) GTY. The segments of society can prepare similar programs and transform exercise in practice giving better quality of life for earth population.

1. Introduction

This paper aims to demonstrate that, integrated actions of industries can achieve the target reduction in CO_2 generation by greater energy efficiency in unit operations and by replacing the oil and gas fuels by biomass. After discussion about the industrial segment impact causing the greenhouse effect, topics of thermal efficiency and renewable energy resources are discussed. Then some activities and calculation methods are suggested for achieving the goals of reducing the generation of CO_2.

According to Johan Rockstrom and others [1] [2] the challenges to sustaining life on planet earth (sustainable) depend on the care of large environmental requirements. These requirements are conditions for the stabilization of the atmosphere and return to equilibrium between the species and nature as they did before the uncontrolled growth of world economy. Climate change is one of the uncontrolled factors indicating the need for urgent action to reduce emissions of CO_2, the main reason. Several programs and initiatives such as the gradual change of the current oil energy by renewable resources should be performed to prevent the growth and maintenance of the economy causing uncontrolled situations in nature and in particular in global climate.

To avoid the impact of gases contributing to air pollution, scientists seek to reduce its generation at source and reduce its inventory too. So they propose a series of actions resulting from studies that treat about the possible sources of energy and energy transformations, from

2010 to 2050, by IEA - International Energy Agency [3]. According to the IEA study, in 2005 CO_2 emissions to the atmosphere were the order of 28 GTY (Giga Ton per year), and imagining that, with the growth of global economies and emerging countries especially BRIC, the issue will be 62 GTY CO_2. With the work proposed here and in several initiatives by the conscious world, we intend to achieve by 2050 a situation of greater sustainability by reducing CO_2 emissions to around 14 GTY, or, half emission of 2005. Humanity needs to cut emissions from 2010 to 2050 on 48 GTY of CO_2 (considering that very little was achieved from 2005 to 2010). Scientists from IEA [3] estimated options about contribution of human activities to emission reduction. From this study, the opportunities to reduce inventory of CO_2 on atmosphere are located in different sectors of the economy. Energy sector has more potential for reduction with 20 GTY of CO_2, industrial sector with half the quota, 10 GTY of CO_2, transportation sector with 13 GTY, and urban areas with 15 GTY of CO_2.

Within the industrial sector, the opportunities to reduce CO_2 generation are: end-use efficiency of fuel utilization and use of new renewable energy resources, using as knowledge base some researches and services in petrochemical, refine and metallurgical industries in Brazil at TECLIM, clean technology research group inside UFBA, Engineering School. These issues are very important to the industry and can be classified as strategic to their survival. The best efficiency in the end-use of fuel is due reductions achieved from thermal energy consumption in furnaces and boilers allowed by new criteria to control these operations proposed to petrochemical industry. New scenery of combustible changing is constructed with substitution of oil by regional biomass in petrochemical industry (thermal-power facility).

2. Methodology

The Methodology to achieve the reduction of this green house gas presented in Figure 1, is divided in: definition of target (total quantity of emission that will be reduced), preliminary assessment, principal strategies, for each strategy definition of a program to be implemented at industrial segment, restrictions analyzes, and, expected results and respective measurement tools. This paper develops programs that treat these strategies: (1) reduction of thermal energy consumption and (2) use of biomass to decrease emissions of CO_2.

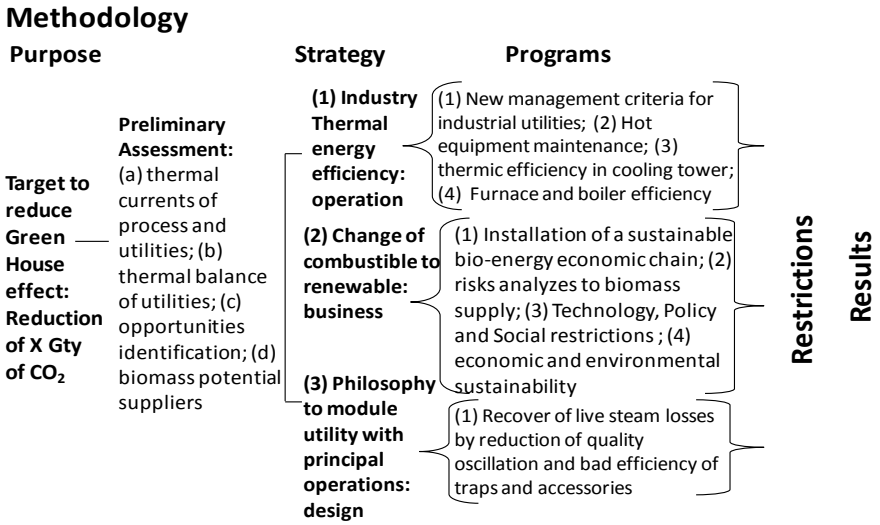

Figure 1. Methodology to investigate about reduction of CO_2 emission by energy control

In these exercises the responsibility to exchange energy type and reduction of thermal energy loss causing reduction in fuel use are of industry. These exercises can point the way for new business with respect to energy consumption and reduction in CO_2 generation. It means that

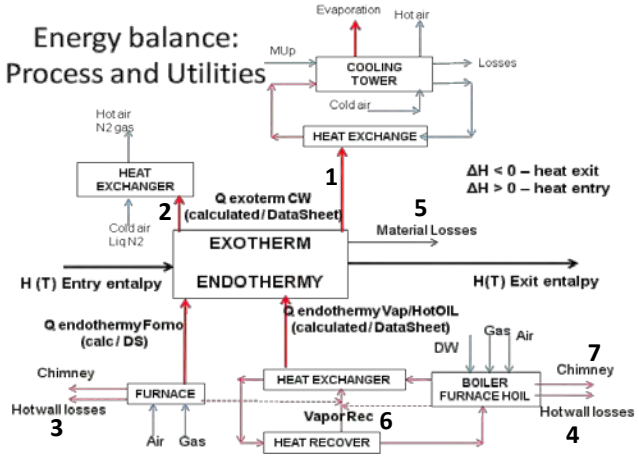
industry intends to achieve a reduction of 12 GTY of CO_2 from burning fuel and 8.4 GTY of free captured CO_2 by photosynthesis after CO_2 balancing with burning biomass.

2.1. Strategy 1: Thermal Energy Efficiency at Industry, a research case

The methods to increase energy efficiency depend on knowledge about energy balance and tasks related to control of thermal energy, cooling and heating systems at industry. Apart from knowledge availability and tasks well-planned, it is important reviewing conduct of the technical groups about management of utilities in the industry. A research about energy control was performed in a local Petrochemical Company [8] and proposes activities: (1) Planning and programming of Production allowing best decision-making in production scheduling (distribution of energy to activity); (2) Greater efficiency in cooling towers and systems allowing reduction of volatile products and hot energy consumption (temperature profile of separation columns); and (3) Efficiency of heat transfer in hot systems (boilers, furnaces, steam distribution, traps, condensate, and turbines) due to criteria of: projects, assemblies, operation, and thermal charge not compatible with the scale causing heat stress.

Although some of these issues involve the operation and maintenance of plants, the criteria of new projects must be adjusted using above standards, leading to a lower investment, to achieve the goal of greater efficiency in the use of fuel at industry and services. The article by Richard Doornbosch [3] present that the part concerning the reduction of fuel consumption is 12 GTY of CO_2, reference number for the industrial sector. The purpose is to work in a more efficient use of cold and hot energy to reduce consumption combustible thus generating smaller quantity of CO_2 into the atmosphere.

To achieve better thermal performance in cooling and heating systems, heat balances were made in research cases at petrochemical [8], oil and metallurgical industry, where: (A) in the balance of the cooling towers are pointed out possibility of recovery losses, improving the thermal performance; (B) in the balance of boilers was identified recovery energy due to: incomplete burning, and failure on steam generation (bad operational procedures ➔ low availability); (C) in the balance of furnace, the heat is too large by radiation, and the use of thermal energy to heat the reaction depends on: configuration of the tubes, complete burning of the furnace, and good insulation to prevent passage of heat through the equipment walls. Figure 2 descript part of topologies to study thermal performance.



1 - Quality of CW and reflux; 2 - Removal of excess heat - thermal inadequate planning; **3 - Losses at wall furnace** due to ingress of cold process fluid; **4 - Losses at wall boiler** and operational inefficiency in purges; **5 - Losses due flare materials** by higher volatile content at the top of separation equipment; **6** - Traps, separators, process control, incorrect scale of equipments causing **loss of alive steam**; **7 - Losses in chimneys** by not recover of residual heat.

Figure 2. Topology of direct and indirect heat transfer [9]

2.2. Strategy 2: Energy substitution, combustible mineral oils by biomass, a case

With the forecast that world oil reserves are exhausted in about 100 years, there will be, in the medium and long term, environmental and economic viability to greater utilization of available biomass energy and currently is found in nature generating methane, most striking than carbon dioxide to the greenhouse effect. The total use of biomass as fuel for industry depends on some difficult to be worked as: complicated logistics, model of business, and need to increase the efficiency of combustion in furnaces and boilers. Biomass has the advantage of being a natural process that performs photosynthesis where the removal of CO_2 occurs from the atmosphere, thus promoting favorable carbon balance. Assuming that each kilogram of CO_2 generated from burning of biomass has direct equivalence for each kilogram of CO_2 captured from atmosphere, we try to relate in Table 1, different types of Brazilian biomass.

Table 1- Comparison between different biomass and diesel

Biomass	gCO_2/kg Biom	MJ/kg Biom	Quantity Biom GTY	*CO_2 GTY
Sugar can bagass	0,075	15,49	200 E-3	0,08
Black liquor	998,79	13,40	2 E-3	0,002
Coconut fiber	1310,87	17,59	0,42 E-3 (peel, fiber)	0,0002
Cake/ Glycerin	1885,77	25,30	2,2 E-3 (5% biofuel)	0,0023
Total			204,62 E-3 = 0,2 GTY	0,0845

The biomasses chosen are present in abundance in Brazil, due to the large production of sugar cane industry, producing about 200 million tons of bagasse, the pulp industry producing about 9 million tons of black liquor, and the incipient biodiesel industry that generates about 2 million tons per year of glycerin and cake. The marketing of coconuts is quite common in Brazil and the waste generated, coconut peel and fiber, are good source of biomass.

2.3. Proposed activities to be performed

The Programs to increase Energy Efficiency and Mineral Combustible Replacement in the Industrial Segment are presented in table 2 and 3 to discussions.

Table 2 – Energy Efficiency Program

- ✓ Energy balance for process integration and definition of production scheduling;
- ✓ Thermal performance in cooling systems and towers to reduce the temperature of water;
- ✓ Thermal performance in heating systems, boilers, furnaces, steam / condensate and oil, in an attempt to reduce wall losses, loss of live steam, the reuse of energy, equipment reliability through proper drainage, and additional measures;
- ✓ Review the criteria for equipment design in operation by reducing the size of the plants and allowing to work with adjusted modules and not unequal growth of utilities;
- ✓ Review the criteria for management of maintenance and operation (tasks with more human reliability) in industrial plants intending to increase the operational availability of systems for cooling and heating.

Table 3 – Renewable biomass replacement program

✓ Mapping the biomass availability;	✓ Installation of local clusters by biomass type;
✓ Installation of processing plants to adequacy the biomass;	✓ Define national and global economic architecture for using biomass;
✓ Prepare managers in biomass area;	✓ Promote the establishment of cooperatives;
✓ Construct logistics scheme;	✓ Training the cooperative managers.

3. Program of activities to increase thermal energy efficiency, Strategy 1, research case

Assuming that the petrochemical plants and industry in general are in high charge/load, under thermal stress, the plants need to install additional equipment, or practicing high reflux flow in the distillation unit operations or similar. After performance tests conducted in the thermal cooling systems, some recommendations about proper operation can reduce by 15% or more, the temperature of cold water. Thus, fitting temperatures at the top of the decanter vessels, it reduces the reflux without losing the quality of final products, in bottom and top of equipments. If the premise that the proportion of decreasing the need for reflux ratio is equivalent to decreasing for hot utility at the bottom of the equipment, means that the reduction of steam consumption achieve the same, 15% (%RTEP1).

Some investigations are performed to reduce top temperature as result of cooling system (based on research case [9] and services): audit programs, calculations, process and operation investigations, and thermal performance tests discussed in Figure 3. The probably activities suggested are: change distribution of top cold pool, maintenance of top valves, vibration analyzes of fans, installation of side filters, temperature control measure with minimum of one decimal, calculation of concentration cycle based on good precision parameters, check of humidity of atmosphere and others. Other possibilities to reduction of losses are due to recovering of energy from: better insulation of hot equipment wall, increase of continuity in furnaces and boilers caused by increasing of human and operational reliability, diminish of mass losses to flare with cold temperature at column top, diminish of loss on energy recovery systems (condensate) by better control of steam quality. All these possibilities can increase the yield from 88% to 93%, saving 10% of fuel consumption to generate steam and fuel consumption in furnaces (%RTEP2). Summing possibilities of energy economy from cooling tower (15%) with better operation and design of hot systems (10%), we can achieve 25% of decreasing of combustible consumption (%RTEP=%RTEP1+%RTEP2).

The hot utility project (steam and condensate) have flexibility to increase 15% when compared with the design capacity, different from the case of large equipment (cooling towers, reactors, separators, heat exchangers and others) with the possibility to lift charges between 50 to 80% more than project charge. Thus, in debottlenecking design, the review of projects is poorly made for utilities generating non conformities with loss of live steam above 25% (%RSE). We consider, in the calculations, the possibility of recovery at least of 25% of live steam lost to the atmosphere.

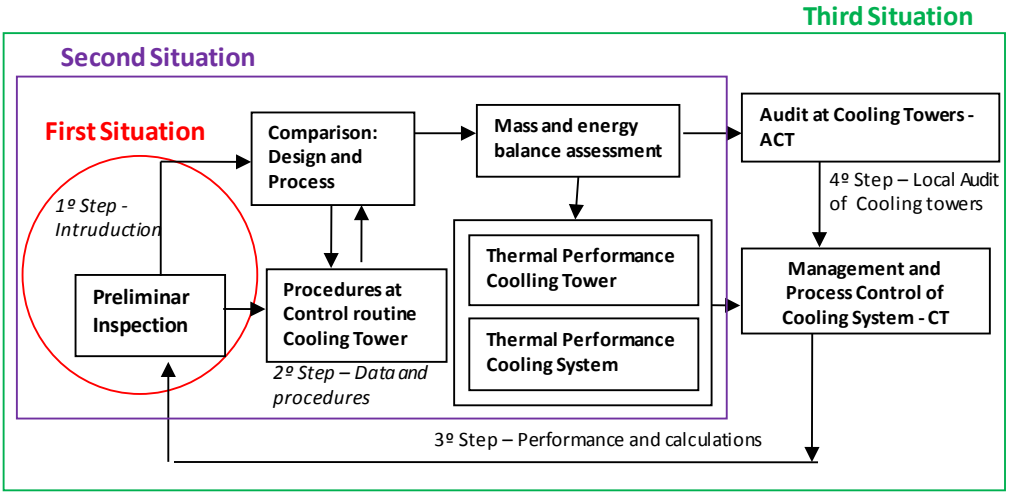


Figure 3. Energy management and audit of cooling system, based on research cases/services

Join knowledge from operation of equipments with technology, including knowledge about human factors in MMI of equipments and including process intensification concerns, is possible to change the design criteria for equipment and processes increasing certainty and decreasing rate of the flexibility of capacity (reducing the engineering coefficients of ignorance in design). So with project of smaller equipments in conjunction with the project of appropriate utility systems increase the load of plant in industrial modules instead of debottlenecking, reducing than, the losses of live steam and reducing factory investment.

Estimation based on Petrochemical Industry X in Brazil and Global Ones (Table 4). Based on data from large petrochemical X in Brazil, the annual production of ethylene is around 142,000 tons per year, and global ethylene production in 2010 was 142 million ton per year [4]. Thus, the calculation of fuel oil consumption and CO_2 generation for petrochemical industries can be multiplied, for exploratory calculations, by 1000 (thousand) that represents all the petrochemical companies worldwide. Thus, for the production of plant X of 260 thousand tons/year and consumption index 16.5 GJ / ton, this means all the energy consumption of around 4.3 million GJ/year. Whereas the average fuel PCI is (43000 KJ/Kg) 43 GJ per ton of fuel for the plant X. Annual consumption of fuels is 100 thousand tons of fuel per year for one plant in place X (*0,0001 Gton/Y).* For calculation to all petrochemicals, in exploratory way, it is considered *0,1 GTY* of fuel.

Table 4 – Data an formula for calculation Petrochemical Industry (Local X and Global)

Pet EGP (Ethylene Global production) = 142.000.000 ton per year	
Pet EXP (Ethylene Local production X) = 142.000 ton per year	
RelG/X (Relation Global/Local) = PetEGP/PetEXP=1000 petrochemical estimated world	
PPetX (Production of Petrochemicals at X) = 260.000 Ton/Y	
CIPetX (Consumption Energy/Mass Index, Petrochemical X) = 16,5 GJ/Ton	
*CcombX (Consumption of combustible per year at X) = PPetX * CIPetX= 4.300.000 GJ/Y*	
COPCI (Combustible Oil - PCI) = 43 GJ/Ton of oil	
FCPetX (Consumption of fuel to Petrochemical X) = CcombX/COPCI= 100.000 Ton of oil/Y	
FCPetX = 0,0001 Gton/Y =1E-4 Gton/Y	
FCPetGlobal(Global Consumption fuel to 1000 Petrochemical)=100.000.000 Ton/Y=0,1GTY	
RelG/X= PetEGP/PetEXP	*(1)*
*CcombX = PPetX*CIPetX*	*(2)*
FCPetX = CcombX/COPCI	*(3)*
*FCPetGlobal = FCPetX * RelG/X*	*(4)*
General Equation to consumption fuel at Global Petrochemicals indystries	
*FCPetGlobal = ((PPetX * CIPetX) / COPCI))* (PetEGP / PetEXP)*	*(5)*

Estimation based on Global Industry (Table 5). Considering that 1 kg of Carbon (C) generates 3 kg of CO_2, giving approximately 2.5 kg of CO_2 per kg of fuel. Thus 0,1 GTY of fuel generates 0,25 GTY of CO_2. If we consider that 1% of industry is of petrochemical type [8] then total industry generates 25 GTY of CO_2. If recovery of 25% of CO_2 by thermal efficiency and recovered is equivalent to 6.25 GTY, fulfilling the quota of efficiency in fuel consumption (12 GTY) for 1000 of petrochemicals X. This recovery is possible with better thermal performance of the separators from better operation of cooling systems and reduction of heat stress. If you consider the projected area, where you can recover 50% of live steam lost in the area, is reduced 25% of total CO_2, since no generation of 12.5 GTY which is higher than the target of 25% from 25 GTY of CO_2, or 6.25 GTY.

Table 5 – Data an formula for calculation Global Industry and decrease of CO_2

GICCO2 (Generation Index CCO2) = 3 kg CO_2/ 1 kg of Carbon
GICO2Fuel (Generation Index CO2Fuel) = 2,5 kg CO_2/1 kg fuel= 2,5 ton CO_2/ ton fuel
*PCO2PetX (Production of CO2 at X) = GICCO2Fuel * FCPetX = 2,5 E-4 Gton CO_2/Y*
PCO2GTotalIndX (Total Ind Production of CO_2 at X) = 2,6 E-2 Gton CO_2/Y [1][8]
Relation (Pet/Total Ind X)= (PCO2PetX/ PCO2GTotalIndX) = 1%
*PCO2PetG (Production of CO_2) = FCPetGlobal * GICO2Fuel= 0,25 Gton/Y of CO_2*
PCO2IndG (Prod of CO_2) = PCO2PetG/ Relation = 25 GTY
%RTEP = %RSE = 25% (recovered steam by thermal programs – operation and design)
*RTEP, Recovered by Thermal Energy Production= (%RTEP*PCO2IndG) = (25% * 25 GTY) = 6,25 GTY of CO_2; RSE (Recovered by Steam economy) = production and design = (%RSE*PCO2IndG) = (25%*25 GTY)=6,25 GTY of CO_2; Total Recovered (TR)=12,5 GTY*
TR ={*(%RTEP+%RSE)*[(FCPetGlobal*GICO2Fuel)/(PCO2PetX/PCO2GTotalIndX)] }(6)

4. Program of Activities to combustible substitution: biomass related to strategy 2

Brazil [5] [6] [7] is an agricultural country and has large area of land available for food crops, has ample opportunity to use the biomass generated as a natural substitute of petroleum. Because of this trend, in very near future, there is a need for the government to invest in productive arrangements to provide this biomass for energy and industrial segment. For this change in the energy supply chain, it is required to mapping sources of biomass, defining the inventory economically feasible to tie their strategies, including political, technical, economic, environmental, ethical and seasonal risks. This Petrochemical Industry in study intends to meet the environmental paradigms to reduce greenhouse gases (carbon balance favorable due to increased carbon sequestration), and meet global energy demand.

There are some steps that the government, together with the industries and society in general must accomplish: • Develop network of institutions and companies with roles to enable installation of a sustainable bio-energy economic chain; • Analyze risks to regular supply of biomass; • Identify restrictions in: Technology, Policy and Social aspects; • Ensure the economic and environmental sustainability. Between policy challenges, there are: prepare economic local clusters, check on the participation of society (cooperatives in logistics and sorting) in this new economic activity, and development of technology to Bio-energy.

5. Discussion of results

In the global, if it is possible to reduce 25% of fuel consumption resulting from energy efficiency program and reduces 20% absolute of live stream to atmosphere is sufficient to meet the challenge posed by the IEA, a reduction of 12 GTY. In the biomass, considering the estimated of last four cases (sugar can bagass, coconut, cake/glycerin from biodiesel, and black liquor), achieves a 0.0845 GTY of CO_2, needing a biomass matrix at least 100 times bigger, including other biomass and other countries like China and India in trying to reduce carbon emissions into the atmosphere. If you reach this goal, with 8.45 GTY versus 9.6 GTY CO_2, quota demanded to be reduced. As mentioned before, the industry emits 25 GTY of CO_2 from fuel combustion, is intended to reduce 8.45 equivalent to 33.8% of the diesel currently used, when you know that above the goal number of 10 %, a third part of necessity, demanding strong economic and political organization and efforts around the biomass.

[1] * General Relation Industry/Petrochemical in Bahia/BR, place X, [8]

6. Conclusion and Restrictions

Work with energy efficiency is simple when Industry management gives importance to utilities as: steam (generated by water and heat from combustible), direct heat to furnace (generated by heat from combustible burning), and cooling water (that depends of cooling tower work). The difficulties are to change managers' decision model that analyze short term problems and does not work to increase human and operational reliability. One other concern is about the necessity to change design criteria preparing factories in smaller size.

Despite the great potential of Brazil to the wide use of biomass, it is not still efficient to process and distribute products in biomass segment; it depends of governments' infrastructure in logistics area. Although there are many searches for new technologies in which the fuel is biomass, it does have large-scale policies or actions that make the distribution of this form of biomass for industry, already ready for use. Therefore, it is necessary to analyze the economics chain in the vertical form, including all activities in the life cycle of different biomasses. For the energetic matrix change to renewable one, some multi-attributes assessment (environment, economic, ethical, policy, social) to choice biomass must be done. The criteria for choice of matrix must be analyzed in biomass to prevent, for lack of planning, the projects unviable after long-term, development policy for biomass, availability of materials, supply guarantees, social and environmental benefits.

Abstract: The paper quantifies the synergy-effects of an areal combination of biogas-plants with plants of the building materials industry (e.g. cement plants) from the energetic and economical point of view. Therefore a model biogas and cement plant are defined and the effects of a combination of both plants in terms of energetic efficiency, investment and operating costs, greenhouse gas emission reduction and overall energy production costs are quantified. The main benefits of this combination are the utilisation of low temperature excess heat sources from the cement plant for fermenter heating and the direct thermal utilisation of unprocessed biogas as a valuable, CO_2-neutral fuel for combustion processes for instance clinker burning. Due to the combination, the energetic efficiency of the biogas plant, defined as utilisable energy output in relation to the energy content of the produced biogas, significantly increases from 63.0% to 83.8%. Concurrently the energy production costs are reduced, turning biogas into a competitive source of energy without the need for federal sponsorship. Calculations show, that from a plant size of around 90 m^3_{STP}/h biogas production costs in combined plants are even lower than the actual market prize of natural gas.

1. Introduction

The anaerobic fermentation of biogenic material presents a well known technology in waste treatment and agriculture. Furthermore the specific production of biogas out of renewable resources provides an opportunity to integrate CO_2-neutral energy sources in the power supply chain. Nevertheless state of the art concepts of biogas utilisation like electricity generation in combined heat and power plants (CHPs) or processing of the raw biogas to inject it in existing gas supply systems are still in need of improvement. Energy losses due to processing and compression steps or the production of a significant amount of excess heat reduce the percentage of useable energy from the raw biogas.

In view of this problem, an alternative way of gas utilisation would be desirable. The combination of biogas plants with plants of the building materials industry especially cement plants, presents a unique opportunity to meet these demands [1]. The main benefits are:

- utilisation of excess heat from the cement plant for fermenter heating
- raw biogas as CO_2-neutral fuel without the need of processing
- ammonia recovery from the digestate and use as reducing agent in DeNOx-processes

High temperature processes in the cement, lime and magnesia industry are a source of waste heat at various temperature levels. The use of this energy for heating a mesophillic biogas fermenter (~35°C) allows the utilisation of excess heat at temperature levels beyond 100°C, which presents a problem for other state-of-the-art solutions.

The average calorific value of biogas with 21 MJ/m³ (60% methane, [2]) is sufficient for a direct use as fuel in cement and clinker burning. Primary fuel combustion in the rotary kiln and secondary combustion in the precalciner can be adjusted to work with natural gas as well as biogas [3]. The demands in terms of gas composition for direct burning are not that strict as for CHP plants or injection in natural gas supply systems. Compression of the gas to the pipeline pressure (30 to 80 bar) is not necessary. Hence, raw biogas can be used directly for burning without processing steps like desulphurisation and NH_3-removal. H_2S in the biogas is oxidised to SO_2 during combustion, which reacts to alkalisulphates with the clinker in the preheating and calcining system [4]. The fate of NH_3 has to be investigated.

The application of biogas reduces the greenhouse-gas emissions of the cement plant due to the substitution of fossil fuels. On the other hand the combination offers the possibility to improve the partially negative ecobalance of some biogas production ways [5].

The third benefit is the potential recovery of ammonia from the digestate. The output of digestate as a fertiliser for agricultural areas is limited to certain times of the year due to ammonia emissions. Processing of digestate and ammonia recovery can solve the problem of temporal dependency with the concurrent benefit of producing a NO_x-reducing agent for cement plants. By decreasing the ammonium concentration in the effluent for example by steam-stripping, the recycling of the liquid phase into the fermenter might be possible.

2. Methodology

To quantify the synergy effects of the areal combination of biogas and cement plants, an Excel-model was developed, in which conventional biogas plants with CHP are compared to the corresponding combined plant in regard to energetic efficiency, CO_2-savings, energy production costs and plant feasibility. The biogas plant scale can be adjusted by varying the amount of substrates. For the actual calculations a substrate mix with 90% manure and 10% co-substrates (4% food leftovers, 3% glycerine and 3% flotate sludge) was chosen.

The energy balances and costs of combining a conventional biogas plant with a production of 250 m^3_{STP}/h respectively 550 kW_{el} installed electrical power with a cement plant with a production capacity of 440 000 $t_{clinker}$/a are presented in detail. Both plants represent a mean plant size in Austria derived from overall production data divided by the number of plants [6, 7]. In biogas production the trend goes to larger plant sizes, wherefore the mean biogas plant size derived from literature data (270 kW_{el}/plant) was doubled. Based on averaged data of numerous existing biogas-plants [8, 9] in combination with data from CHP evaluations [10] a basic energy balance for a model biogas-plant was determined. To quantify the main excess heat sources of a model cement plant, the mean thermal energy balance was calculated from averaged literature data for Austrian cement plants [11].

Investment and operating costs of the conventional plant were calculated with four different literature models [2, 9, 12, 13] to prove consistency. The estimations were converted to actual costs on the basis of 2009 by correction with the harmonised index of consumer prices in Austria. The most suited model due to its modular configuration (FNR, 2008) was chosen for the economical comparison of conventional and combined plants. Based on the published FNR-data, compensating curves for specific investment and operating costs were implemented to calculate the scale dependent energy production costs. Investment and operating costs of the combined plant do not comprise expenses for CHP and desulphurisation units but an additional cost factor for the combination (burner, gas pipeline, excess heat utilisation). This factor is made up of fixed costs and scale dependent additional costs

(investment costs combination in € = 30000 + (actual plant size [m^3_{STP}/h] / 500) * 100000). It is assumed that substrate and digestate processing costs are the same for both plants, wherefore these expenses remain unaccounted for.

The determined operating costs together with the depreciation charges result in mean energy production costs in ct/kWh, when divided by the useable energy output. Depreciation charges were calculated on the basis of an annuity factor for 16 years deprication period and an imputed interest rate of 6%. The income of the conventional biogas plant comprises the sale of electricity and thermal energy according to the renewable energy feed-in tariff of the ÖSVO 2010 [14]. In case of the combined plants, the income is considered to result from cost savings for fossil fuels (natural gas and fuel oil) [15] and CO_2-savings valuated with an actual emission certificate price of 15 €/t CO_2. Electrical energy to cover the internal demand of the combined plant has to be bought on the market [16]. Based on these data the ROI and payback-period for the conventional and combined plant can be calculated.

The determination of the CO_2-savings is based on a representative mixture of cement plant fuels from literature [6]. It is assumed, that first natural gas and then fuel oil are replaced by biogas, as far as the produced amount of biogas can cover the demands of these fuels. Mean CO_2-savings were calculated from literature data for CO_2-emission rates of fossil fuels [17]. The electrical energy demand of the combined plant is covered by electricity from national power networks, which decreases the CO_2-savings due to emission of greenhouse gases during the production of conventional electrical energy [18].

3. Results

The basic energy balance of a 250 m^3_{STP}/h model biogas plant is visualised in figure 1.

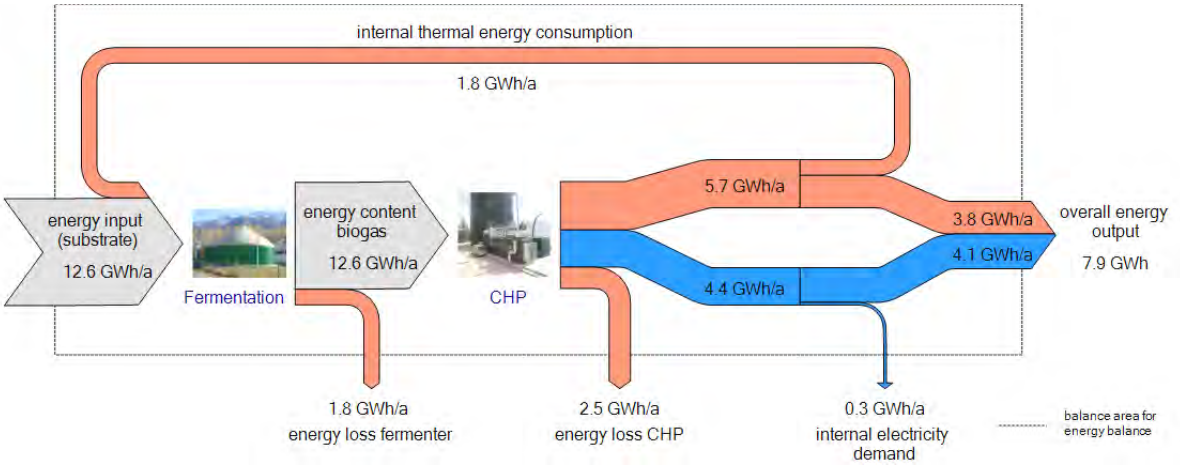

Fig. 1. Energy balance of a conventional biogas plant (250 m^3_{STP}/h) with combined heat and power unit (CHP, 550 kWh_{el} installed electrical power); for detailed data see table 2.

Figure 1 shows that only 35% of the input energy of 12.6 GWh/a can be converted to electrical energy with 45% low temperature excess heat from the CHP. After deduction of the internal electrical and thermal energy demand, 30.5% thermal energy and 32.5% electrical energy remain, giving an overall energetic plant efficiency of 63%. The high amounts of energy needed for fermenter heating and a CHP efficiency of 80% significantly decrease the overall plant efficiency. Moreover, this calculation represents the ideal case, where 100% of the available thermal energy is utilised for example for drying processes or district heating.

The thermal energy balance of the model cement plant (440 000 $t_{clinker}$/a) is visualised in figure 2.

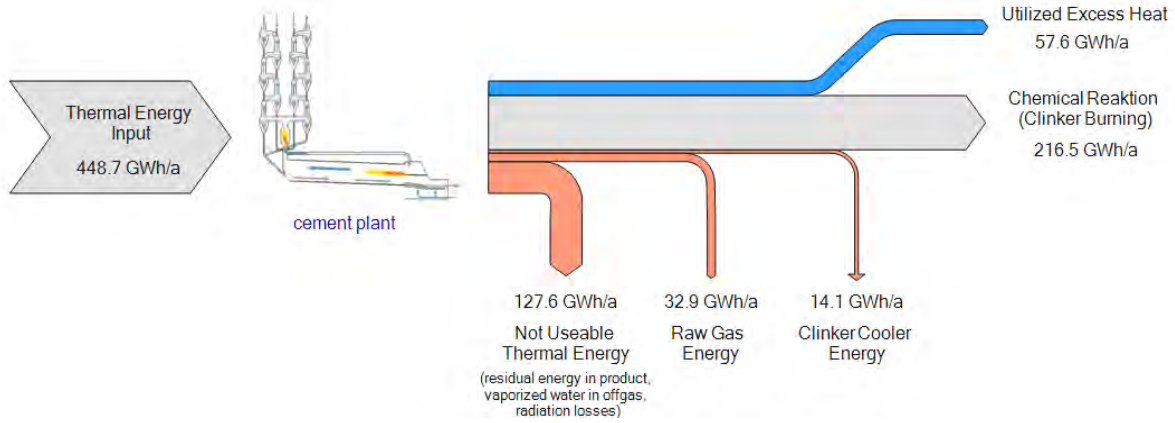

Fig. 2. Thermal energy balance of a conventional cement plant (440 000 $t_{clinker}$ /a)

Not useable thermal energy like the remaining energy content in the product, vaporised water in the offgas and thermal radiation turn out to be the main excess heat sources. The residual energy in the cooling air after the clinker cooler and the energy in the raw gas after the raw mill can easily be utilised for fermenter heating by adequate heat recovery concepts, for example the installation of gas/fluid heat exchangers as shown in figure 3.

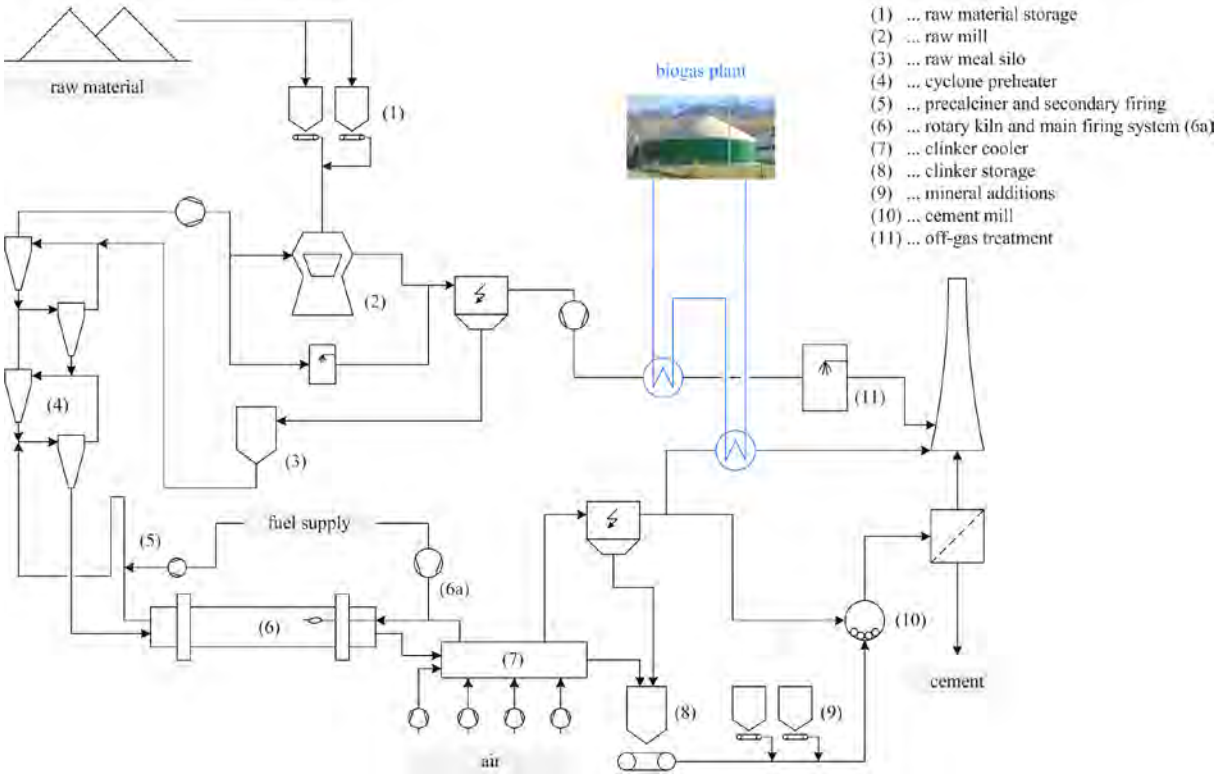

Fig. 3. Process flowchart of a combined biogas and cement plant.

Figure 4 illustrates the effects of this combination on the energy balance of a 250 m^3_{STP}/h biogas plant. Clinker cooler and raw gas excess energy together offer nearly the 27-fold amount of energy needed for fermenter heating. Electrical energy has to be bought in addition. The direct use of raw biogas enhances the utilisable energy of the biogas plant,

leading to a major increase from 63.0 to 83.8% in the overall plant efficiency (cf. table 2). The thermal efficiency of the cement plant only slightly increases from 61.3 to 61.5% due to its large excess heat production compared to the energy demand of the biogas plant. On the basis of the above defined plants scales, 2.7% of the thermal energy consumption of the cement plant can be replaced by raw biogas, resulting in a decrease in greenhouse gas emissions of around 2860 t CO_2/a or 0.8% of the annual CO_2-emissions of the cement plant.

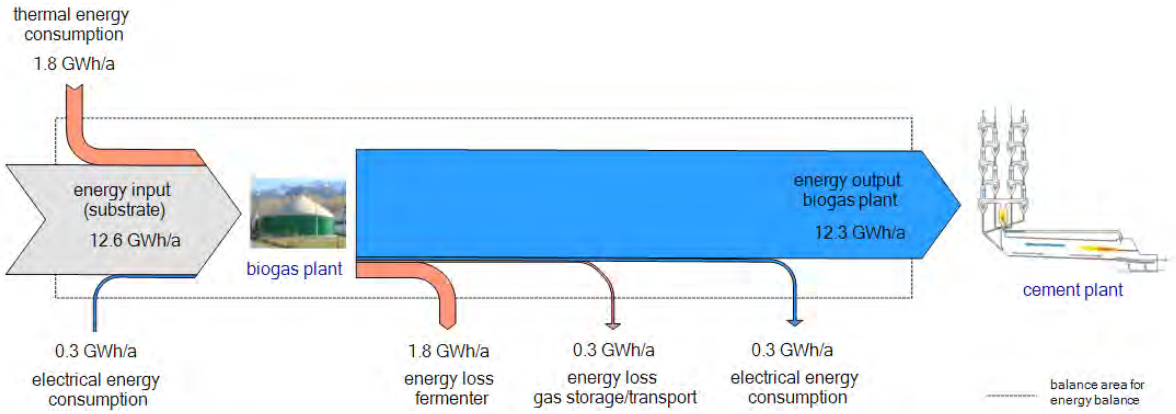

Fig. 4. Energy balance of a combined plant; biogas plant (250 m^3_{STP}/h) coupled with a cement plant (440 000 $t_{clinker}$/a)

Table 1 comprises the estimated investment costs for a conventional biogas plant (250 m^3_{STP}/h) with biogas utilisation via a CHP. The results of the models generally fit together, with the FNR model being the closest to the mean investment costs of 1,750,819€ derived from all models.

Table 1. Investment costs for a conventional biogas plant (250 m^3_{STP}/h) based on different models

		FNR [12]	KTBL [9]	LfU Bayern [2]	Hornbacher* [13]
plant investment costs	[€]	1,172,538	943,757	-	1,578,733
CHP investment costs	[€]	493,729	626,819	-	336,284
total investment costs	**[€]**	**1,666,267**	**1,570,577**	**1,851,414**	**1,915,017**

* estimation excl. CHP, CHP costs estimated with different model (ASUE [10])

Table 2 shows the results of the energy balance as well as the energy production costs and plant feasibility calculations of a conventional plant compared with the combined alternative.

Investment and operating costs of the combined plant are considerably lower because of the missing CHP plant. Together with the higher amount of energy output in terms of fuel, the production costs of energy in a combined plant are around 3.2 ct/kWh compared to 7.0 ct/kWh for a conventional plant, in which 100% of the thermal energy output of the CHP are utilised. Electricity production costs without thermal energy utilisation are 13.5 ct/kWh_{el}. The ROI of the combined plant is somewhat higher and the payback period shorter because of the lower investment and operating costs compared to the conventional plant.

Table 2. Base data of a conventional biogas plant compared with an equally scaled combined plant

		FNR conventional plant	FNR combined plants
biogas production	[m^3_{STP}/h]	250	250
plant energy input	[kWh/a]	12,580,295	14,718,946
electrical energy output	[kWh_{el}/a]	4,088,596	0
thermal energy output	[kWh_{th}/a]	3,836,990	0
utilisable energy output	[kWh/a]	7,925,586	12,328,,689
overall plant efficiency	**[%]**	**63.0**	**83.8**
total investment costs	[€]	1,666,267	1,175,732

thermal energy income	[€/a]	92,088	0
total income	[€/a]	599,074	517,494
total profit	[€/a]	47,012	120,098
ROI (profit/investment)	[%]	2.8	10.2
payback period (debt-repayment method)	[a]	11.0	6.1

* 100% utilisation of thermal energy

The depiction of the energy production costs of the conventional and combined plant over the plant scale shows the typical decrease in production costs with increasing plant size (figure 5).

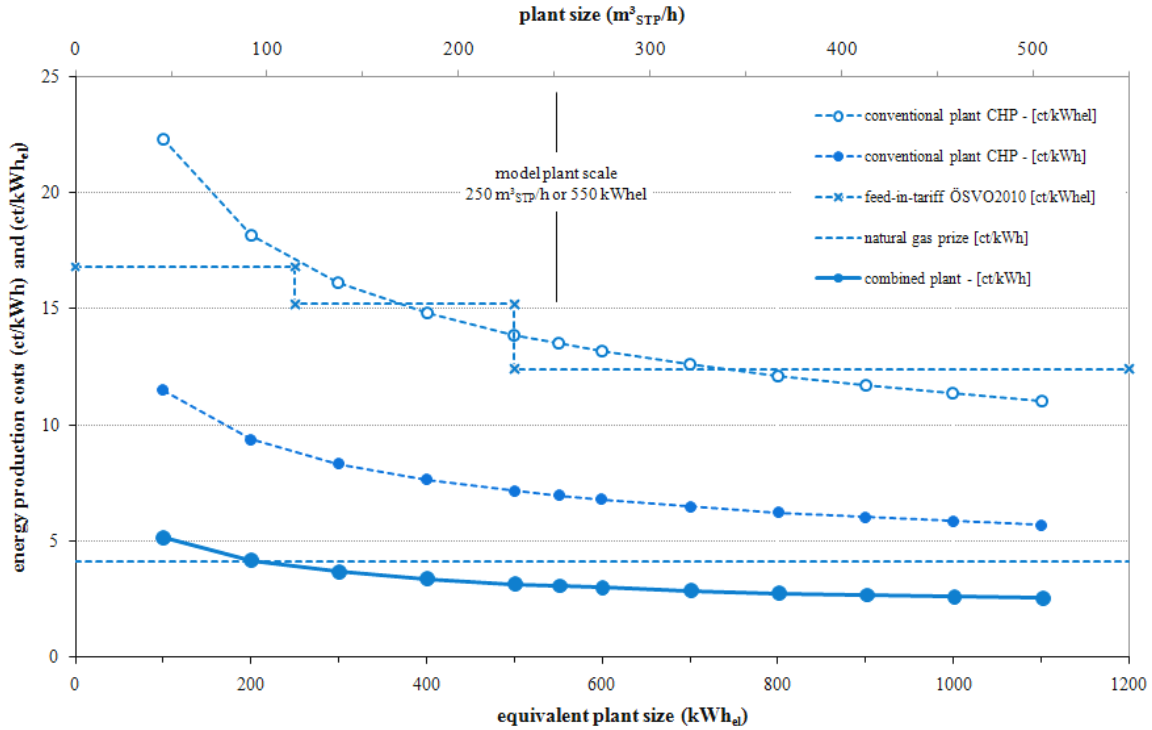

Fig. 5. Energy production costs (electrical and thermal energy) for various plant sizes.

Conventional biogas plants without thermal energy utilisation have electrical energy production costs from 20 to 12 ct/kWh$_{el}$. The simultaneous use of 100% of the CHPs thermal energy output can decrease the energy production costs to values between 11 and 6 ct/kWh but is difficult to implement. Compared to the feed-in-tariff in accordance with the ÖSVO 2010 [14] one can see, that the combined use of thermal energy is essential for the feasibility of a conventional biogas plant. The energy production costs of combined plants (~ 5 and 2.5 ct/kWh) are well below conventional plants due to the higher amount of energy utilised as fuel for clinker burning. From a plant size of 200 kWh$_{el}$ (~ 90 m$^3_{STP}$/h) the production costs of biogas in combined plants actually fall below the costs for natural gas [20].

4. Conclusions

The combination of a biogas plant with a cement plant is a possibility to significantly increase the overall efficiency of a biogas plant. The use of unprocessed biogas as a fuel for clinker burning and the utilisation of excess heat from the cement plant enables biogas costs to be competitive to natural gas costs even without federal sponsorship.

Nevertheless, there are still points that have to be investigated, first and foremost the fate of H_2S and NH_3 in the clinker burning process and their contribution to NOx and SO_2 emissions of the cement plant. Moreover, solutions for the gas utilisation during maintenance periods of the cement plant have to be found. Whereas these periods might also be used for servicing the biogas plant, concepts must be developed for a controlled diminishing of the biogas production rate by reducing or altering the substrate feed and concurrent burning of biogas. Thereby, the internal thermal energy demand of the biogas plant can be covered temporarily.

The recovery of ammonia from the digestate for DeNOx-processes would be a major benefit for the cement plant. Potential technical solutions like steam-stripping of liquid digestate have to be investigated. Especially substrates with the potential to cause ammonia inhibition of the fermentation process might be processed in combined plants, if ammonia recovery is feasible. The practicability also strongly depends on the type of substrates, which have to be suited for fermentation but not for direct burning. Important parameters for waste fuels in cement plants are calorific value along with the content of water, ash, sulphur, chlorine and heavy metals as well as the suitability for the burners [3]. Examples for substrates with limited applicability are liquid manure and brewery and agricultural residues due to the high water content. The inhomogeneity of food residues as well as slaughterhouse waste and similar materials impede direct burning, but otherwise present wastes high in biogas production.

Due to sufficiently available waste heat energy and the huge fuel consumption of cement plants, the share of fuel provided by biogas can be increased almost arbitrarily, resulting in cheaper biogas production costs and significant CO_2-savings. One 2 MW biogas plant can substitute over 10% of the energy consumption of a 440 000 t$_{clinker}$/a cement plant and save around 13 000 t CO_2/a. The substitution is only limited by the available amount of substrates for the biogas plant. Nevertheless, also small scale options are possible, because any industrial plant with high temperature processes and utilisable excess heat, high fossil fuel consumption and the need of a denitrification system is a potential site where biogas plants can be installed. In many cases this combination would be the better alternative compared to biogas plants in the open countryside. With the developed model, site specific questions like maximum substrate and transport costs for economical plant operation can be estimated. Thereby, the number of potential biogas plant sites increases and the role of biogas as CO_2-neutral fuel in power supply can be strenghtened due to the installation of sustainable energy systems.

Abstract: In recent years, there has been great incentive to improve the energy utilization with which the existing capital in offshore and onshore surface facilities is utilized. One of the most energy intensive processes in oil upstream industry is natural gas liquid or NGL recovery plant. The main gorge of energy consumption in conventional NGL plants is propane refrigeration. Hence, more attention should be focused on the effective utilization of propane chillers in a NGL plant. In this study, a novel process configuration for recovery of natural gas liquids in NGL plant is purposed. The required refrigeration in this configuration is obtained by a self-refrigeration system. In summary, the novel scheme generates refrigeration internally, decreasing cooling load of propane chiller and providing additional refrigeration for inlet gas cooling due to plant capacity increase. Besides, the recycled stripping gas also eliminates the need for external reboiler heat. The warmer the stripping gas, the less demand is placed upon the bottom reboiler, thereby saving fuel and energy cost. In this investigation, a simulation model has been developed on the basis of using novel configuration in Gachsaran NGL1200 in south of Iran. The model has been applied for evaluating of energy utilization in this plant. Results of the model show decreasing in total electricity demand of the plant from 268 kWh/t_{NGL} to 175 kWh/t_{NGL} by decreasing cooling load and electricity consumption in propane chiller. Also, the need for reboiler heat is satisfied and efficacy of demethanizer column is improved from 72% to 84% by more NGL recovery. Finally, economical analysis of the new retrofit has been studied.

Keywords: *NGL plant, self-refrigeration, SGR, energy utilization*

1. Introduction

Natural Liquid gas factories which produce NGL are one of the important and energy intensive units of offshore industries. In these units, natural gas liquids are separated from the sweet gas which has been sweetened in gas sweetening units before. Recovery of natural gas liquids (NGL) components in gas not only may be required for hydrocarbon dew point control in a natural gas stream, but also yields a source of revenue, e.g., natural gas may include up to about fifty percent by volume of heavier hydrocarbons recovered as NGL [1].

Most of the NGL plants in operation today use conventional single-stage turbo expander technology for moderately high ethane recovery. Based on this technology, after the inlet gas is treated to remove water and other contaminants, it's cooled by cold residue gas in gas/gas exchangers. Propane refrigeration is often required to help in condensing the heavy components for a rich gas. Then, liquid condensed from the inlet gas is separated and fed to the tower for further fractionation after being flashed to the tower pressure. The remaining non-condensed vapor portion is subject to turbo-expansion to the top section of the demethanizer column, with the cold liquids acting as the top reflux to enhance recovery of heavier hydrocarbon components.

The growing economic opportunities offered by the markets associated with natural gas liquids determined the development of using different technologies in NGL recovery units. The difference between the various technologies lays in the energy recovery strategies that each of them utilizes [2].

One of the most attractive technologies for reducing energy intensity in NGL recovery unit is Stripping Gas Refrigeration (SGR) method. SGR is a self-refrigeration system is widely

applicable not only for new, grass-root plants but for revamping old, existing plants. This technology utilizes a slipstream from the demethanizer bottom. This stream is totally or partially vaporized, providing additional refrigeration for inlet gas cooling. The flashed vapor generated from the self-refrigeration cycle is recycled back to the column, where it serves as stripping gas. Stripping gas increases the critical pressure thus enhancing the relative volatility.

This paper focuses on revamping existing plants using the stripping gas refrigeration scheme. To this aim, factory of NGL 1200 in south of Iran is selected as case study. The results show the economic return on retrofit investment is much more attractive and also, there are opportunities for upgrading the performance of the plant, e.g., plant capacity increases and energy intensity decreases over the time [3].

2. NGL recovery process

The process flow diagram of a NGL plant based on the simulation of NGL1200 by HYSYS software is depicted in figure (1). According to this figure, inlet sweet gas flows into the two stages of gas to gas heat exchanging process (E_1 and E_3) and exchanges its heat with separated gas stream form the three phases separator (E_6) and therefore, its temperature is decreased from 65^{0C} to 25^{0C}. Then, outflow stream from second heat exchanger enters into two stages of propane chilling system (E_4 and E_5) and it is cooled to temperature lower than -29 centigrade degrees to condense out the liquids. At the exit point of chilling system, gas has two phases condition and therefore liquid and vapor phases should be separated by separator (E_6). The vapor phase returns to the heat exchanger (E_3) and the liquid phase is then fed into the demethanizer column which has 9 trays to stabilize gas liquids and separate light compounds. Demethanizer column also has a kettle reboiler for providing required heat in the bottom section of the column for vaporizing heavy product and recycling it to the column. Overhead flow of column which has more methane and ethane will be recompressed by compressor (E_{11}) and will be returned to the gas injection unit; propane, butane and condensates are separated as bottom product and sent to the pressurized refrigerated storage vessels to await transportation to market [4].

Table (1) represents physical properties of streams which have been approximated by the Peng-Robinson equation of state formula through developing simulation model by HYSYS software. The aforementioned simulation model has been applied for analysis of performance of the factory of NGL1200 and estimation total energy intensity and efficiency of this plant [5].

According to results of simulation, total performance and energy intensity of NGL1200 are represented in table (2). Also, major energy intensive equipments of NGL1200 are reported in table (3).

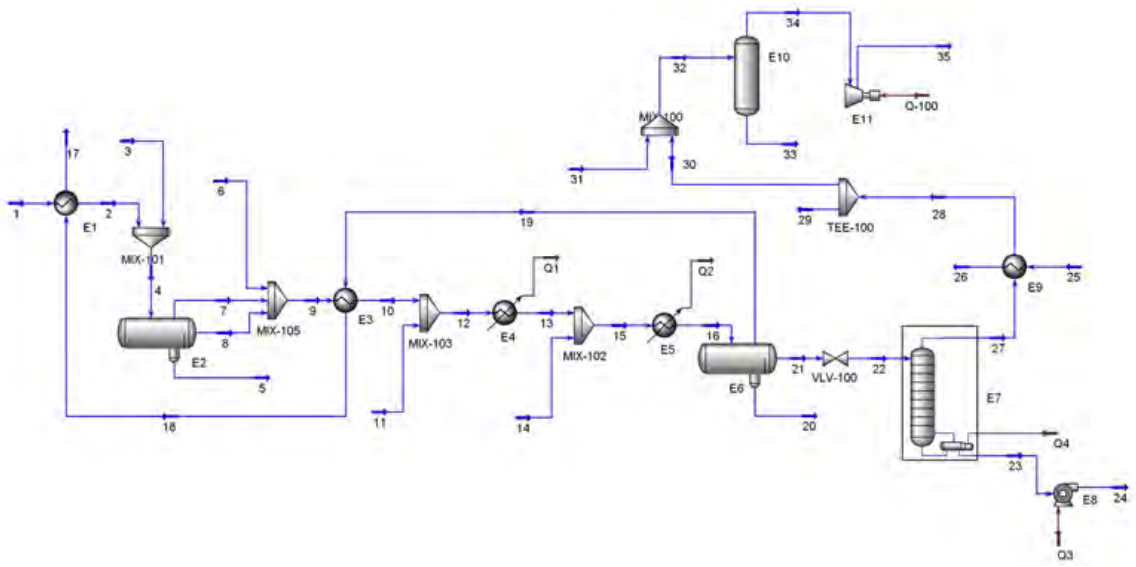

Fig. 1 Process flow diagram of NGL1200

3. Self-refrigeration method

Self- refrigeration method is a modern method to increase NGL plant capacity, to decrease plant electricity consumption and to eliminate the need for external reboiler load. Also, application of this method increases critical pressure and volatility of demethanizer column and therefore, efficacy of column will be improved. This method is known as Stripping Gas Refrigeration (SGR) method [6].

SGR method generates internal refrigeration by expanding a liquid stream from the bottom of the demethanizer column. Simulated process of SGR method and its application in NGL1200 is represented in figure (2)**.** According to this figure, liquid stream from the bottom of the column (stream 39) is then heated by indirect heat exchange with inlet sweet gas to generate a two-phase stream. The two-phase stream (stream 42) is flashed in a separator. The flashed vapor (stream 44) is compressed and recycled to the demethanizer as a stripping gas, which increases the ethane and propane concentration in the column. The flashed liquid stream (stream 43) is pumped and mixed with other NGL product streams.

Three major advantages of using SGR method in a NGL plant may be concluded by following items [7]:

1) Increasing production level up to 20%.
2) Increasing recovery of ethane. Concentration of ethane and propane will be increased in the column and heat profile on the trays will be decreased significantly.
3) Increasing operational pressure of the column is one of the other advantages of this method which increases volatility of propane and ethane and then separation efficacy of column will be increased.

Modification of physical properties of streams after using SGR method in NGL1300 is represented in table (4) [8].

Table1. Physical properties and flow rate of streams

Stream line	1	2	3	4	5	6	7
Temperature (C)	60.5	37	62.1	38.3	38.3	25	38.3
Pressure (kPa)	3690	3680	3770	3680	3680	4300	3680
Mass flow (t/h)	200.6	200.6	12.8	213.4	0.47	2.3	211.5
Stream line	8	9	10	11	12	13	14

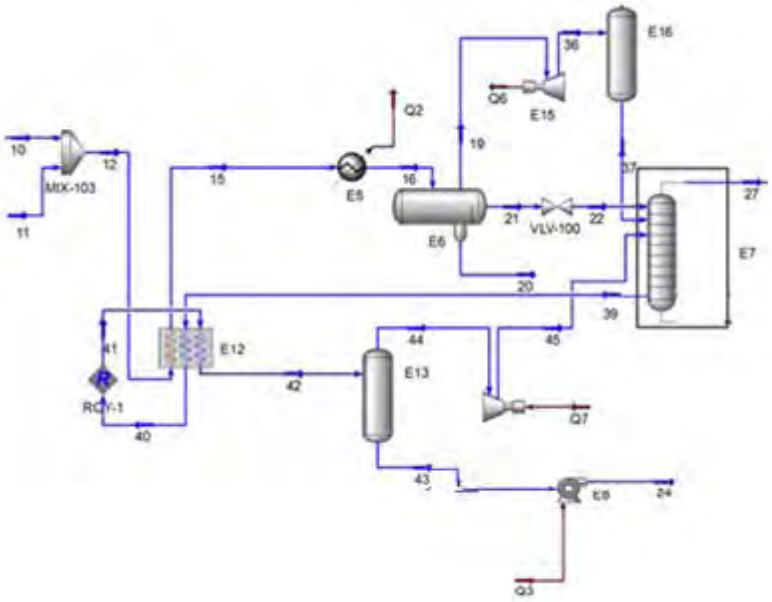

Fig. 2 Using SGR method in NGL1200

4. Results and Discussions

Comparison between results of simulation of NGL1200 before and after using SGR method is represented by table (5).

Table5. Comparison between obtained results before and after using SGR method

	Before	After
NGL production rate (t/h)	78 t/h	92.8
Electricity intensity (kWh/t_{NGL})	268.5	175
Thermal energy intensity (kWh/t_{NGL})	56.4	0
Demethanizer efficacy (%)	72	84

The results indicate that, application of self-refrigeration method reduces electricity intensity of the plant up to 34.7 % and also eliminates the need for reboiler heat load completely. Decreasing in electricity intensity is obtained directly from replacing cooling load of propane per-chiller by heat exchanging of liquid stream from the bottom of demethanizer column with inlet sweet gas. Required capital investment for improving this novel configuration in Gachsaran NGL1200 is represented in table (6).

Table6. Capital investment of SGR method

Item	Capital Investment (10^3 $)
Expander	256
Separators	21.6
Compressor	25.6
Pump	15
Two phase heat exchanger	336
Installation	182

The results of feasibility study show payback period of total investment of project will be lower than 2 years when the unit price of electricity and NGL is considered consequently, 4 cent per kWh and 500 cent per kg [10].

5. Conclusion

The objective of this research work has been to introduce a novel configuration in NGL plants which is obtained by a self-refrigeration system name as Stripping Gas Refrigeration (SGR). SGR scheme provides overall energy integration and replaces propane refrigeration system. The main results of using this configuration may be concluded as decreasing propane refrigeration, eliminating external heat source of reboiler, decreasing compression hoarse power of the plant. Also, using this method is accompanied with lower capital and operating cost with less impact to the existing equipment of the plant. With purposing total capital investment around 836 thousands dollars including, net present value (NPV) of project may be estimated at 5.6 millions dollars through 15 years operation of the system and its economical feasibility will be supported [11].

Abstract: There is potential for optimizing thermal oxidizer plants to increase industrial energy efficiency results in environmental and economic dimension of sustainability. In the present work, genetic algorithm is implemented for three thermal oxidizer cases in three different petrochemical plants to optimize the fuel cost for the three Heat Recovery Steam Generators (HRSG's) which are going to be used for the recovery of the heat from the outlet of the thermal oxidizer units. Generally, thermal oxidizers are used in petrochemical plants to burn waste gases in the plant to reduce the environmental impact of the off-gases of plant and normally the waste heat are released to the atmosphere via a stack. The optimization results have been compared for three cases. Five decision variables have been selected and the objective function was optimized. By increasing the fuel price, the values of thermo-economical decision variables tend to those thermodynamically optimal designs.

1. Introduction

One of the important ways to reduce the effects of environmental impacts of industrial plants is increasing energy efficiency of the plants. Developing techniques for designing efficient and cost-effective energy systems is one of the foremost challenges of energy engineering face. In a world with finite natural resources and increasing energy demand by developing countries, it becomes increasingly important to understand the mechanisms which degrade energy and resources and to develop systematic approaches for improving the design of

energy systems and reducing the impact on t he environment. The second law of thermodynamics combined with economics represents a very powerful tool for the systematic study and optimization of energy systems. This combination forms the basis of the relatively new field of thermo-economics.

Ethylene is the main feed of LDPE (Low density polyethylene) plant to produce LDPE product(s) in high pressure. By using a compressor system, excess ethylene in different units of the plant, some traced gases like Methane and Propane, small quantity of water and air are forced to a multi channel combustion chamber of thermal oxidizer unit to burn and diminish the concentration of pollutant, as consequences of imposed environmental limitations that exist for the petrochemical off-gases. After burning the off-gases in the combustion chamber, the considerable medium quality waste gas is released to atmosphere via vent stack. In practise, in most of the petrochemical plants the thermal oxidizer units work continuously as a matter of excess amount of ethylene and other mentioned substances.

For a medium LDPE plant, maximum volume off gases reaches 55000 kg/h with constant steady state pressure. This flow produces an average thermal caloric value of 45000 KJ/kg with average 300 °C flue gas.

The structure of a common thermal oxidizer is illustrated in figure 1. The installation consists of two compressor systems, multi channel combustion chambers, fuel supply and burner systems. In current models for the environmental condition the following are considered (T = 298.15 K and P = 1.013 bar). The operating fuel for the total plant is natural gas (taken as methane) with a lower heating value (LHV) equal to 50000 kJ/kg.

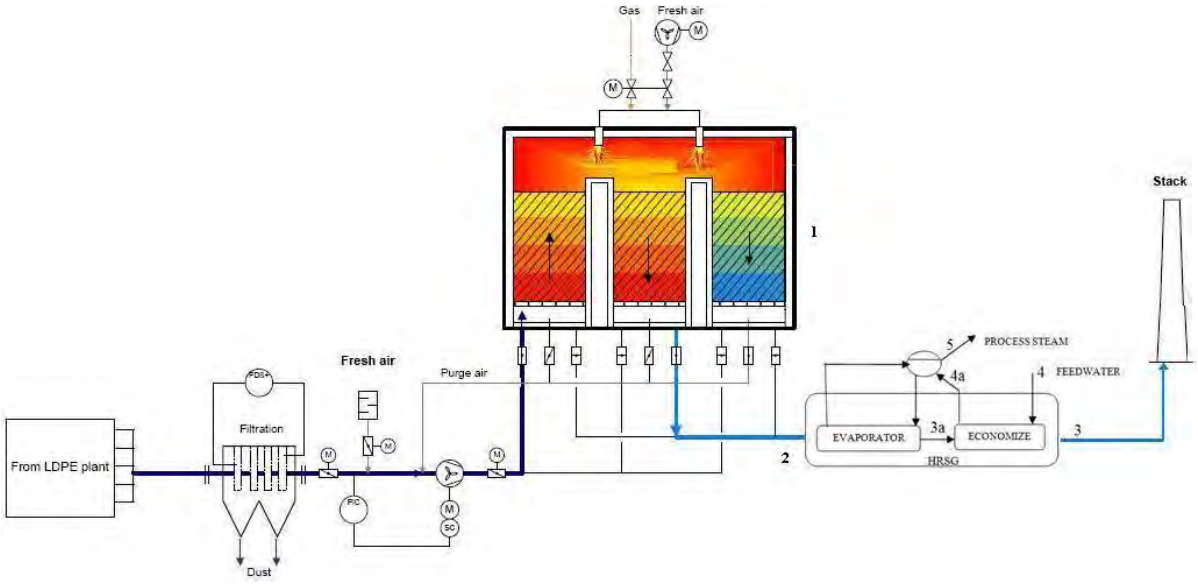

Fig. 1. Schematic sketch of thermal oxidizer with HRSG

In the current research, a part of waste heat energy system (thermal oxidizer) in LDPE (Low Density Polyethylene) plant is optimized according to some decision variables. The hot gases from the combustion chamber are conducted to a HRSG (Heat Recovery Steam Generator) to be utilized for producing steam and hot water. This steam and/or hot water can be used in different ways in this plant (LDPE Plant) or other adjacent industrial plants. Moreover, in this investigation three different thermal oxidizers units were studied and data obtained are analysed for research validation. The models used in this paper are realistic but incomplete

from an engineering point of view since the object of this study is to present distinct models of thermoeconomic optimization. Therefore, it would be unreasonable to use an excessively complicated mathematical model to describe the performance of the plant.

2. Methodology

For modelling the system three categories of equations have been considered, the equations which describe the behaviour of the system (physical model), the equations for calculating the capital costs of the components (economic model) and the equations which has been used to calculate the thermodynamic properties (thermodynamic model) [1,2]. The decision variables selected for the optimization are the compressor pressure ratio P,/Pr, the isentropic efficiencies of the compressor (η_c), inlet humidity percent (r_{ih}), the temperature of the combustion gas at the HRSG inlet (T_2) and thermal efficiency of thermal oxidizer (η_{to}).

The following models are formulated as a function of these decision variables. To simplify these models without loss of methodological generality, the following assumptions are made: (1) The air and the combustion gases behave as ideal gases with constant specific heats. (2) For combustion calculations, the fuel is taken to be methane CH4 (3) All components, except the combustion chamber, are adiabatic. (4) Reasonable values are chosen for the pressure loss of the air and gas flows in the combustion chamber and recuperate boiler.

Our optimization program that is based on evolutionary algorithm has good convergence and better results due to using three input category data from three different petrochemical plants. As we know the optimization procedure is so crucial in engineering fields, especially mechanical engineering. Among the various techniques evolutionary algorithms (EAs) are of the greatest importance because of their convergence rate. Among EA algorithms, the Genetic Algorithm is the best option due to its less time consuming for iteration time as well as satisfying the several constraints. Besides, at the end of this study the influence of alteration in the demanded steam on the design parameters has been also studied.

In this paper, after thermodynamic modelling of the system and formation of the objective function, a cogeneration unit with thermal characteristics of well known problem [1,3,4,5] are simulated, optimized, and its results are compared to the results of other cases; in order to ensure the validity of our physical modelling and optimization procedure. Subsequently, parameters of problem are modified to match the conditions and requirements of the present work.

2.1. Thermodynamic modeling of thermal oxidizer with HRSG

Having known the values of decision variables (r_c, η_c, η_{to}, T2 and r_{ih}) for a set of fixed demands of process steam, the values of temperature and pressure in all lines of system was computed. Consequently, the value of fuel mass flow rate $\dot{m}_f$, which should be expressed in terms of decision variables, is determined. The relations of thermodynamic modelling are as follows:

Air compressor

$$T_{out} = T_{in}\left\{1+\frac{1}{\eta_{AC}}\left[r_c^{\frac{\gamma_a-1}{\gamma_a}}-1\right]\right\}, \quad (1)$$

$$\dot{W}_{ac} = \dot{m}_a.c_{p,a}(T_{out}-T_{in}) \quad (2)$$

Combustion chamber

$$\dot{m}_a h_1 + \dot{m}_f \, LHV = \dot{m}_g h_2 + (1-\eta_{cc})\,\dot{m}_f \, LHV \quad (3)$$

$$\frac{P_2}{P_1} = (1 - \Delta P_{cc}) \quad (4)$$

Heat recovery steam generator

$$\dot{m}_s (h_5 - h_4) = \dot{m}_g (h_2 - h_3) \quad (5)$$

$$\dot{m}_s (h_5 - h_{4a}) = \dot{m}_g (h_2 - h_{3a}) \quad (6)$$

2.2. Objective function

The objective function is defined as the sum of two parts; the operational cost rate, which is related to the fuel expense, the rate of capital cost which stands for the capital investment and maintenance expenses. Therefore, the objective function represents total cost rate of the plant in terms of dollar per unit of time.

$$Obj.Func. = c_f \dot{m}_f LHV + \sum \dot{Z}_k \quad (7)$$

Since the amounts of ultimate products (process steam) are fixed, the objective function is to be minimized so that the values of optimal design parameters would be obtained. For calculating the rate of operating cost equation, we have:

$$\dot{c}_f = c_f \dot{m}_f LHV \quad (8)$$

In which c_f = 0.003 $/MJ is the regional cost of fuel per unit of energy,$\dot{m}_f$ is the fuel mass flow rate, and LHV = 50000 kJ/kg is the lower heating value of Methane.

For expressing the purchase cost of equipment in terms of design parameters, several method have been suggested [2, 7-11]. In this paper, we used the cost functions mentioned in ref [2]. However, some modifications were made to tailor these results to the regional conditions in Iran and taking into account the inflammation rate. For converting the capital investment into cost per time unit:

$$\dot{Z}_k = Z_k . CRF . \varphi / (N \times 3600) \quad (9)$$

Where, Z_k is the purchase cost of component in dollar, CRF (18%) is the capital recovery factor, N is the annual number of the operation hours of the unit (7500 hr), and φ (1.06) is the maintenance factor.

2.3. Optimization Procedure

Minimizing the objective function Eq.7 is a nonlinear optimization problem. In order to achieve feasible design parameters some physical constraints should be considered seriously. The list of these constraints and their reasons are briefed in table 1. Moreover, the following inequality constraints should be satisfied in heat exchangers (air pre-heater and heat recovery steam generator).

$$T_2 > T_1, \quad T_2 > T_5, \quad T_{3a} > T_5 + \Delta T_{pinch,\,min} \tag{10}$$

In the present work a genetic algorithm code is developed in Matlab Software Programming.

Table1. The list of constraints

Constraints	Reason
$T_2 \le 1600^{\circ} K$	Material limitation
$r_c \le 16$	Commercial availability
$\eta_{ac} \le 0.9$	Commercial availability
$\eta_{to} \le 0.96$	Commercial availability
$T_3 \ge 400^{\circ} K$	To avoid formation of sulfuric acid in exhaust gases
$T_{4a} = T_5 - 15^{\circ} K$	To avoid evaporation of water in HRSG economizer

2.4. Evolutionary algorithm (Genetic Algorithm)

Such algorithms simulate an evolutionary process where the goal is to evolve solutions by means of cross over, mutation, and selection based on their quality (fitness) with respect to the optimization problem at hand. Evolutionary algorithms (EAs) are highly relevant for industrial applications, because they are capable of handling problems with non-linear constraints, multiple objectives and dynamic components properties that frequently appear in real-world problems. Moreover the input and output values for Genetic Algorithm method used in this study are shown in tables 2, 3.

Table 2. Genetic algorithm input

Tuning Parameters	Value
Population size	500
Maximum number of generation	1000
PC(Probability of Crossover) %	70
Pm (Probability of mutation) %	1
Number of crossover	2
Selection in process	Tournament
Tournament size	2

3. Discussion and result

The numerical values of the optimum design parameters of the thermal oxidizer with HRSG are listed in table 3. Moreover, the constraints of the problem are listed in table 1. These

results are compared with other case's results. Figure 2 depicts the changes in the objective function versus generation in the developed genetic algorithm code.

Table 3. The comparison of simulation and optimization numerical output for three mentioned cases.

Decision variable	Optimum design	Optimum design	Optimum design
r_c	8.597	8.523	8.504
η_C	0.8465	0.8468	0.83292
η_{to}	94.5	95	95.4
T_2 (K)	504	573	642.3
r_{ih} (K)	80	70	65
Objective Function	0.362 ($/s)	0.3617 ($/s)	0.3294 ($/s)

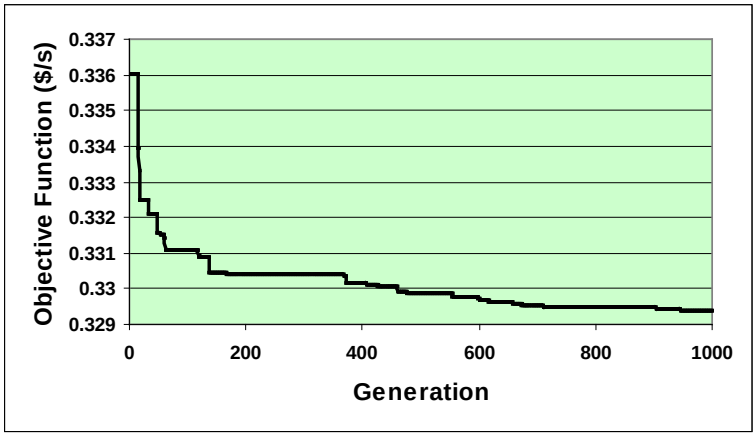

Fig. 2. Variation of Objective Function of the system with Generation (CE=.003$/MJ).

Study of the variation of the optimal decision variables versus fuel unit cost reveals that by increasing the fuel cost optimal decision variables generally shift to thermodynamically more efficient design. As it can be clearly seen the values of decision variables r_p, η_{ac}, and HRSG inlet temperature (T_2) increase with increasing fuel unit cost. It is worthy to mention that while increasing combustion inlet temperature (T_1) reduces the exergy destruction in combustion chamber and heat exchangers (HRSG), due to the exhaust gases constraint ($T_3 >$ 400K); it decreases with increasing the fuel unit cost. It should be noted that for each T_2 there exists a T_1 in which the best thermodynamical efficiency may be achieved. Moreover, an increase in HRSG inlet temperature reduces the exergy destruction in combustion chamber; and since increasing T_2 results in higher exhaust temperature of exhaust gases, the constraint $T_3 >$ 400K does not cause any limitation for rising T_2. Due the fact that any increase in T_2 will dramatically affects the HRSG investment cost, figures 3-5 show the influence of the unit cost of fuel on the values of some the optimal decision variables. Figure 5 shows that when the fuel price increased the combustion chamber fuel mass flow rate decrease for minimizing the objective function. Due to uncertainty of capital investment data, it is imperative to study the results of capital expense variation on the optimal values of decision variables.

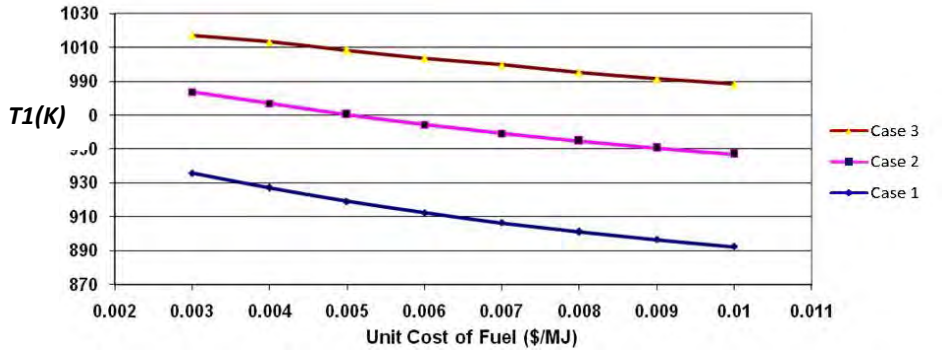

Fig. 3. The effects of fuel unit cost on the optimal value of combustion chamber inlet temperature, T1

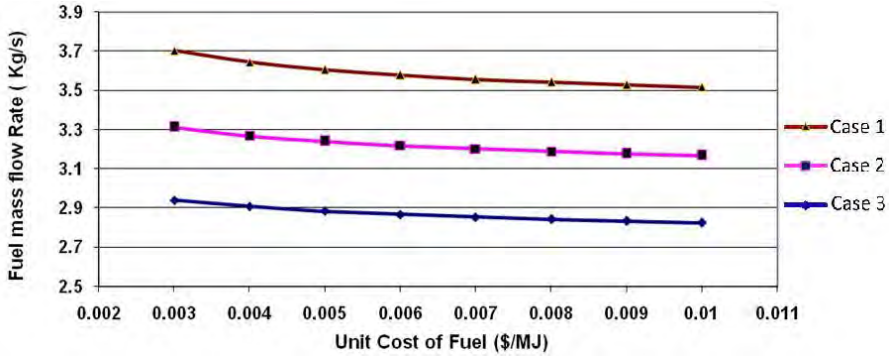

Fig. 4. The effects of fuel unit cost on the optimal value of Fuel Mass Flow Rate, mf

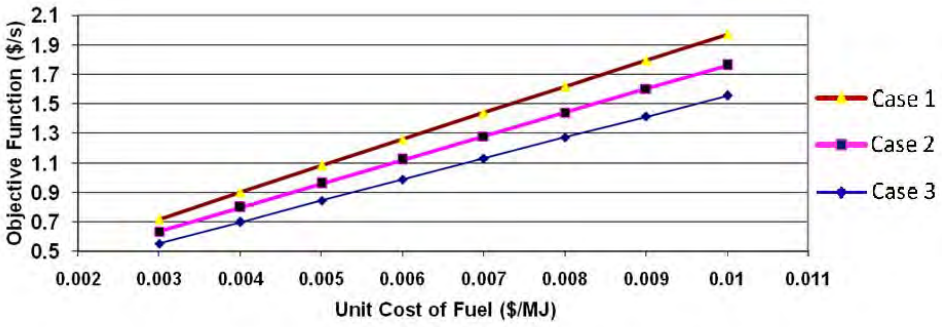

Fig. 5. The effects of fuel unit cost on the optimal value of Objective Function ($/s)

4. Conclusion

The determined optimum design parameters for thermal oxidizer with HRSG apparently show a trade-off between thermodynamically and economically optimal designs. For example, from thermodynamic point of view, the decision variable η_c should be selected as high as possible while this leads to an increase in capital cost. It should be noted that any change in the numerical values of a decision variable not only affects the performance of the related equipment but also all the performance of other equipments as well. It can be deduced from the figures 3-5 that by increasing the fuel price the values of decision variable in thermo-economically optimal design tend to those of thermodynamically optimal design.

Using heat recovery, thermal oxidizers cause more energy efficiency and decrease the level of green house gases accordingly. In spite of the fact that utilizing these types of technologies

categorized as an end-of-pipe solution, nevertheless according to the three pillars of sustainability it contribute to both environmental dimension and economic dimension of sustainability.

Abstract: Increased competition among power generating companies, changes in generating system load requirements, lower allowable plant emissions, and changes in fuel availability and cost accentuate the need to closely assess the economics and performance of older electric generating units. Generally, decisions must be made as to whether these units should be retired and replaced with new generation capacity, whether capacity should be purchased from other generation companies, or if these existing units should be repowered. These decisions usually require the evaluation of many factors. The analysis is usually complicated due to the interaction of all the factors involved. In this paper, evaluation of a 156MW steam power plant and proposed repowered scenario has been performed. The exergy and exergoeconomic analysis method was applied in order to evaluate the proposed repowered plant. Simulation of each case has been performed in Thermoflow software. Also, computer code has been developed for exergy and exergoeconomic analysis. It is anticipated that the results provide insights useful to designers into the relations between the thermodynamic losses and capital costs, it also helps to demonstrate the merits of second law analysis over the more conventional first law analysis techniques.

1. Introduction

Deregulation and competition are further fueling the demand for new power generation equipment worldwide. Due to the availability and cleanliness of gas, and the ease of consent, gas turbine applications have increased over the last few years. This development is driven by the addition of capacity, but also by major replacement programs.[1] Almost all industrialized countries are now facing some degree of electric power shortage. The major problem is probably the lack of suitable sites for building new power plants of whatever type or size. Moreover, increasing environmental awareness has resulted in more demanding requirements in terms of preliminary analysis, prolonging and complicating the plant commissioning process. All these problems have led many utilities to consider extending the life of existing plants by repowering. Basically, these interventions have been done on gas fired steam plants by addition of a natural gas fired turbine. This reduces specific emissions of the existing steam plant while maintaining or even slightly improving its efficiency. As a rule, a repowered plant can be expected to give a lower cost per kW h produced as well as per kW installed repowering of steam plants can be achieved in two ways: feed water repowering and boiler repowering. The first option uses heat from the turbine exhaust to raise the feed water temperature instead of bleeding steam. This means that increased steam flow has to be managed by the low pressure section of the original steam turbine, requiring either extensive modification of the steam turbine or impairing the repowered plant performance. The other

option, boiler repowering, entails major steam generator redesign[2]. Energy systems involve a large number and various types of interactions with the world outside their physical boundaries. The designer must, therefore, face many issues, which deal primarily with the energetic and economic aspects of the system. Thermodynamic laws govern energy conversion processes, costs are involved in obtaining the final products (expenses for the purchase of equipment and input energy resources, operation and maintenance costs), and the effects of undesired fluxes to the ambient must be evaluated in order to answer environmental concerns. Second law analysis has been widely used in the last several decades by many researchers. Exergy analysis usually predicts the thermodynamic performance of an energy system and the efficiency of the system components by accurately quantifying the entropy-generation of the components [3]. Furthermore, exergoeconomic analysis estimates the unit cost of products such as electricity, steam and quantifies monetary loss due to irreversibility. Also, this analysis provides a tool for the optimum design and operation of complex thermal systems [3], [4], [5].

In this study, exergetic, thermoeconomic and exergy analyses have been performed for 156MW steam cycle and repowered gas fired steam power plants. In these analyses, mass and energy conservation laws were applied to each component. Quantitative balance of the exergies and exergy costs for each component and for the whole system was carefully considered. The exergy-balance equation developed by Oh et al. [6] and the corresponding exergy cost-balance equations developed by Kimet al. [7] were used in these analyses. In this regard, computer program has been developed for energy, exergy, exergoeconomic and exergy analysis of both of cases in different load conditions. Furthermore, it can also used to study plant characteristics, namely, thermodynamic performance and sensitivity to changes in process and/or component design variables. In this paper, the authors evaluate and compare repowered power planet and steam power plants in view of exergy and thermoeconomic analysis.

2 Process description

In this paper, GHAZVIN steam cycle power plant has repowered and compared with old steam cycle. The steam cycle power plant encompasses three turbines, that work with three different pressures and 6 feed water heaters. The Steam cycle has been modeled by MATLAB code and STEAM PRO (THERMOFLOW). Results of modeling steam cycle have been introduced and compared with real data in table.1.

Table1. Compare result of modeling steam cycle

	THERMOFLOW	Simulation code	Real
Plant Gross power(kW)	156300	156305	156294
Plant Gross Heat Rate(kJ/kWh)	9010	9120	8976
Plant Gross Efficiency (LHV)	39.9%	39.4%	40.1%
Superheater Capacity(kg/s)	133	130	136
Reheater Capacity(kg/s)	115	114	117

3. Repowering

There are several alternatives to combine and integrate a gas turbine into an existing steam power plant. For 156MW steam power plant unit in Iran, the best alternative is full repowering because its boiler is very old and boiler life time is concluded. Full repowering is defined as complete replacement of the original boiler with a combination of one or more gas turbines (GT) and heat-recovery steam generators (HRSG), and is widely used with very old

plants with boilers at the end of their lifetime. It is considered as one of the simplest ways of repowering for existing plant.
For this power plant, Full Repowering with SGT5-4000F (formerly known as CC 2.V94.3A) with triple pressure reheat cycle was found to be the most economic approach.
Schematic flow diagram of combined cycle with the components is shown in Fig. 2. The gas cycle is selected as a topping cycle. The heating devices in the HRSG are arranged from the high temperature (HT) to the low temperature (LT) exchangers in the flue gas path to get the minimum temperature difference between the flue gas and the water/steam.

4. Exergoeconomic Analysis

All costs due to owning and operating a plant depend on the type of financing, the required capital, the expected life of a component, and so on. The annualized (levelized) cost method of Moran [9] was used to estimate the capital cost of system components in this study. The amortization cost for a particular plant component may be written as:

$$PW = C_t - S_n PWF(t,n) \quad (1)$$

$$\dot{C}(\$/year) = PW \times CRF(t,n) \quad (2)$$

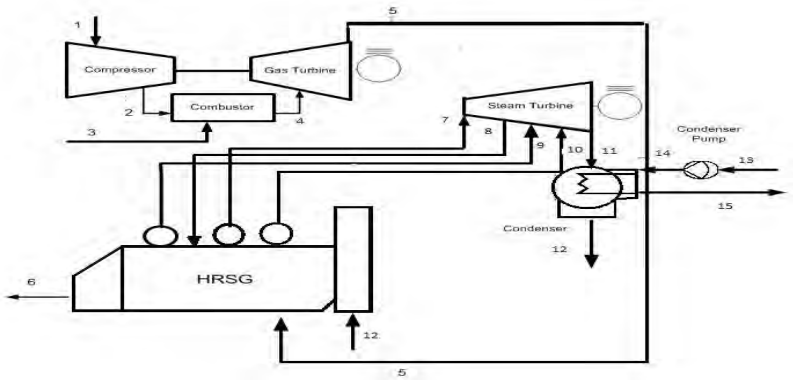

Fig 1.- combined cycle power plant

The present worth of the component is converted to annualized cost by using the capital recovery factor CRF(*i*,*n*), i.e [4]. Dividing the levelized cost by 8000 annual operating hours, we obtain the following capital cost for the *k*th component of the plant.

$$Z_k = \Phi_k \dot{C}_k/(3600 \times 8000) \quad (3)$$

The maintenance cost is taken into consideration through the factor $\Phi_k = 1.06$ for each plant component whose expected life is assumed to be 15 years [6].

4.1 Thermoeconomic Modeling

The results from an exergy analysis constitute a unique base for exergoeconomics, an exergy-aided cost reduction method. A general exergy-balance equation, applicable to any component of a thermal system may be formulated by utilizing the first and second law of thermodynamics [4].
The cost balance expresses that the cost rate associated with the product of the system (C_P), the cost rates equals the total rate of expenditure made to generate the product, namely the fuel cost rate (C_F), the cost rates associated with capital investment (Z^{CI}), operating and

maintenance (Z^{OM}) [12].In a conventional economic analysis, a cost balance is usually formulated for the overall system (subscript tot) operating at steady state [11]:

$$\dot{C}_{P,tot} = \dot{C}_{Ftot} + Z_{tot} \quad (4)$$

Accordingly, for a component receiving a heat transfer and generating power, we would write [4]:

$$\sum_e \dot{C}_{e,k} + \dot{C}_{w,k} = \dot{C}_{q,k} - \sum_i \dot{C}_{i,k} + Z_k \quad (5)$$

To solve for the unknown variables, it is necessary to develop a system of equations applying Eq. (5) to each component, and it some cases we need to apply some additional equations, to fit the number of unknown variables with the number of equations [12]. A general exergy-balance equation, able to any component of a thermal system may be formulated by utilizing the first and second law of thermodynamics. In a conventional economic analysis a cost balance is usually formulated for the overall system operating at steady state. To derive the cost balance equation for each component, we assigned a unit cost to the principal product for each component. Depending on the type of fuel consumed in the production process different unit cost of product should be assigned [13].

Table2. Combined cycle results

	Repowering
Gas Turbine(kW)	278041
Steam Turbine(kW)	125655
Plant Total (kW)	403695
Plant net LHV efficiency (%)	55.27
Plant net LHV heat rate(kJ/kWh)	6514
Gas turbine LHV efficiency (%)	39.05
Steam turbine efficiency (%)	34.59

5. Results and discussion

In this paper, computer codes have been developed for thermodynamic simulation and analysis of 156-MW old steam cycle and 400-MW repowered combined power plants. The enthalpy and entropy of non-interacting gas species were calculated by using appropriate polynomials fitted to the thermophysical data in the JANAF Tables [14]. Also the values of physical properties such as enthalpy and entropy for water and steam were evaluated by using equations suggested by the International Association for the Properties of Water and Steam IAPWS-IF97) [14].

Table 2 indicates specification of repowered plant. It shows that, 68% of total power is produced by gas turbine cycle with 39% efficiency, in addition remained power are produced by steam cycle with 34% overall efficiency. Repowered cycle produces 250MW more than old power plant. Heat rate in repowering power plant is 6500(KJ/KWh) and 1500(KJ/KWh) more than old power plant. As a result of repowering, overall efficiency rises 15% and new power plant produce net power with less reduction of energy. The combined cycle results have been developed for gas turbine partial load. Load condition varied from 30% to 100% of full load and figure 2 presents load variation and net power of cycles. Further, entire rate of

exergy destruction has been shown in this figure. However full load has the most exergy destruction, ratio of exregy destruction to supplied energy is less than partial load. In figure 3 efficiency of combined cycle accompaniment gas turbine cycle and steam cycle exhibited. Gas turbine efficiency severely depends on design load and it is decreased when works at partial load states. Since supplied energy for steam cycle depends on exit flow stream of gas turbine, steam cycle efficiency is just independent of load condition. Combined cycle efficiency varied from 40% to 55% and deteriorates with variation from design load.

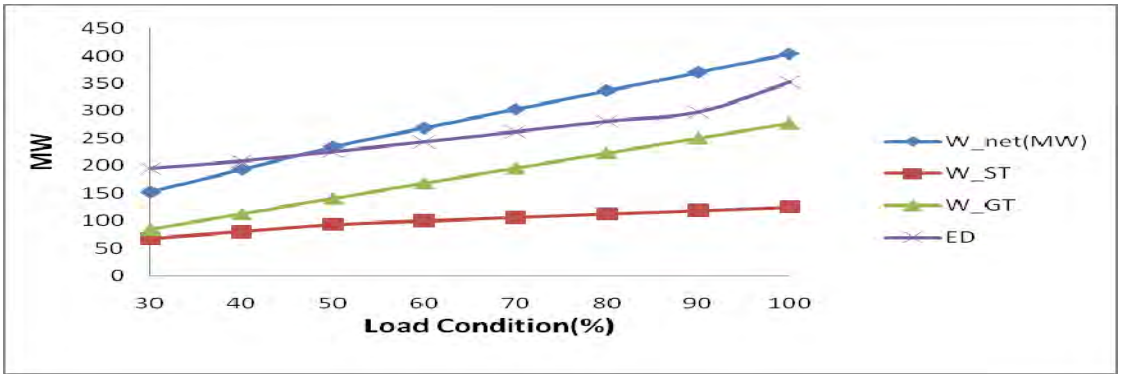

Fig 2. Variation of output power

In this regard, exergy flow and cost flow rates of exergy with and without considering capital investment for each stream in old power plant and repowering plant have been calculated. Also, Table 3 and 4 show Exergy destruction and cost fuel and product rates of exergy with and without considering capital investment for each component in old and repowered power plants. These results represent that boiler in old steam power plant and that combustion chamber and heat recovery steam generator in repowered combined cycle has most exergy and exergy cost destruction due to nature of combustion; however combustor in gas fired combined cycle plant shares about 51% TED, 44% TCD0 and 43% TCD. In next steps, compressor and steam generator of repowered have most exergy and exergy cost destruction. Cost product of steam turbine and gas turbine for combined cycle with and without considering capital investment at various load conditions has been presented in figure 4. As results shown, CP_0 and CP increase when load condition reduces because the thermal efficiency decreases. Therefore full load has the best and minimum cost product. In figure 5 rate of total cost exergy destruction has been shown at different load. As results shown, TCD0 and TCD0 reduce when load condition decreases and vice versa because the fuel consumption decreases when load condition reduces and vice versa, so TCD0 and TCD have direct relation with load conditions. In steam cycle power plant 430 MW exergy is destructed and more than 85% of exergy destruction happened in boiler. However combined cycle produced 250 MW net power more than steam cycle, Total exergy destruction in combined cycle is 296 MW and 70% of steam cycle exergy destruction. Since cost product of gas turbine in combined cycle is less than steam turbine and majority of output power produced with gas turbine, combined cycle cost product is reasonable. Therefore repowered power plant generated more power than old power plant with recuperated efficiency and more reasonable cost product.

6. Conclusion

In this paper, an exergy-costing method has been applied to both cases to estimate the unit costs of electricity produced from steam turbines. The computer program that was developed which shows that the exergy and the thermoeconomic analysis presented here can be applied to any energy system systematically and elegantly. If correct information on the initial investments, salvage values and maintenance costs for each component can be supplied, the unit cost of products can be evaluated.

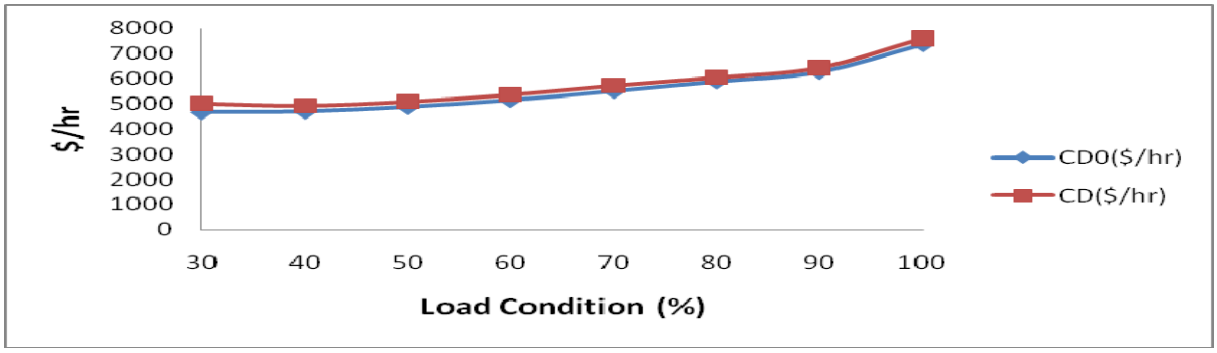

Fig 5.CD, CD_0 of repowered power plants at different load

Although the overall picture of a system can be shown and major directions for improving the system performance can be identified from the above two levels of analysis, the maximum potential or the limit of improvement for individual units and processes are still uncertain, since the exergy loss analysis so far is based on the concept of total exergy loss. In some cases, the suggestions for promising modifications based on the total exergy loss may be misleading, since they do not consider the minimum exergy loss which is required to operate a process.

Abstract: Decomposition methodologies are necessary to examine the causal factors of energy use trends in an economy. This paper suggests a new approach -the Multiple Calibration Decomposition Analysis (MCDA)- to investigate the sources of change in industrial energy use in the Japanese economy. The multiple calibration technique is utilized for an *ex post* decomposition analysis of structural change between periods, enabling distinction between price substitution and technological change for each sector. This paper explains the theoretical properties of MCDA and applies it to an empirical case -the change in energy use in Japanese industry from 1970 to 1990. This paper clarifies how industrial energy use was affected by price substitution or technological change through the experience of the two oil crises, focusing on energy-intensive industry. The paper shows that technological change played an important role in reducing industrial energy use in the Japanese economy. Remarkably, oil-saving technological change advanced by 60% or more in energy-intensive industry during the 1980s.

Keywords: *calibration, decomposition, industrial energy efficiency, price substitution, technological change*

1. Introduction

New interest has arisen in energy demand analysis, reflecting the rapid fluctuation of oil prices, and by the same token the problem of climate change (e.g., Dowlatabadi and Oravetz [1], Metcalf [2], Sue Wing [3]). From a historical point of view, discussions of energy demand analysis have been lively since the oil crises of the 1970s. A vast amount of literature has been devoted to such analyses, including classic works by Hudson and Jorgenson [4] Berndt and Wood [5], Manne [6], Borges and Goulder [7], and Solow [8].

Change in energy use is caused by various factors, including price substitution and autonomous technological development. Determining the contribution of these factors to energy use trends is a difficult but necessary quest, for which decomposition techniques are required. In this context, many decomposition methodologies have been accepted for the quantification of causal factors: for example, Index Decomposition (ID; see, e.g., Ang and Zhang [9], Hoekstra [10]) and Structural Decomposition Analysis (SDA; see, e.g., Rose and Casler [11], Rose [12], Hoekstra [10]), which are well-established decomposition methodologies for this purpose.

This paper proposes a new approach -the Multiple Calibration Decomposition Analysis (MCDA)- to investigate the driving forces of change in industrial energy use in the Japanese economy. The MCDA methodology was originally proposed by Okushima and Tamura [13]. The multiple calibration technique is applied to an *ex post* decomposition analysis of structural change between periods, enabling distinction between price substitution and technological change for each sector. This approach has sounder microtheoretical foundations than conventional methods.

In this paper, the MCDA methodology is applied to the decomposition analysis of change in industrial energy use following the oil crises of 1970-1990, focusing on energy-intensive industry. This period includes two oil crises, during which a rise in oil prices influenced the

Japanese economy to an enormous extent. Moreover, energy use by industry, especially energy-intensive industry, is a key factor of change in energy use in the economy. This is an appropriate area to apply this method to evaluate the extent to which industrial energy use was affected by price substitution or technological change. Besides that, this kind of analysis may add to our stock of information for future Japanese energy or environmental policy.

The remainder of the paper is structured as follows. Section 2 explains the MCDA methodology. Section 3 applies the method to an empirical case, energy use in Japanese industry from 1970 to 1990. The final section provides concluding remarks.

2. Methodology

This section outlines a new decomposition methodology -the Multiple Calibration Decomposition Analysis (MCDA)- originally proposed by Okushima and Tamura [13]. The method explicitly defines two-tier constant elasticity of substitution (CES) production functions as an underlying model to separate price substitution effects from other types of technological change. For more information on CES functions, see, e.g., Shoven and Whalley [14]. The MCDA decomposes structural change in the economy, shown by the change in factor inputs per unit of output between periods (CFI), into two parts: one attributable to price substitution (PS) and the other attributable to technological change (TC).

This paper assumes the model structure in the MCDA to be as shown in Fig. 1. The two models which are identical except for the number of sectors are employed in the following section. The production functions are given by two-tier constant-returns-to-scale CES functions. The model comprises capital *K*, labor *L*, energy aggregate *E*, and material aggregate *M*, as well as energy and material inputs. Capital *K* and labor *L* are the primary factors of production.

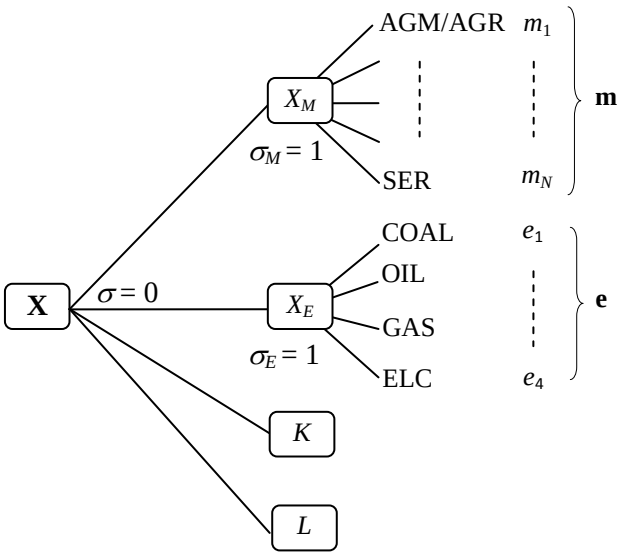

Fig. 1. The model (N = 5 in the 9-sector model and N=14 in the 18-sector model)

Fig. 2 illustrates the MCDA methodology. The MCDA can exactly decompose the CFI into PS and TC. PS, which depends upon the elasticity of substitution (σ) and the change in relative prices between the periods ($p^{t-1} \to p^t$), represents the price substitution effects, while TC represents those portions of the factor input change that cannot be interpreted by the price substitution effects ($\lambda^{t-1} \to \lambda^t$), including autonomous technological development. The

counterfactual points of the MCDA mean the junctures into which the effects of the relative price change between the initial and terminal periods are incorporated. From a theoretical perspective, PS means a change in factor inputs along the production function, while TC refers to shifts in the production function. Therefore, the decomposition of the MCDA is consistent with production theory in microeconomics. The method has clear microtheoretical foundations; then, the decomposition components can be interpreted in a theoretically meaningful way. For more details of the MCDA methodology, see Okushima and Tamura [13].

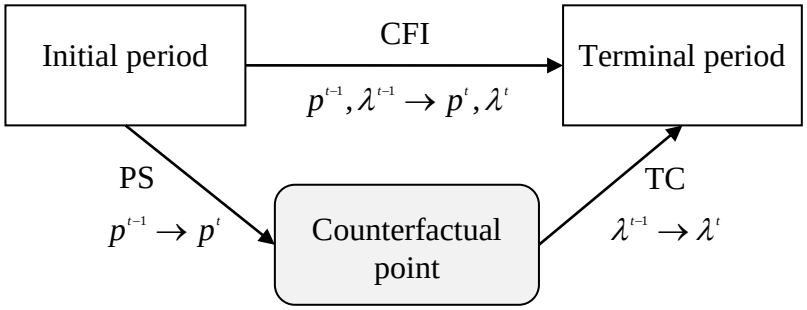

Fig. 2. The methodology

3. Empirical results

This paper applies the Multiple Calibration Decomposition Analysis (MCDA) to investigate the sources of change in industrial energy use in Japan. While Okushima and Tamura [13] is a comprehensive study of changes in energy use and carbon dioxide emissions in the Japanese economy from 1970 to 1995, this paper centers on the change in industrial energy use, especially energy-intensive industry, in the 1970-1990 period. This period includes two oil crises: one in 1973 and a second in 1979. It is widely recognized that skyrocketing oil prices had a huge influence on the Japanese economy during this time, and that the structural changes had a great impact on manufacturing energy use (see, e.g., IEA [15]). This situation presents a typical context in which to apply the method, which can provide a detailed analysis of how change in industrial energy use was caused by price substitution or technological change.

This section analyzes the change in industrial energy use, using data from 1970 to 1990. Nominal outputs (factor inputs) are obtained from the 1970-75-80 and 1985-90-95 Linked Input-Output Tables (Management and Coordination Agency). Real outputs (factor inputs) are obtained by deflating the nominal values by the corresponding prices. Prices of goods and services are from the Domestic Wholesale Price Index (Bank of Japan) or Deflators on Outputs of National Accounts (Economic Planning Agency). Capital and labor prices are estimated following Ito and Murota [16]. In the MCDA, these prices are normalized such that the prices in the initial period are at unity. This units convention, originally proposed by Harberger [17] and widely adopted since (Shoven and Whalley[14], [18], Dawkins et al. [19]), permits the analysis of consistent units across time. The elasticities of substitution are assumed, for the purposes of simplicity, to be $\sigma = 0$ and $\sigma_E, \sigma_M = 1$ as in Fig. 1; nevertheless, these estimates are not significantly different from those in the previous literature that econometrically estimates these elasticities for the Japanese economy (see, e.g., Okushima and Goto [20]).

As in Fig. 1, the sectors are classified into five industries and four energy inputs in the 9-sector model. On the other hand, the sectors are classified into fourteen industries and four

energy inputs in the 18-sector model. Please see the notes accompanying Table 1 and Table 2 for the sector classification.

First, Fig. 3 is a summary of the trends in Japan's energy use (see, e.g., IEA[15]). Energy use in the Japanese economy has continuously increased in volume since the 1970s. However, the growth rate in the early 1980s after the oil crises was lower than in other periods. It is recognized that Japan succeeded in the field of energy conservation and substitution from oil as a result of the lessons of the oil crises (see, e.g., Gregory [21]). The proportion of oil in both primary supply and final consumption has decreased after the oil crises, while the proportions of gas and electricity have increased, mainly owing to the use of natural gas and nuclear power. The primary supply of coal, such as for power generation, is gradually increasing while final consumption has remained almost unchanged, and its share of final consumption is diminishing. Following the trend of final energy consumption, the changes in factor inputs (CFIs) also reflect this experience. Table 1 shows that the CFIs for coal and oil are mostly negative while those for gas and electricity are the opposite. The CFIs should be caused by various effects such as price substitution or technological change.

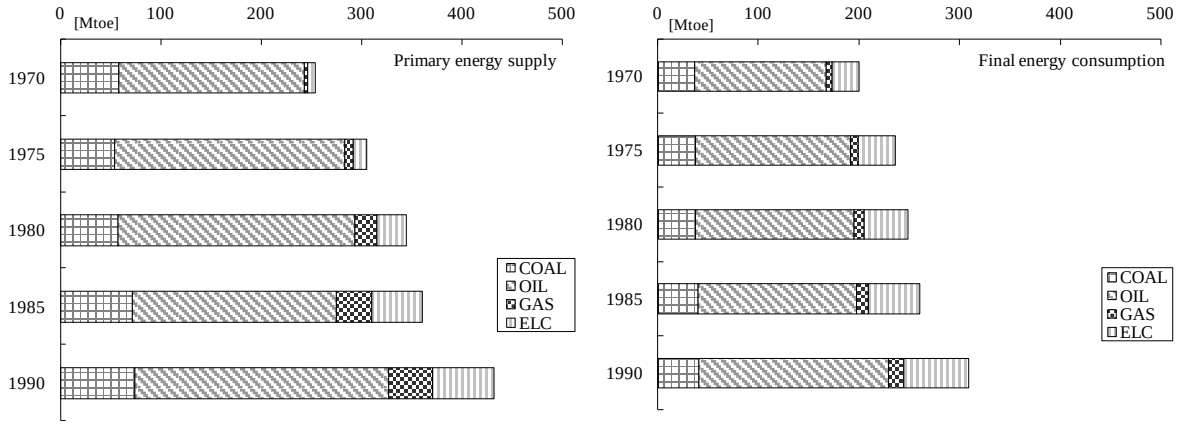

Fig. 3. Primary energy supply and final energy consumption in Japan (Source: IEA[22])

Table 1 illustrates the decomposition of the CFIs by the MCDA with the 9-sector model. The MCDA decomposes the CFI into technological change (TC) and price substitution (PS). The advantage of the method is that it can evaluate these causal factors in terms of types of energy, sectors, or periods, respectively. Table 1 demonstrates that in the 1970s the PSs for oil are negative in all sectors while those for the other types of energy are mostly positive. This means that the rise in oil prices decreased the factor inputs of oil while the demand for coal, gas, and electricity increased because of relatively low prices. Conversely, the PSs for oil become positive in the 1980s, reflecting the fall in oil prices, while those for other types of energy, coal and electricity, become negative. It is remarkable that the PSs for coal form a sharp contrast with those for oil. The PSs for gas are mostly positive. This indicates that the industries had expanded their use of gas because of its price advantage. Thus, the MCDA can clearly show the price substitution effect consistent with the production theory; that is, substitution from inputs with higher prices to those with lower prices.

Table 1 also reveals that the TCs for oil are largely negative in the 1980s. Theoretically, this means that the CFIs for oil had decreased to a greater degree than was expected from the price substitution effect (PS). This is consistent with other empirical studies, such as Han and Lakshmanan [23] and Unander et al. [24], which suggest that improvements in energy efficiency took place in the period even without higher prices. The result indicates that oil-

saving technological change had occurred primarily in the 1980s rather than in the 1970s. In addition, the TCs for coal are almost all negative throughout the periods. The result shows the importance of technological change in reducing industrial energy use.

Note: (1) The values are percentage changes.
(2) Classifications are as follows.
AGM: Agriculture, forestry, fishery, and mining; EII: Energy-intensive industry (paper and pulp, chemical, ceramics, and iron and steel); MAC: Machinery; OMF: Other manufacturing; SER: Services and others (including construction); COAL: Coal and coal products; OIL: Oil and oil products; GAS: Gas; ELC: Electricity.
(3) Periods are as follows. (i): 1970-75; (ii): 1975-80; (iii): 1980-85; (iv): 1985-90.

Next, this paper investigates the details of energy use in energy-intensive industry (EII), using the 18-sector model. Here, EII represents the following four industries: paper and pulp (PAP), chemical (CHM), ceramics (CRM), and iron and steel (IAS). These industries account for a large proportion -i.e., about seventy percent- of the industrial energy use in the Japanese economy. It is widely known that EII contributed greatly to the reduction of energy consumption in the period. METI [25] shows that energy efficiency rose dramatically by 42% in PAP, 34% in CHM, 26% in CRM, and 17% in IAS between 1973 and 1990 (see also, e.g., Toichi [26]). Unander et al. [24] examines such improvements in energy efficiency and implies that both price change and other factors induce it. The MCDA has the advantage of enabling the decomposition of CFI, i.e., the change in energy efficiency, into PS and TC. Hence, this section examines the energy use of EII more closely using the MCDA.

Table 2 illustrates the decomposition result. The PSs for oil are negative in all sectors in the 1970s, while they all become positive in the 1980s. Among the other types of energy, coal shows a clear contrast in terms of PSs during these periods. This shows an offsetting effect of a demand for coal as a substitute for oil, because of its price advantage. The trend in PSs nearly corresponds with that of the EII total in Table 1.

Table 2 also shows that the TCs for oil are strongly negative in the 1980s. Corresponding with the above result in Table 1, oil-saving technological change was primarily developed in the 1980s for those industries. These results are supported by engineering studies indicating that energy conservation was attained by means of an improvement in operations in the 1970s, while full-scale energy conservation was advanced by the introduction of various kinds of energy-saving technology in the 1980s after the second oil crisis (see, e.g., the Study Group on Energy and Industry [27]). In fact, multifarious technological innovations took place during that period; specifically, the continuous casting or waste heat recovery in IAS, and the waste heat recovery equipment of plants in CHM (see, e.g., METI [25]).

There is a point of contrast regarding PAP and CRM: the TCs for coal in these industries from 1975 to 1985 are sizably positive, although those in other EIIs are mostly negative. At this point, engineering studies indicate that PAP and CRM increased the use of coal by installing new combustion equipment in that period (see, e.g., the Study Group on Energy and Industry [27], METI [25]). The trend is reflected in these backgrounds. As a result, the CFIs for coal in PAP and CRM greatly increased; the TCs also increased without regard to the trend of PSs. The results in this section indicate that technological change is important for diminishing industrial energy use.

4. Conclusions

This paper suggests a new approach -the Multiple Calibration Decomposition Analysis (MCDA)- to investigate the sources of change in industrial energy use in the Japanese economy during the 1970-1990 period. The primary contribution of this paper is to use the new methodology to examine the causal factors of energy use change in energy-intensive

industry (EII) following the oil crises. The MCDA can decompose the change in factor inputs per unit of output (CFI) into price substitution (PS) and technological change (TC) in a multisector general equilibrium framework. The empirical result in Section 3 shows how industrial energy use was influenced by price substitution or technological change through the experience of the two oil crises. It illustrates that price substitution from oil to other types of energy occurred in the 1970s, while the reverse occurred in the 1980s. Nevertheless, factor inputs of oil decreased in the 1980s, because oil-saving technological change primarily occurred in that period. Notably, oil-saving technological change in EII advanced by 60% or more in the 1980s. This paper casts light on EII and investigates the details of its contribution. The results show the important role of technological change in curtailing industrial energy use in the Japanese economy.

This study presents the MCDA, which could serve as a practical tool for energy analysis. Finally, it clarifies the assumptions upon which the MCDA depends. It is notable that the method employs a deterministic procedure, and the reliability of empirical results depends on the empirical validity of elasticity parameters. Hence, the MCDA has similar defects to applied general equilibrium analysis. In practice, there are still problems in acquiring reliable elasticity parameters. Nevertheless, the method would be a great help in energy analysis with the support of other conventional methods.

Abstract: Coal mine methane is a general description for all methane released prior to, during and after mining operations. As such, there is considerable variability in flow rate and composition of the various gas emissions during mining operations. It would be highly desirable to recover energy from emitted methane of coal mine to generate electricity. Hence, more attention should be focused on the effective utilization of emitted methane in coal mines. The energy recovery system, as one of the promising technologies, has been attracting increased attention to generate electricity from emitted methane in Tabas mine. Some energy recovery systems with different configurations may be proposed such as gas turbine and gas engines. In this investigation, a simulation model has been developed in Hysys software environment to predict generated power from combination of ventilation air and drainage gas (mixture with 1.6 % methane concentration) form Tabas mine by using a lean-burn gas turbine.

Keywords: *Coal bed gas, energy recovery system, lean-burn gas turbine, simulation*

1. Introduction

New natural gas reserves are vital to guaranteeing a steady supply of affordable fuel to generate electricity and preserve quality of life. Coal bed gas is a form of natural gas reserve which is extracted from coal beds. In recent decades it has become an important source of energy in many countries of the world. It is mainly composed of methane with variable amounts of ethane, nitrogen, and carbon dioxide [1].

A large portion of the methane emitted from coal mines comes from gob areas (collapsed rock over mined-out coal). Coal mines frequently do not use medium-quality gas from gob wells and instead vent the gas to the atmosphere, contributing to global warming. However, gas with a methane concentration exceeding 35% can in fact be used as a fuel for on-site power generation [2]. Given their large energy requirements, coal mines can recover methane and generate electricity with energy recovery systems to realize significant economic savings and reduce greenhouse gas emissions. Generating electricity is an attractive option because most coal mines have significant electricity loads. Electricity is required to run nearly every piece of equipment including mining machines, conveyor belts, desalination plants, coal preparation plants, and ventilation fans [3].

Coal bed gas methane is emitted in two streams: (1) mine ventilation air (0.1–1% CH4) and (2) gas drained from the seam before and after mining (60–95%) CH4. Drainage gas can be utilized to generate electricity directly [4]. For example, internal combustion engines, such as compression fired diesel engines and compression ignition engines modified to be spark-fired engines commonly use drainage gas to generate electricity[5]. The main problem of using drainage gas is related to its periodic extraction from the mine. Also, ventilation air methane is the most difficult source of methane to use as an energy source, as the air volume is large and the methane resource is dilute and variable in concentration and flow rate. Because of low concentration of methane in mine ventilation air, effective technology will be required to utilize it and generate electricity. As brilliant idea, it will be possible to combine ventilation air and drainage gas and produce mixture with sufficient concentration of methane. The

mixture then can be used as fuel in low concentration methane combustion process such as lean-burn gas turbine for on-site power generation in the mine location [6].
In this investigation, a simulation model has been developed in Hysys software environment to predict generated power from combination of ventilation air and drainage methane in an energy recovery system. To this aim, Tabas mine is considered as case study. The results of the simulation model show that the large portion of total electricity demand of the Tabas coal mine can be supplied from the coal bed gas.

2. Materials and Methods

2.1. System description

There are several technologies that can be used for stationary power generation by directly using drainage gas, namely conventional gas turbines and gas engines or every internal combustion engine. However, it would be expected that variation of methane concentration and amount of the drainage gas should affect the continuous and stable operation of the power generation units.
The mechanism for generation power from ventilation air may be considered in two categories: 1) Catalytic oxidation 2) Thermal oxidation. In general, catalytic combustion is a multi-step process involving diffusion methane to the catalyst surface, adsorption onto the catalyst, reaction, and release of the product species from the catalyst surface and diffusion back into the bulk [7].

Thermal oxidation can be occurred in combustion chamber of lean-burn gas turbine. The lean-burn gas turbine is a recuperative gas turbine, which uses heat from the combustion process to preheat the air containing methane to the auto-ignition temperature (in the range 700–1000 C), with the combusted gas being used to drive a turbine. This gas turbine can operate continuously when the methane concentration in air is above 1.6%, which leads to the air being preheated to 700 C before combustion. Therefore, it requires the addition of substantial quantities of methane to the ventilation air to reach adequate methane concentrations from drainage methane. The mixture is preheated by a recuperator to 450 C. Then a recuperative combustion chamber uses the hot combustion products to further heat the fuel–air mixture to a point where ignition occurs. The fuel and air mixture is injected through stainless steel tubes into the combustion region. The burnt gas then passes up the outside of the stainless steel tubes to heat incoming air, and then enters into the turbine inlet to drive the turbine. This heat exchange reduces the exit temperature of air to 850 C, which is the same as the standard Centaur turbine. With this design, there is a need to use a turbine that has a low combustion temperature [8].

In this paper, Tabas mine is considered as a case study. Tabas mine is located in Yazd Province, 80 km south of Tabas City of Iran. This mine is the first mechanized coal mine of Iran that is designed by room and pillar method. Overall specifications of the mine are represented in table (1).

Table1. Overall specifications of Tabas Mine

Total production per year (2009)	1.2 Millions tones
Ventilation air flow rate (0.18 % CH4 by volume)	360000 Nm^3/h
Drainage gas flow rate (76.5% CH4 by volume)	2271 Nm^3/h
Total installed electricity demand	10.8 MW

Concentration of methane in ventilation air is available by on site measuring system. Figure (1) shows the variation of methane concentration in ventilation air flow during 7 months.

According to this figure, the higher peak and average value of methane concentration are measured around 0.25% and 0.18% respectively. It is clear that, the concentration of methane in ventilation air is not sufficient for burning in combustion chamber of lean-burn gas turbine. Therefore, mixing of certain amount of drainage gas will be required to improve the level of methane concentration up to 1.6%.

Schematic of energy recovery system which may be used for methane recovery in Tabas coal mine is depicted in figure (2). According to this figure, ventilation air and drainage gas are mixed together in the mixer storage and with suitable concentration will be fed into the lean-burn gas turbine. It may be possible to use remainder amount of drainage gas in a gas engine for generating excess electricity.

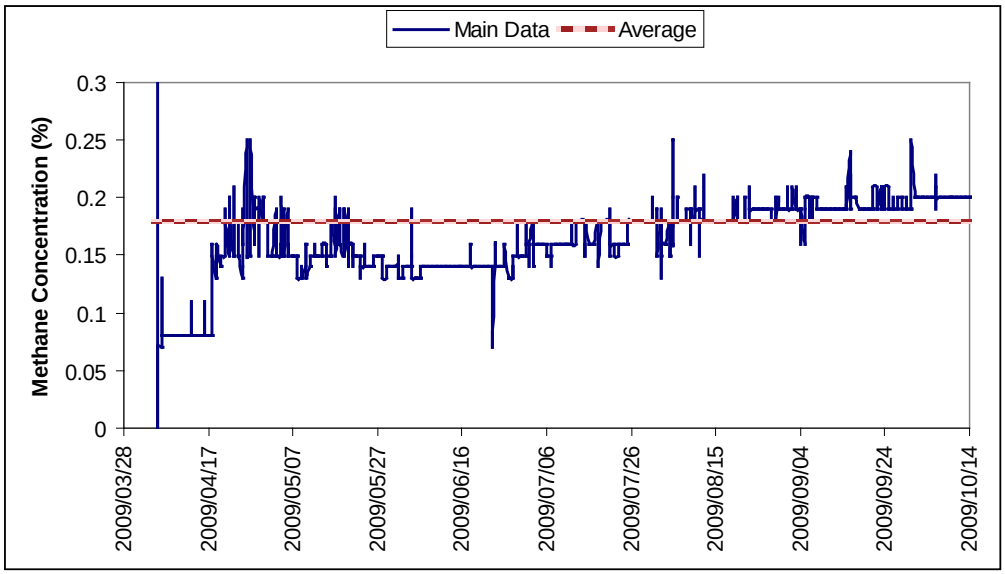

Fig. 1 Variation of methane concentration of ventilation air in Tabas mine

2.2. Methodology

The simulation model has been found on the theoretical principles of first and second lows of thermodynamics and it has been tailored to identify the design condition of specified energy recovery system for power generation in Tabas coal mine. To this aim, HYSYS simulator is used. Simulated framework of the energy recovery system in Tabas coal mine is represented in figure (3). While, the methane concentration of ventilation air of Tabas mine is very low, total amount of drainage gas should be consumed for generating power in lean-burn gas turbine cycle. Therefore, no gas engine will be required for excess power generation. Physical properties of streams are approximated by the Peng-Robinson equation of state formula through developing simulation model by HYSYS software [9].

3. Results and Discussions

The aforementioned simulation model has been applied for performance analysis of the energy recovery system and estimation total generated power form the energy recovery system in Tabas coal mine. According to represented results in table (2), 6.193 MW power can be generated by the energy recovery system. The thermal efficiency of the cycle is obtained at 24.74% because of low concentration of methane in the inlet feed of combustion chamber of lean-burn gas turbine.

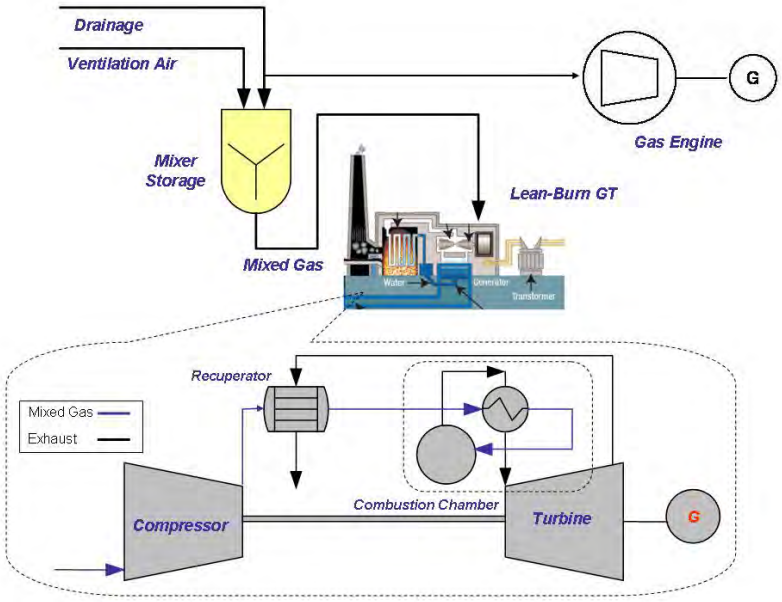

Fig. 2 schematic of energy recovery system in coal mine

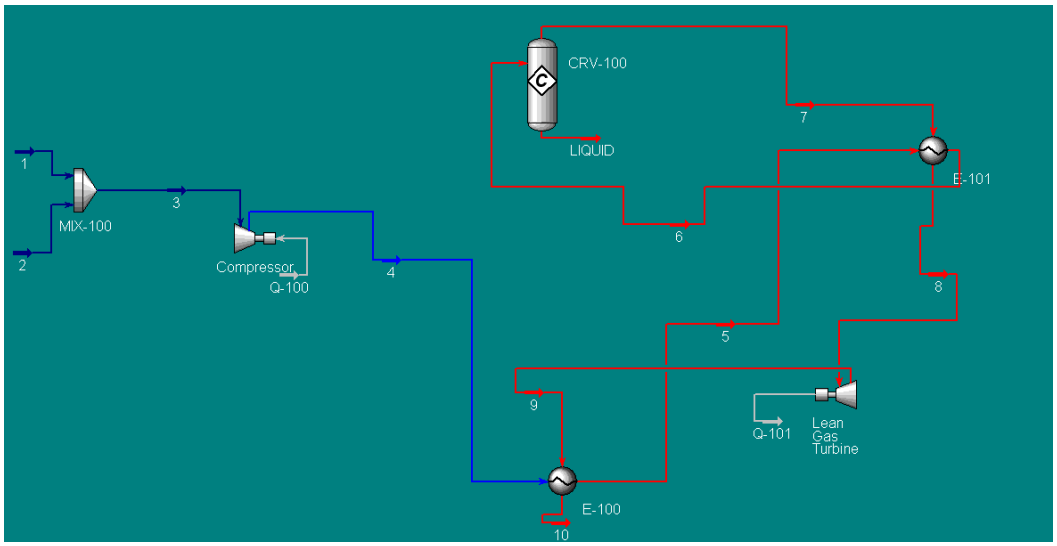

Fig. 3 Simulated frame work of energy recovery system in HYSYS simulator

Table2. Simulation results

Turbine power generated (MW)	12.60
Compressor power consumed (MW)	6.407
Net power generated by cycle (MW)	6.193
Thermal efficiency of cycle (%)	24.74
Usage percentage of ventilation air (%)	54
Usage percentage of drainage gas (%)	100

According to simulation results, physical properties and flow rate of streams are represented in table (3). Also, compositions of main streams are reported in table (4).

Table3. Physical properties and flow rate of streams

Line	1	2	3	4	5
Temperature(C)	50	25	25.57	139.3	352
Pressure(kPa)	150	150	150	400	350
Flow(kg/h)	2503	194000	196503	196503	196503
Line	6	7	8	9	10
Temperature(C)	773.5	1137	738.1	538.5	334.5
Pressure(kPa)	300	300	297	106	100
Flow(kg/h)	196503	196503	196503	196503	196503

Table4. Composition of main streams

(Mole Fraction)	**1**	**2**	**3**	**7**	**8**	**10**
Oxygen	0.006	0.2116	0.2078	0.176	0.176	0.177
Nitrogen	0.16	0.7766	0.7651	0.7651	0.7651	0.764
Ethane	0.020	0	0.0004	0.0004	0.0004	0.0003
H_2O	0	0	0	0.0317	0.0317	0.0317
CO_2	0.048	0.010	0.0107	0.0266	0.0266	0.0263
CH_4	0.765	0.0018	0.0160	0.0002	0.0002	0.0002

Figure (4-a) shows variation of the thermal efficiency with the compression ratio. It is clear that the thermal efficiency will be increased with increasing of compression ratio in compressor. It can be observed in this figure that, the thermal efficiency of cycle reaches to its maximum point at each selected value of compression ratio by increasing methane concentration in inlet fuel mixture of lean-burn gas turbine. As shown in figure (4-b), increasing of the compression ratio is accompanied with increasing of the methane concentration in the intake feed at each turbine inlet temperature (TIT). However, it can be observed from combination of figure (4-a) and (4-b), at the same pressure ratio, higher thermal efficiency may be obtained at higher TIT and higher concentration of methane.

4. Conclusion

The objective of this research work has been to introduce an energy recovery system for power generation from coal bed gas of Tabas coal mine of Iran. With the aim of developing more efficient, cost-effective technologies for mitigating and utilizing the diluted coal mine, this paper studied a novel energy recovery system, which can be powered with about 1.6 % methane (volume) in intake mixture. The results indicate that, the methane concentration of ventilation air and also temporal availability of drainage gas should be considered as main factors for developing any power generation system in a coal mine. Based on the obtained results from simulation, 6.193 MW power may be generated from coal bed gas recovery in Tabas coal mine. Therefore, 57% of total electricity demand of the mine can be supplied by the on-site power generation in this mine. If electricity unit price is considered as 0.09 $/kWh and with purposing total capital investment around 6.7 millions dollars including lean-burn gas turbine, ventilation fan, drainage fan, mixer and piping, internal rate of ratio (IRR) and net present value (NPV) of project may be estimated at 41% and 14.6 millions dollars respectively and its economical feasibility will be supported.

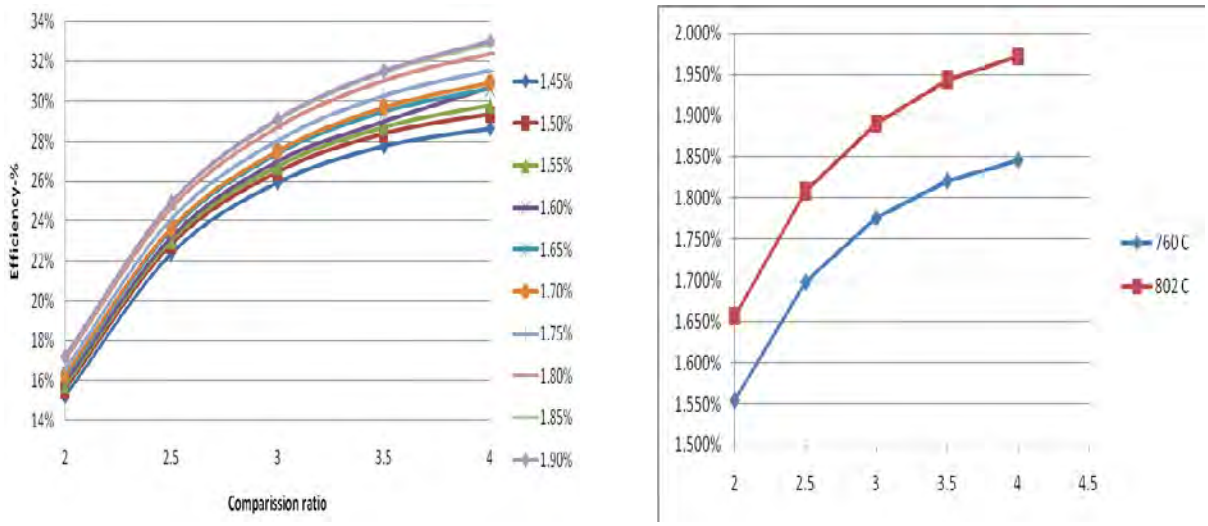

Fig. 4: a) Variation of thermal efficiency with compression ratio b) variation of TIT with compression ratio and different methane concentration

Abstract: Industrial energy systems are complicated networks, where changes in one process influence its neighboring processes. Saving energy in one unit does not necessarily lead to energy savings for the total system. A study has been carried out on the possibility to use the exergy concept in the analysis of industrial energy systems. The exergy concept defines the quality of an amount of energy in relation to its surrounding, expressing the part that could be converted into work. The study consists of literature studies and general evaluations, an extensive case study and an interview study. In the latter it was found that non technical factors are major obstacles to the introduction of exergy.

Keywords: *Energy efficiency, Exergy, Process integration, User acceptance, Industrial energy system*

1. Introduction

1.1. The need and development of process integration in Swedish industry

Energy use in Swedish industry amounts to more than 40% of the national energy use. The three most energy-intensive industrial branches in Sweden, pulp and paper, iron and steel and chemical industries use more than two thirds of industrial energy use. Over the years a large effort has been made to increase industrial energy efficiency. This includes measures to increase energy efficiency as well as increased use of excess energy in other branches, e.g. for heat and electricity generation.

One problem is that industrial energy systems are complicated networks where changes in one process, influence its neighboring processes. Thus saving energy in one unit does not necessarily lead to an energy saving for the whole system. A system approach is needed to avoid sub optimization. One early attempt to make a more systematic analysis of this type of problems, the Pinch analysis, was made at Manchester University [1] during the 1970s. A method, pinch analysis, was developed, where the heat-carrying media are categorized as either cold streams (media that are heated during the process) or hot streams (media that are cooled down during the process). They are then added to one hot and one cold stream. The system could be characterized by the point where the composite streams are closest to each other, the pinch point. Exergy analysis [2] and mathematical programming, e.g. the MIND method [3], have been developed for industrial energy system studies starting in the 1980s. A national program to support research, development and use of process integration in Sweden was initiated and financed in cooperation between the Swedish Energy Agency and the Swedish energy-intensive industry [4],[5]. It started 1997 and ended in 2010.

The energy systems of the steel industry are characterized by large high temperature flows of molten solid and gaseous materials, as well as energy intensive chemical reactions. Mathematical programming was considered most suitable for that type of system. A methodology, reMIND, was developed and implemented for practical steel plant use (ref [6]-

[9]). Based on successful industrial applications three research supporting agencies and a group of Scandinavian steel- and mining companies decided to start and finance an excellence center for process integration in the steel industry, PRISMA which is located at Swerea MEFOS AB in Luleå.

The national program focused on three process integration technologies: Pinch analysis, mathematical programming and exergy analysis. When the work was summarized, it was seen that the main part of research was on mathematical programming and pinch analysis, whereas only a very limited work was made on exergy studies. Considering this, the Process Integration Program of the Swedish Energy Agency has supported a special study on the usefulness of the exergy concept, as well as its limitations and obstacles to future use.

1.2. What is exergy?

Energy balances are a common tool in technical energy studies. In these balances energy input equals energy output. This is based on the first law of thermodynamics: energy can neither be destroyed nor be created. The balances also include energy losses. The lost energy has not disappeared; it is converted into a practically useless flow of low-value energy, e.g. used cooling water or waste gas. This indicates the need of a way to describe also the quality of energy flows. The exergy concept defines the quality of an amount of energy in relation to its surrounding, expressing the part that can be converted into work. It is based on the second law of thermodynamics: the entropy of an isolated system never decreases. A certain media can produce work only if there is a difference e.g. in temperature and pressure versus the surrounding. The exergy expression describes the theoretically possible production of work as a function of that difference:

$$E = \Delta H - T_0 * \Delta S \quad (1)$$

Where E = exergy, H = enthalpy, S = entropy, ΔH and ΔS are differences from the reference state (the surroundings) and T_0 = the absolute temperature at the reference state.

For a non compressible liquid or solid with constant specific heat the entropy difference can be calculated as

$$\Delta S = m * c_p * \ln\left(\frac{T}{T_0}\right) \quad (2)$$

And for an ideal gas as

$$\Delta S = m * \left(c_p * \ln\left(\frac{T}{T_0}\right) + R * \ln\left(\frac{p_0}{p}\right)\right) \quad (3)$$

Where m and c_p are mass and specific heat, T and p are absolute temperature and pressure of the substance and T_0 and p_0 are temperature and pressure at the reference state.

1.3. Scope of paper

The main scope is to improve the knowledge of when and how exergy analysis is useful on its own or in combination with other methods and methodologies, as well as on the improvements needed to increase the use of exergy analysis in process integration projects. It was considered important to cover both technical and nontechnical limitations to an improved use. The work was structured in the following parts: literature study, analysis, interview study, case study and synthesis.

2. Methodology

The study was carried out in five steps

Step 1. A literature study with the aim to provide an overview on the utilization and advantages of the exergy analysis method in several systems, especially in industrial ones.

Step 2. An analysis where literature data and experience of the project partners were used to define subsystems where exergy can be used as well as identifying problems and unanswered questions.

Step 3. An interview study with the aim to find the reasons why Exergy was used or not used by different actors. The method was based on a combination of in-depth, semi-structured interviews and a more straight-forward questionnaire [10]. Both technical and non-technical aspects were studied. The questions were formulated using the results of the analysis study

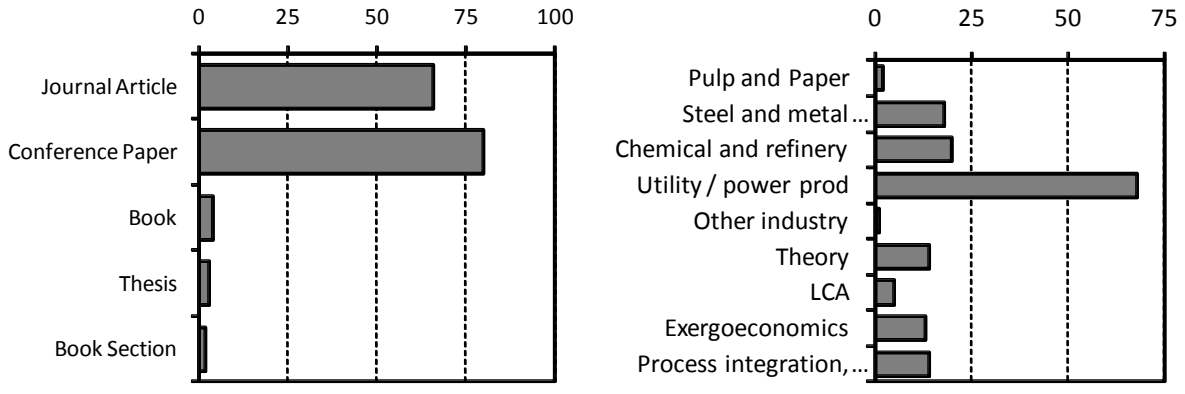
Step 4. A case study to demonstrate the practical application on an industrial system. The case chosen was the Luleå Energy: The SSAB steel plant, CHP (combined heat and power plant) and district heating. Collected production data were used for exergy calculations both for the total system and some subsystems

Step 5. A synthesis based on the results from step 1-4 with the aim to answer the following questions: Which criteria for comparison should be used? Should the methodology be used in combination with other methods? Should there be increased dissemination? When should the exergy concept be used? Is exergy research worthwhile? Could the formulation of the exergy concept be explained in a better way? When should the exergy concept and exergy studies be used? Is there a need for exergy research

3. Results

3.1. Literature study

155 references were included, and 115 of these were described in some detail. The distribution between publication categories is illustrated in Fig. 1 a. The main part of material is distributed almost evenly between journal and conference publications.



a) Category of publication *b) Subject of publication*

Fig. 1 Distribution of literature references between publication types and subjects. The diagrams show the number of references per category

The collected references described the use in different industrial branches and for specific equipment, some more sophisticated uses, e.g. in LCA or exergoecoonomics, as well as some general studies. The distribution between these subjects is illustrated

The use is relatively small in the pulp and paper industry. The reason is probably that the transport and exchange of thermal energy is a dominant part of the energy system, which gives a preference for pinch analysis. A higher frequency of references is shown for steel and chemical industry where chemical reactions and energies are important. The power industry and utilities show the highest frequency in Fig. 1 b. A reason can be that components like boilers, turbines, valves and heat exchangers usually entail large exergy destruction rates. The solutions proposed to minimize these losses are often to change operation parameters or to install new equipment with different operating characteristics. The most common action proposed to increase exergy efficiency is to decrease the temperature difference in heat transfer equipment. Since this decreases the driving force, investment costs are likely to increase.

In a system of nodes and streams, exergy analysis is applied to the efficiency of nodes. This can lead to more capital-intensive suggestions e.g. change of process technology.

Several authors suggest using combined pinch and exergy analysis to achieve better results. Pinch analysis could be used to determine minimum cooling and heating demands, thereafter exergy analysis could be used to detect inefficiencies. Finally, the design capabilities of pinch analysis could be used to synthesize a heat exchanger network.

3.2. Analysis

The usefulness of the Exergy concept was analyzed separately in pulp and paper, steel industry, mining industry, cement industry, use for electricity generation and for regional cooperation. The result varied between branches. Two interesting uses can be: energy quality to compare subsystems and recovering excess energies. Presently there is a lack of comparison data. Creating a BAT (Best Available Technology) database for energy efficiency and exergy destruction could be interesting. This study also produced parameters for the interview study

3.3. Interview study

The aim was to observe the effect of technical and non-technical factors which were of great importance for the introduction of exergy studies as well as for failure or success in the application. The interview form consisted of an interview part where questions were answered in words and a short questionnaire part, where the respondents could rank different obstacles to each other. Fig. 2 illustrates the weighted summary of important obstacles in the questionnaire part. The most important factor seems to be the lack of strategy. Points like lack of time, priorities, lack of capital and slim organization got a low priority. A comment when these points were discussed was: “When we get the job to make an energy analysis the priority is always very high, so those limitations (to the use of exergy analysis, author’s remark) are not relevant”.

Fig. 2 Weighted summary of obstacles for exergy analysis. Often important =1, sometimes important =0.5, seldom Important = 0.

The answers to the in-depth interview questions indicated that one reason for the low rate of applications of exergy analysis is that most missions in the industry, according to respondents, do not require this type of tool, e.g. studies for small and medium-sized businesses. Only about 600 of 59 000 manufacturing companies in Sweden are defined as energy-intensive. This can be linked to the obstacles heterogeneity, i.e. the method is not considered by respondents to be applicable in most industries. One reason for the low level of potential applications, however, seems to be that several respondents felt that exergy was difficult to use. One conclusion from this is that the development of software for exergy could promote its use. The major obstacle to exergy analysis that was detected in the interview study was heterogeneity in the technical system level and information imperfections and asymmetries in the socio-technical systems level. (The heterogeneity refers to the fact that different companies have differing conditions for the use of exergy. Imperfections refer to lack of sufficient information and asymmetry to differences in information between different actors.) The highest ranked obstacle to the use of exergy analysis was a lack of strategy. This can be linked to one respondent who indicated that exergy often competes with cost analysis. One conclusion from this is that the tool should be competitive in the analysis of large technical systems where it can be used as decision support for industries or society.

3.4. Case study

The case study was made for the Luleå energy system. Existing data for the steel plant site, see ref [11] were extended by data collected from the CHP plant and District heating network.

An example of Sankey diagrams showing energy and exergy flows from the SSAB study 2005 is shown in Fig. 3. In the energy diagram for the blast furnace there is an energy input of 100%, whereas the output is 86.7 % export and 13.3 % losses. The sum of input flows is equal to the sum of the output flows because energy is indestructible according to the first law of thermodynamics. If we instead look at the exergy diagram, both the export and the heat loss flows are lower because the energy consists of energy forms of lower exergy value. Also the

output exergy is lower than the input exergy. The difference is irreversibly destroyed and corresponds to the entropy increase.

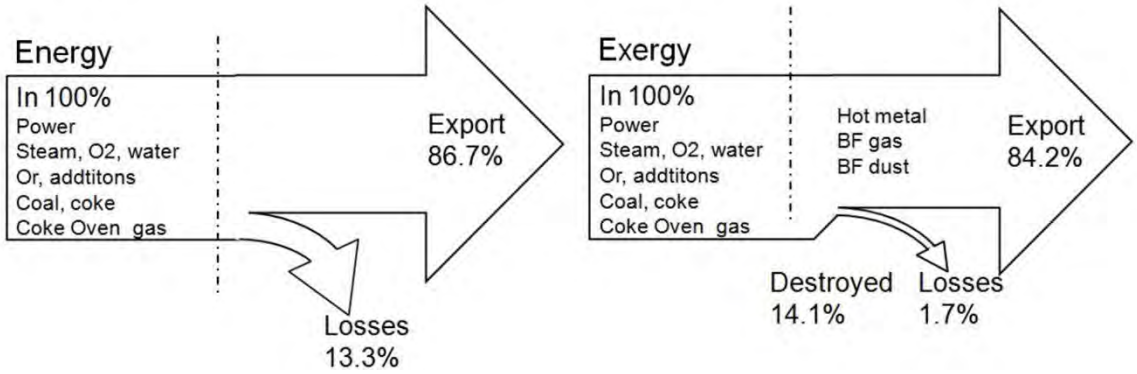


Fig. 3 SSAB Study 2005, Example on Energy-Exergy Diagrams for the blast furnace [12].

The destroyed exergy is a measure of the inefficiency of the unit in question. The heat loss exergy is a measure on the energy that could possibly be recovered.

Fig. 4 shows similar values for the heat and power plant. There are comparatively small heat loss flows, but a relatively high amount of destroyed exergy. The destruction rate is quite different between the units in Fig. 4. It is highest for the boiler and more moderate for the heat exchanger and turbine.

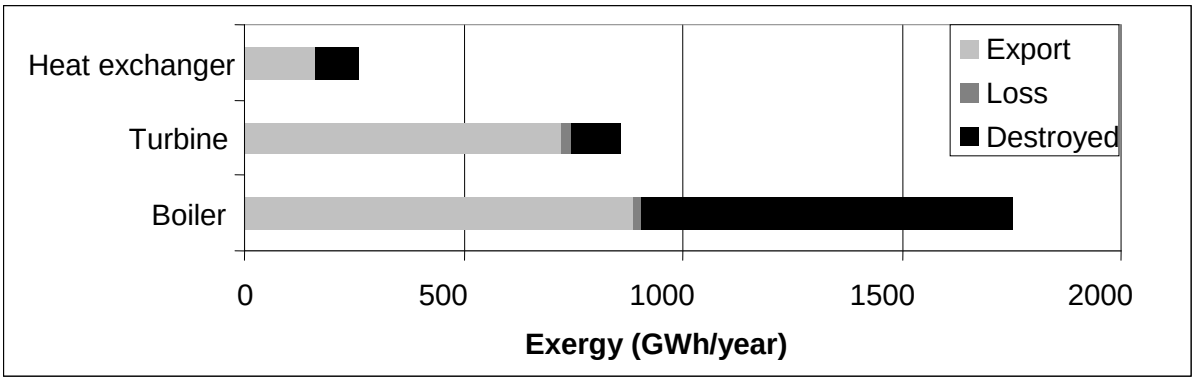

Fig. 4 Example on Exergy balances for the heat and power plant.

The reason for the higher destruction rate in the boiler is that it converts fuel energy (in principle 100% exergy) into high pressure steam with an exergy content that is roughly 50% of the enthalpy. It does not indicate a problem with the boiler; the boiler simply has a function where exergy destruction is inevitable. An important conclusion of this is that exergy destruction rate (or exergy efficiency) can be a tool to find out where to look. However, if it is to be used to judge bad or good function a reference value is needed. This could be previous data from the unit or published data. A catalogue for reference exergy data could perhaps be of interest.

Fig. 5 shows a Sankey diagram for the total system: Steel plant – Heat and power plant – District heating. The exergy in heat loss flows was relatively small in Fig. 3 but has increased when all steel plant units are increased. This flow represents energy that theoretically could be recovered as higher forms. These results have initiated quantitative studies on recovery e.g. by ORC turbine It can be seen that the exergy is destroyed stepwise through the system. The low amount of exergy in the district heating indicates that a large amount of energy sent to users with a low exergy demand. This can be a potential use for energy recovery from the steel plant. This can be expected to produce media flows with low or moderate exergy content.

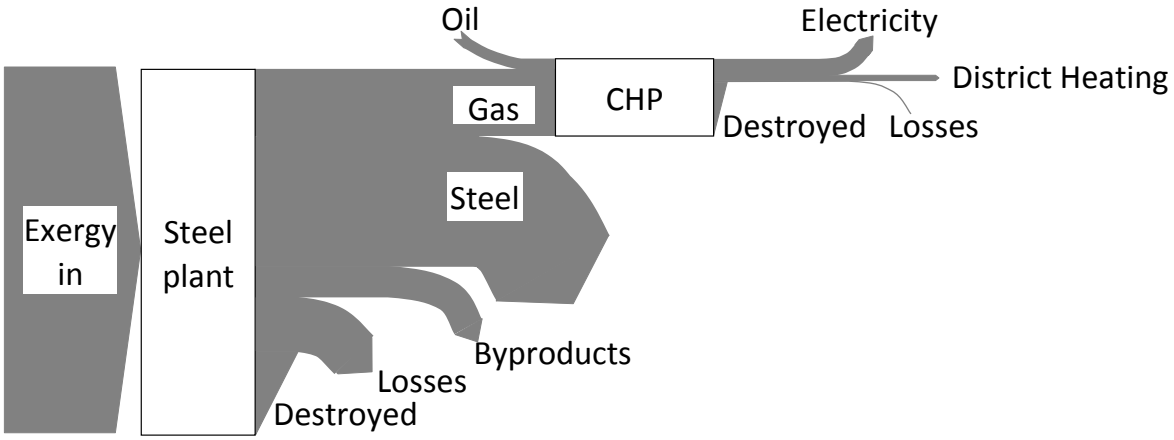

Fig. 5 Exergy flows through the total system

4. Synthesis, Discussion and Conclusions

In the project it was shown that:

- Exergy analysis is most competitive for industrial systems dominated by chemical conversions and energies other than thermal energies, e.g. chemical energy. Good examples are the steel industry and the chemical industry, especially refineries. Another important use is systems with different pressures and where production of electricity is of interest.
- Exergy expressions can be used to study process efficiency, possible modifications and mapping possibilities for excess energy recovery.
- Relatively much exergy is used for heating with a low need for exergy, compare Fig. 5. A study to decrease the imbalance using a modified system temperature is planned. Variations in the hot water balance for district heating are also influencing the energy efficiency.
- It is probably better to use a combination of Process integration methods than to only focus on one.
- Inclusion of exergy calculations in the mathematical programming tool reMIND was explored in the case study [15]. Continued work is interesting.
- Non-technical factors are responsible for the slow adoption of exergy analysis, e.g. lack of strategy, heterogeneity, information imperfections and asymmetries.
- The interview study has given an insight into the effect of non-technical parameters. The present technique has a relatively broad spectrum of questions which gives a good result even with a limited amount of respondents.
- Exergy studies are becoming established for system studies in the steel industry. Extension to further sites is being planned.
- A catalogue of reference data would be of interest for better interpretation of results

Acknowledgements

The authors would like to thank the Swedish Energy Agency for financing the project. We would also like to thank the many interviewees who kindly answered our questions and the people at SSAB, Lulekraft and Luleå Energi who have helped with data collection.

Abstract: An exergy analysis to a Mexican flavor industry, which uses liquefied petroleum gas as a primary energy fuel in their process equipment was carried out. .
The analysis used a proposed method that quantifies efficiency by means of exergetic indicators. To apply it to this case study equipment, the system or process was assumed to be a block that interacts with the surroundings in three ways: heat, work and mass transfer. The analyzed blocks were boilers, a thermal oxidizer, dryers, a distillation tower and extractors. Work and heat needs were covered by liquefied petroleum gas.
The exergy indicators quantify the degradation of energy by determinining the difference between the actual operation efficiency of the block and the maximum operation, both of them obtained from second law point of view. These indicators were exergy loss, efficiency, effectiveness, performance and potential of improvement.
Following the exergetic method application, it was found that the indicators of the effectiveness and performance in all blocks analyzed are near zero. This means that the process equipments are using a high exergy source to perform their function and also in large quantity. The results show that the oxidizer presented the major irreversibilities, and it is the equipment with the greatest potential for improvement and the key to reducing fuel consumption.

1. Introduction

The industry sector is sensitive to the variability of the energy prices; as a result it adjusts the production priority to an efficient energy consumption to obtain advantages in cost. The economic factor is not the only reason to reach an efficient energy consumption in a country. The environmental negative impact as a result of an inefficient use of an energy resource is important as well [1,2].

Efficient energy use in the industry sector is possible with energy consumption analysis. Two problems promptly arise: the scarce information about an optimum use of energy in the industrial processes and the use of inefficient technology. [3,4].

The exergy analysis is especially useful when it is necessary to detect equipment, systems or processes that use a high quality energy source that is unnecessary for the objective, because

in this case important exergy losses arise [3]. Exergy analysis has been applied since the early 1970's with the aim of finding the most rational use of energy, which means at the same time reducing fossil fuel consumption, applying energy efficiency and matching the quality levels of the energy supplied and demanded [5]. The exergy method is useful for improving the efficiency of energy-resource use, for it quantifies the locations, types and magnitudes of wastes and losses. Also it is useful in identifying the causes, locations and magnitudes of process inefficiencies [6].

This paper discusses an exergy analysis of a flavoring industry plant (FIP) located in Morelos, Mexico. The monitoring of energy utilization of different equipments used in the process was necessary in order to investigate, analyze, verify and compare the data so as to try to understand the actual condition. The monitoring and data collection lasted from March to December, 2009. Table 1 shows the analyzed equipment:

Table 1. Identify and capacity of the analyzed equipment.

Identification	Capacity	Units
Distillation column A-001	700	l
Distillation column A-002	700	l
Distillation column A-004	70	l
Distillation column A-009	1900	l
Extractor A-103	2734	l
Extractor A-104	2734	l
Extractor A-106	7570	l
Extractor A-107	7570	l
Dryer S-01	30	kg/h
Dryer S-02	40	kg/h
Dryer S-03	150	kg/h
Dryer S-05	100	kg/h
Boiler CA-01	250	hp(S)
Boiler CA-02	100	hp(S)
Oxidizer		

l: liters, kg/h: kilograms per hour, hp(S) Boiler horsepower

These five kinds of equipments have the following function in the FIP:

- *Distillation column*: To separate mixtures based on differences in their volatilities in a boiling liquid mixture.
- *Extractor*: To separate a substance from a matrix. In the case of the FIP we refer to solid phase extraction.
- *Dryers*: To eliminate the liquid in a substance. The powder production starts by atomizing the emulsion in a hot air stream inside the dryer chamber in which the liquids evaporate instantly. The active material in the emulsion is encapsulated inside the film material.
- *Boiler*: To generate steam with the liquefied petroleum gas (LPG) combustion. The liquid water changes to vapor phase due to the high temperatures obtained.

2. Methodology of exergetic analysis

Exergy is defined as the maximum theoretical work obtainable from the interaction of a system with its environment until the equilibrium state between both is reached [7], it can also be seen as the departure state of one system from that of the reference environment [8]. Therefore, exergy is a thermodynamic potential dependent on the state of the system under

analysis and its surrounding environment, so called "reference state". The environment is regarded as a part of the system surroundings, large in extent so that no changes in its intensive properties, pressure P_0 and temperature T_0 mainly, occur as a result of the interaction with the system considered.

The exergy method quantifies the energy degradation using six different indicators. We assume the equipment, system or process to be a block that is interacting with the surroundings through heat, work and mass transfer. The work and the heat refer to the energy such as electricity solar radiation, mechanic work, etc. The mass transfer is the inflow and outflow of chemical substance, flows like vapor and fuel [9]. In the analyzer equipments in the flavor industry, the required work and heat are provided by LPG.

The exergy is the quality of energy in the block and is defined as:

$$Ex = (H - H_0) - [T_0(S - S_0)] \quad (1)$$

In Eq (1), the first term is the total enthalpy of the system that includes the thermal, mechanical, chemiscal, kinetic and potential energy. The second term, on the right -hand side, is the total entropy. The enthalpy (H_0) and entropy (S_0) of the reference state are defined by its pressure, composition, velocity, position and temperature.

2.1. Exergetic indicators

In order to quantify the energy degradation of the block, a series of exergy indicators were used. These indicators were: exergy losses (Irr), efficiency (η), effectiveness (ε), performance (ζ), potential of improvement (*Pot*). These are the relationship between the reality and the ideality expressed by fraction or percentage [4]. Table 2 shows the corresponding indicators:

Table2. Exergetic indicators to quantify the energy.

Exergy indicator	Equation
Exergy losses	$Irr = \sum (Ex_{tte} - Ex_{tts})$
Efficiency	$\eta = \frac{\sum Ex_{tts}}{\sum Ex_{tte}}$
Effectiveness	$\varepsilon = \frac{Ex_{ntp}}{Ex_{nts}}$
Performance	$\zeta = \frac{Ex_{uts}}{Ex_{tte}}$
Potential improvement	$Pot = Irr(1-\varepsilon) + Efl$

Below is a brief explanation of each indicator:

- *Exergy losses.* The measure of the total exergy provided by the inflow such as fuel and raw material, and the total exergy at the outlet such as products and effluents.
- *Efficiency.* The ratio of the total exergy at the outlet of the block in relation to the total exergy of the inlet.
- *Effectiveness.* It evaluates if the analyzed block satisfies its function, considering the term "net" means difference (Δ). The net exergy produced is the one obtained by the products and the net exergy supplied is provided by the energy resource, for instance LPG.
- *Performance.* Relation of the useful outlet exergy and total entrance exergy.

- *Potential improvement.* It is the measurement of block improvement. The equation has been obtained through the combination by exergy losses and the system effectiveness. The exergy losses are due to two different sources, the first one derives from the internal use of the block and is referred to as irreversibilities (Irr) and the last one arises from the effluents (Efl), that are released into the environment like wastes.

To obtain the reference temperature, the actual hourly temperature in the process plant was registered for a week. The value was 29.3 ºC±1.9°C. The pressure was considered constant at 101.325 kPa.

2.2. Blocks

As mentioned in the introduction, five different equipments were analyzed. The exergetic balance of each equipment was different and depended on the way that it operated, the energy quantities they require, and the energy wasted in irreversibilities, so it was necessary to consider an exergetic balance for each case.

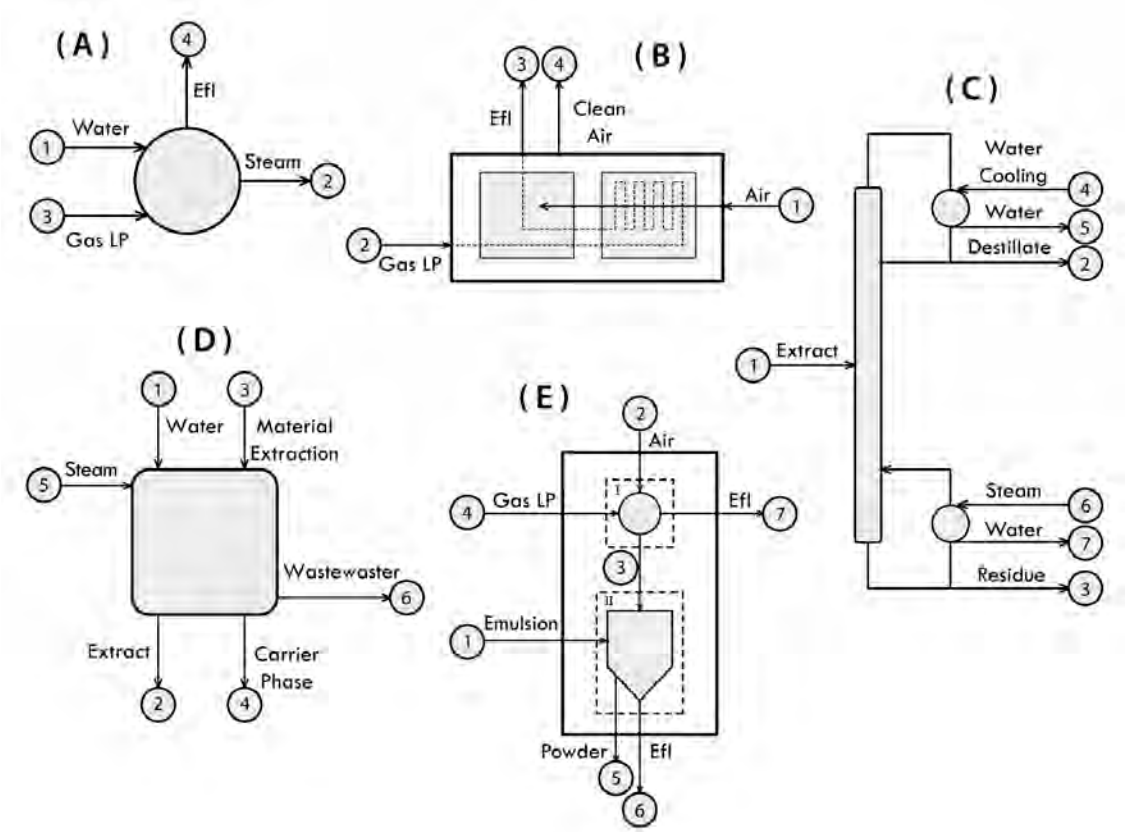

Fig. 1. Diagrams of the blocks. Boiler (A), Oxidizer (B), Distillation tower (C), Extractor (D) and Dryer (E)

Figure 1 shows the diagrams of the different blocks to be analyzed. The numbers represent the process streams of each case. When the arrows point inwards, it refers to the stream with the exergy that enters the equipment; it could be fuel, vapor or fluid. Conversely, when the arrow points outwards, it refers to the stream with the exergy that goes to the environment, such as products, effluents or wastes. Table 3 shows all the exergetic balances obtained for the blocks.

Table 3. Exergetic balance

Block	Ex_{tte}	Ex_{tts}	Ex_{nts}	Ex_{ntp}
Distillation tower	$Ex_1 + Ex_4 + Ex_6$	$Ex_2 + Ex_3 + Ex_5 + Ex_7$	$(Ex_6 - Ex_7) + [Ex_1 - (Ex_2 + Ex_3)] + (Ex_4 - Ex_5)$	$(Ex_2 + Ex_3) - Ex_1$
Extractor	$Ex_1 + Ex_3 + Ex_5$	$Ex_5 + Ex_4 + Ex_6$	$Ex_5 - Ex_6$	$(Ex_2 + Ex_4) - (Ex_1 + Ex_3)$
Dryer	$Ex_1 + Ex_2 + Ex_4$	$Ex_5 + Ex_6 + Ex_7$	$Ex_4 - Ex_7$	$Ex_5 - Ex_1$
Boiler	$Ex_1 + Ex_3$	$Ex_2 + Ex_4$	$Ex_3 - Ex_4$	$Ex_2 - Ex_1$
Oxidizer	$Ex_1 + Ex_2$	$Ex_3 + Ex_4$	$Ex_2 - Ex_3$	$Ex_4 - Ex_1$

Finally, with the exergy balance of each block it is necessary to calculate the exergetic indicators with the equations presented in Table 2.

3. Results

The values of the indicators in all the equipments studied were plotted with the objective of analyzing and comparing the behavior in the FIP.

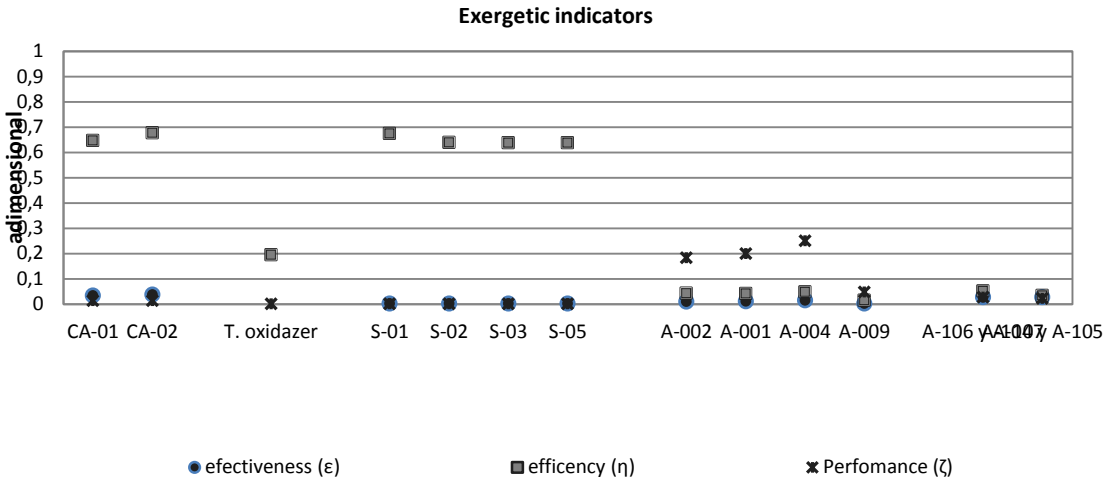

Fig. 2. Effectiveness, efficiency, performance of the analyzer blocks in the FIP

Figure 2 presents the dimensionless indicators: the effectiveness, efficiency and performance. The effectiveness is near a zero value in all the blocks as a consequence of the important quantity of exergy required to carry out their objective. This happens commonly with old equipment where the design does not have priority on saving fuel. The performance is larger in the distillation columns 0,2 to 0,3 because they do not require high temperatures for their function and the effluents are smaller than in others blocks. The efficiency of the combustion equipment is estimated at 0.7 which shows a large amount of effluent in the total output exergy, with up to 65% of exergy provided by the LPG thrown into the atmosphere as combustion gases.

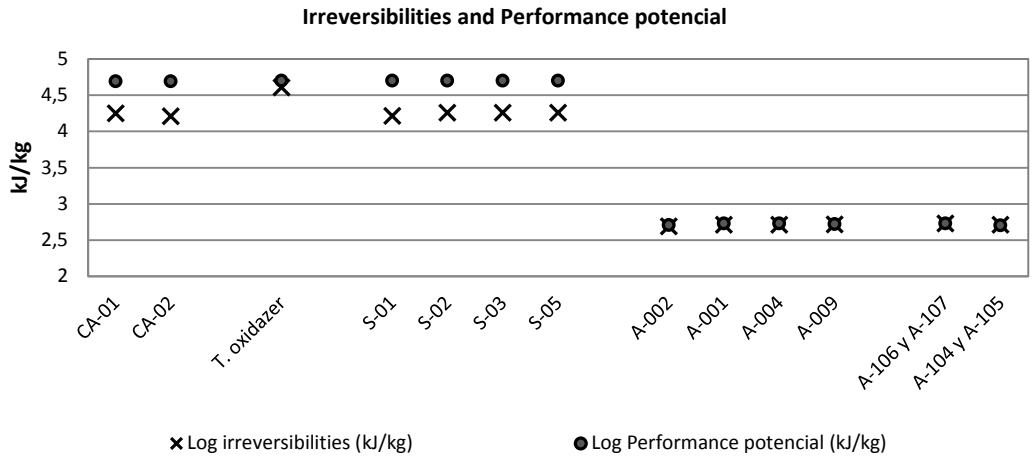

Fig. 3. Irreversibility and improvement potential of the analyzer blocks in the FIP

In Figure 3, the distillations columns and extractors present similar improvement potential values and irreversibilities due to the fact that the effluents are insignificant, a slight flow of water between 60°C to 80°C from the steam used to obtain the process temperature circulating in the insulation of the equipments. In contrast in the combustion equipment their improvement potential is higher than the irreversibbilities because of the large quantity of effluents, 33000 kJ/kg. These blocks have an important feasibility of optimization, by recovering heat from the effluents to preheat the water used in the boiler.

As a result of the method, the global exergy flow of the plant can be represented with a Sankey diagram; this diagram is a summary of the exergy analysis of all equipments of the FIP. The width of the arrow gives the flow, specifies the effluents (arrows pointing upwards), irreversibilities (arrows pointing downwards) and the net exergy produced (arrows pointing to the right), the numbers outside the arrows in parenthesis describe the percentage of the total exergy in the FIP, and the numbers inside the blocks in parenthesis describe the quantity of equipment that represents each block. The indicators represent a specific aspect of the equipment and the Sankey diagram the interaction of all the blocks in the FIP. In Figure 4, an expansion in scale from the steam of the oulet of the boilers to the inlet of the extractors and distillation tower was necessary, because only the 0.35% is the net produced exergy as steam.

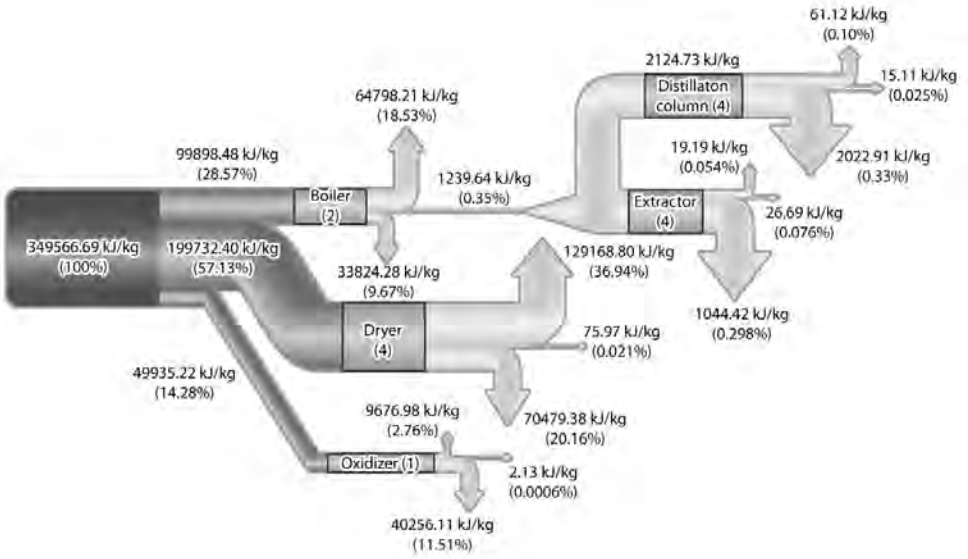

Fig. 4. Sankey diagram for the global exergy flow in a FIP

The diagram shows that the exergy provided by the LPG energy source is 349,566 kJ/kg, and is distributed to the process blocks. Over half of the exergy 57.1% is used for the driying process in which only 0.021% of the net exergy produced is obtained as powder.

The distillation columns and extractors have small effluents of approximately 20 kJ/kg per equipment, compared with the combustions blocks with 33000 kJ/kg. On the other hand. they have more important irreversibilities, as compared to the combustion blocks. To optimize these equipments it is necessary to analyze how they operate and find an improvement in their design. [10].

4. Conclusions

In this paper a second law analysis in a flavor industry was carried out. The process blocks with higher efficiency, close to 0.7, were the boilers and the dryers. This is to the fact that the total output exergy includes the effluents, that represent 90% of the total of the exergy that is provided by the fuel.

The thermal oxidizer does not present important losses in effluents (9,676.98 kJ/kg), but its irreversibilities are the largest with 40,256.11 kJ/kg and an effectiveness close to zero. As a result, this block has the highest performance potential 49,933.6 kJ/kg and is the main equipment in which to focus in order to achieve a low fuel consumption. It is possible to use other kind of equipment for the same objective (eliminates unpleasant odor) without using combustion.

The distillation towers and extractors present low effluents (20 kJ/kg) per equipment approximately as compare with combustion blocks (33,000 kJ/kg). This means that the energy is degraded in the distillation columns due to the presence of significant irreversibilities. To optimize these equipments it is necessary analyze their performance and find a design improvement, owing to the fact that they are more than 30 years old with no technological improvements. The best solution is to upgrade the equipments.

The indicators in all equipments such as efficiency, effectiveness, and performance are close to zero. This means that the FIP requires a high exergy source and a large quantity forcarried out its objective, approximately 350,000 kJ/kg. This consumption decrease at least 68% applying waste heat recovery of the effluents of the combustion equipments, like boilers, dryers and oxidizer, to warm currents in other processes such as in the extractors where the optimal temperature is 60 °C. [10].

5. Acknowledges

The authors thank CONACYT and Posgrado UNAM for their support. Thanks to the FIP for accepting do the analysis and providing the necessary access and information. Finally we want to thank the graphic designer, Hernán A. Perez for making the diagrams necessary for the paper.

Abstract: There are a number of cooling systems known across the world. For decades they have undergone development, changing coolants and their chemical composition, but water has, thanks to its universal properties, remained an undying presence in this technology. Water is used as a carrier heat or cold for cooling spaces and some cooling equipment itself, for accumulating and radiating heat to an environment with lower heat potential, for heat evaporation, and as a solvent which is great at dissolving substances we know as cooling agents.
Pools are an especially practical and aesthetically appealing execution of a co oling system – provided appropriate temperature modes and external air temperature during the operational season. In centralised heat supply conditions, heat production companies choose to install cogeneration engines to increase energy production efficiency and profitability, allowing both electricity and heat to be produced from one type of fuel. However, the world at large has also seen trigeneration systems: such large urban areas as New York and Tokyo have long been using one type of fuel to produce electricity and, adjusting to weather patterns, either heat or cold energy. Of course, these enormous cities and their energy delivery patterns cannot be compared to those of small cities and rural towns which are common in the Baltic and CIS countries. Conversion of heat into cold energy takes place at heat absorption cooling facilities. Heat absorption facilities require a fluid overcooling cycle to store a concentrated fluid. The temperature modes of this cycle (which vary between producers) produce low-potential heat which cannot be reused to produce heat energy, e.g. 35-29*C. To support such a temperature schedule, producers generally recommend installing heat evaporation towers, but they are expensive and will often clash visually with the landscape. A cooling pool may be used instead for both practical and aesthetic reasons, using water sprayers to promote evaporation. Water spraying is necessary to increase the surface area of water-to-air contact: this way, the surface area is equal to the combined areas of all water droplets. The depth of a pool must be no less than 1.5 m, preventing heating by sun rays. Pool cooling properties improve with finer droplet size, although this carries higher electricity expenses to produce adequately high pressure before pulverisation. Such pools may use fountains which serve both as a cooling facility and an attractive landscaping piece. An evaporation pool is also significantly cheaper to build than an evaporation tower, although water loss may be higher.
In consideration of the facts described above, a pool with a water spraying device was built for this research project. With appropriate air temperature, pressure and relative humidity, heat yield and yield changes were measured.
The goal of this study was to compare the research and experimental parts of the project to similar studies performed previously, in order to determine the practical viability of using heat evaporation pools as well as to develop a complete prototype which may be used as the basis for building similar structures.

Keywords: *cooling systems, heat evaporation pools*

1. Introduction

Latvia is located in a climate region where heat is necessary not only for improving quality of life, but also as a prerequisite for survival during the winter, which lasts for about 200 calendar days. Therefore, heat supply is a particularly important part of Latvia's power industry, as evident from the fact that over 60% of the country's energy resource consumption goes into heating. Increasing the efficiency of heat supply, especially centralised heat supply, which provides 30% of the heat required within the country by households and technological facilities (the proportion of centralised heat supply in the housing sector exceeds 45%). Increasing the efficiency of centralised heat supply systems also has a d eciding role in ensuring the competitive ability of heat supply companies, which in turn is a requirement for using the possibilities and advantages of centralised heat supply systems. In the large part of country (one-third of the primary energy consumption) as the raw material for the energy

production (including centralized heating) is used natural gas. It increases the dependence of the energy import and the energy purchase price. There is as a large potential of renewable energy in Latvia, it could be used in energy production, but in many cases necessary investment for communication shift are hardly to attract, that's way there musts be done everything to improve current centralised heat supply, to make maximum benefit for the energy supplier ad it's user.

2.1. Purpose of Introducing a Trigeneration System

One of the solutions for improving the efficiency of the centralised heat supply system might be introducing a trigeneration system in the centralised municipal heat supply system. Traditional producers of electricity produce electricity from fuel, such as fuel oil, diesel or natural gas, however this process is inefficient: it produces waste heat, which may be converted into various types of energy and put to use. At cogeneration facilities, this heat is used to supply nearby household or industrial demand. In case of trigeneration, fuel is used to produce electricity, heat, and, if necessary, convert the heat into cold energy, to be used for household or industrial cooling; additional heat is removed from smoke and gas before they are emitted into the atmosphere, producing additional heat for heating or cooling of spaces. Trigeneration systems in large urban areas as New York and Tokyo have long been using one type of fuel to produce electricity and, adjusting to weather patterns, either heat or cold energy, but it is a great challenge to adjust this system in areas that do not requires such great energy consumption.
Purpose of introducing a trigeneration system:

- Consumption of heat load during the summer period
- Economically advantageous conditions for using the heat source
- Constant loading of the cogeneration facility year-round
- Potential for reducing heat energy tariffs

The centralised heat supply system works according to a specific temperature schedule adapted to changes in external air temperature. The city boiler house works according to such a temperature schedule. The boiler house generally services not only tenement and private houses, but also office spaces, utility consumers and often production facilities interested in heat absorption capacities for their cooling equipment during the summer. There is no need for heating inside the city's residential spaces; the heat supply system works according to a 65-40°C temperature schedule (not Riga). The heat producer considers the issue of profitable heat carrier temperature during summer months – it is well known that with increased heat carrier temperature, heat carrier surface heat loss increases as well (the temperature schedule for trigeneration heat absorption equipment is 95-70°C). Here, one must consider the usefulness of maintaining adequate heat carrier temperature for heat absorption equipment, while at the same time providing the same temperature to tenement houses, which only use hot water. On the other hand, it is useful because cogeneration facilities may be operated at higher loads during the summer period. An assessment of issues related to introducing a trigeneration system must consider the possibility of dividing the heat supply network into primary and secondary circuits. This means that a heat source would produce heat both for delivering hot water to consumers during the summer period and for cooling spaces. The principal layout of a trigeneration system is shown in Figure No. 1. However, the following obstacles complicate the introduction of a trigeneration system:

- Heating network configuration must be adjusted
- A heat supply and temperature schedule must be specified for consumers
- Daily heat consumption patterns must be analysed
- Strategic choice of absorption equipment (centralised, decentralised)
- **Building an evaporation tower**

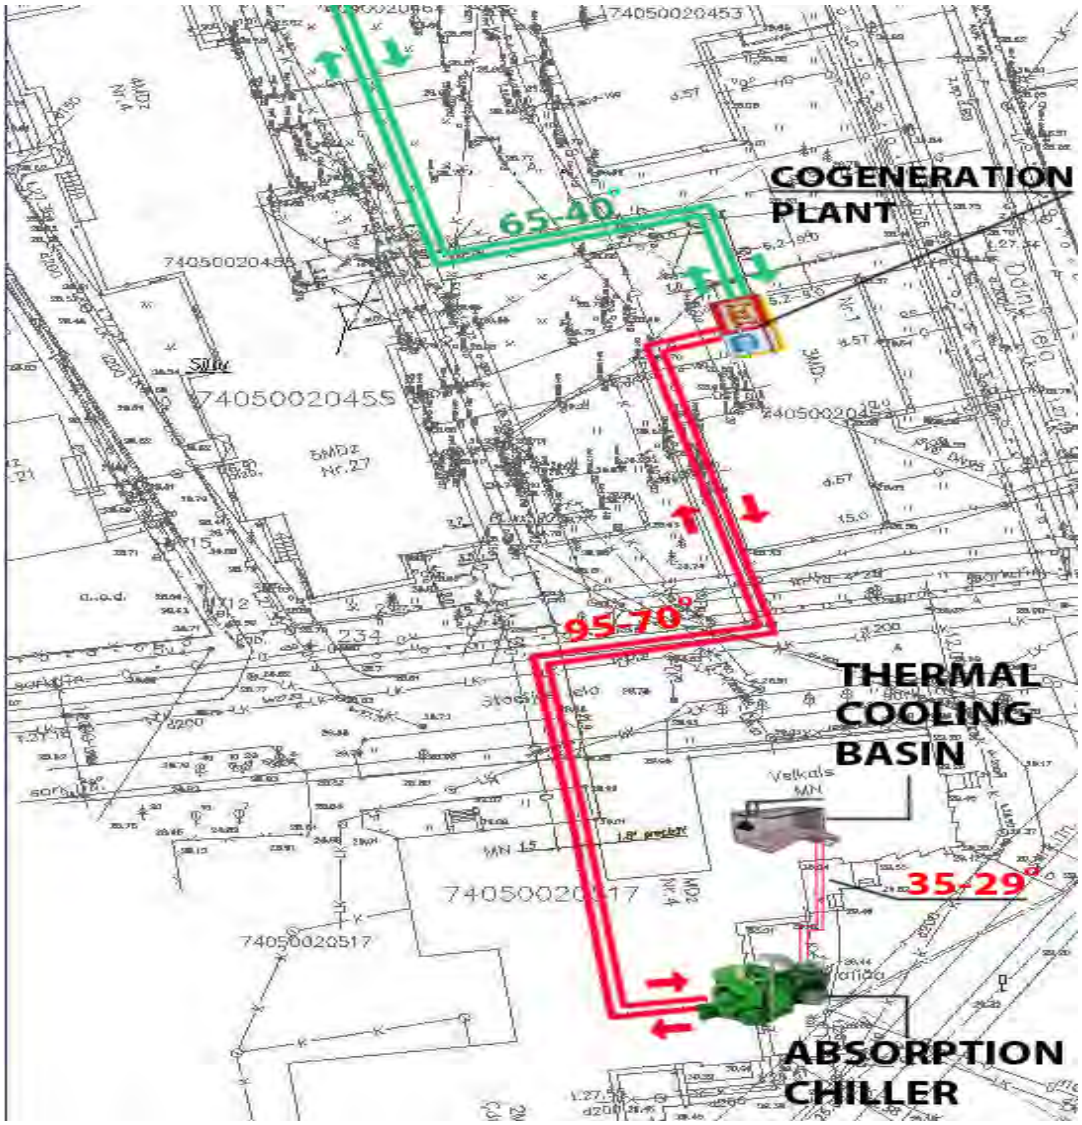

Fig. 1. Principal layout of a trigeneration system

2.2. Heat Evaporation Pools as an Alternative to Cooling Towers

Heat conversion into cold energy takes place at heat absorption chillers. A heat absorption chiller can be seen in Figure No. 2. Two connection points to the cooling tower are shown on the layout, the heat absorption facility may instead be connected to a heat evaporation pool. In order to contain a concentrated fluid, heat absorption facilities require a fluid supercooling cycle. The heat carrier temperatures within this cycle (depending on the manufacturer, this value may vary) are usually low, such as 35-29°C. In order to ensure a temperature schedule for such a cycle, the manufacturer usually recommends building heat evaporation towers, although these are expensive and often clash with the landscape. For practical as well as aesthetic reasons, a heat evaporation pool may be used here, employing water sprinklers to boost cooling efficiency. Water sprinkling is necessary for increasing the area of contact between water and air because the area of contact is equal to the sum of the areas of all airborne droplets of water.

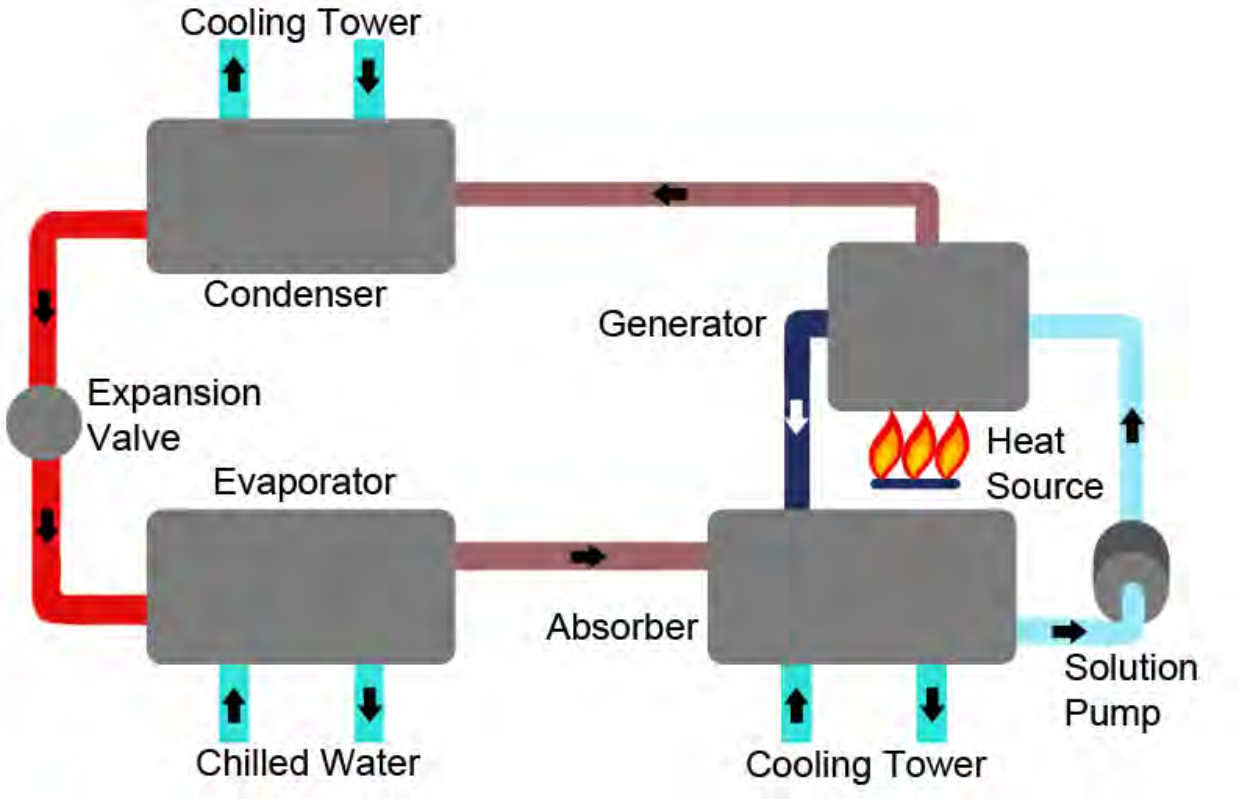

Fig. 2. Heat absorption chiller

The pool may not be shallower than 1.5 m, to prevent heating by solar rays. The cooling properties of the pool will improve with sprinkling of finer droplets, although this leads to higher water losses as well.
A heat evaporation pool (as seen in figure No. 3) may be a heat engineering structure; its advantages include:

- A heat evaporation pool is much cheaper to build than an evaporation tower
- An evaporation pool is a closed system which may therefore be located in public areas
- An evaporation pool is a significantly smaller structure than a tower
- An evaporation pool is more visually appealing and landscape-friendly than an evaporation tower.

2.3. Analysis of Heat Evaporation Pools for Heat Engineering Calculations

The purpose of this research is to perform a study and compare the experimental data to similar studies done previously across the world in order to determine the possibility of practically implementing a heat evaporation pool, as well as to develop a full prototype that would make the basis for building similar structures. In the past sever Russian scientist's worked at this scope, thermal cooling basins where located nearby nuclear and thermal power plants because turbine cooling required heat potential reduction. Those pools where open systems without heater. Water from turbines was supplied directly to the basin and sprinklers. In such a system it's easier to cool because heat potential is usually much higher than the outdoor air temperature (the coolant temperature is considerably higher). Remove maximum heat from the heater and refrigerate with the sprinkler spray in sufficient quantity within the prescribed limits is a challenge in closed – cycle refrigeration. Closed system allows locate

basins in public places because the cooling circuit is protected against pollution.The research stand visualisation is provided in Figure No. 3.

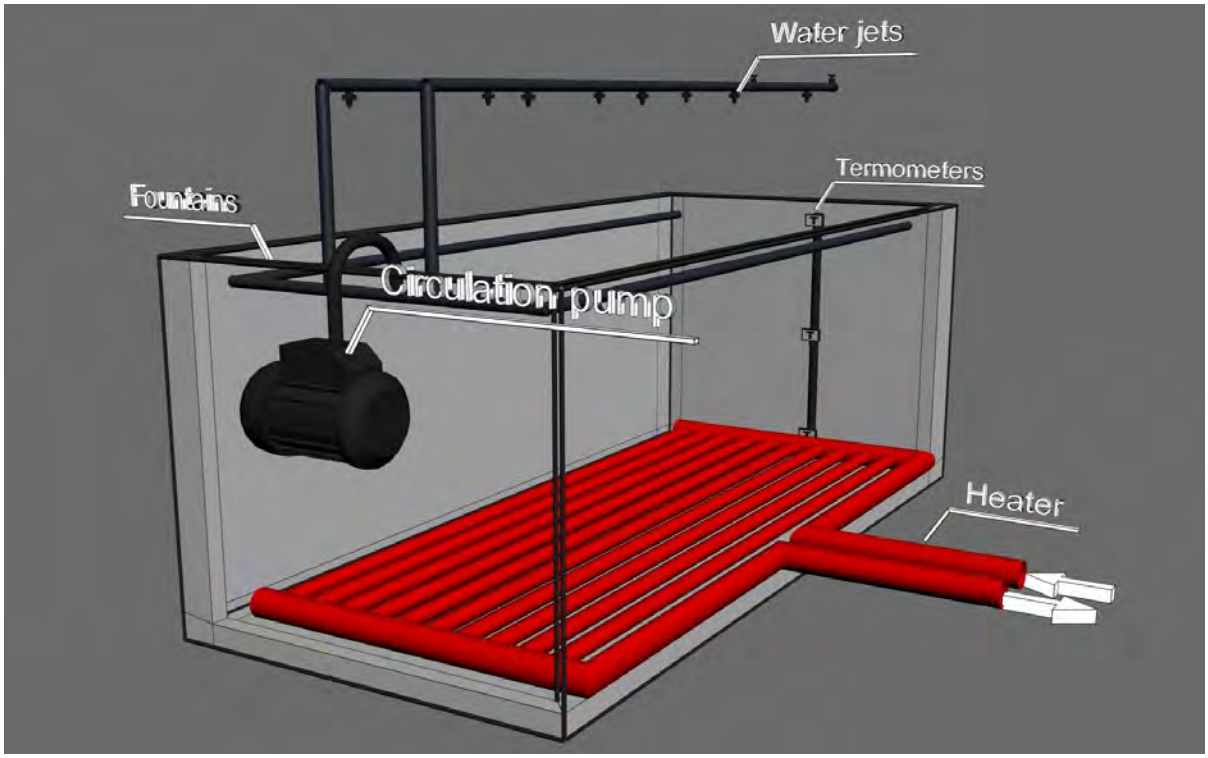

Fig. 3. Visualisation of Heat Evaporation Pool

The heat evaporation pool idea is based on the concept of uniting two systems; a heating element is placed inside the pool and a circulation pump is connected to deliver water inside the pool into sprinklers located above its surface. Compared to an evaporation tower, which is an open system, a pool is a closed system, which means that an evaporation pool may be located in inhabited areas, such as towns, parks, parking spaces etc.

Circulation pump: by adjusting the circulation pump's throughput, the intensity of droplet sprinkling may be adjusted, which will in turn be reflected in the cooling performance of the fluid. It should be considered that the cooling performance of a pool is also affected by a number of outside conditions, such as external air temperature, relative humidity, external wind speed; these parameters must are measured during the experiment, and the parameter value will be applied to the results of the heat engineering calculations. The heat transfer ratio must be adjusted depending on external air parameters. Near the basin is located weather detection station to obtain ear condition data during the experiment, up to now fully equipped experiment has lasted only for days in October 2010, when the outdoor air temperature at the ranged from +7 till +12° C per day. It was clear after comparing the temperature curves that at low outdoor air temperature cooling capacity was directly related the outdoor air temperature fluctuations, it can be seen in Figure No. 4. Graf shoes that basin cooling properties increases when outdoor temperature drops, it cannot be observed literally because of a heat storage. The other parameters made a minor impact on cooling capacity, except wind speed, it increases cooling properties and water loss. There are three thermometers placed in the basin to determine temperature changes in different strata. First is placed 0.3 m above the heater, the second 0.5 m below the air / water contact surface, the third is already over the air and water contact surface. All of these thermometers show the different temperatures.

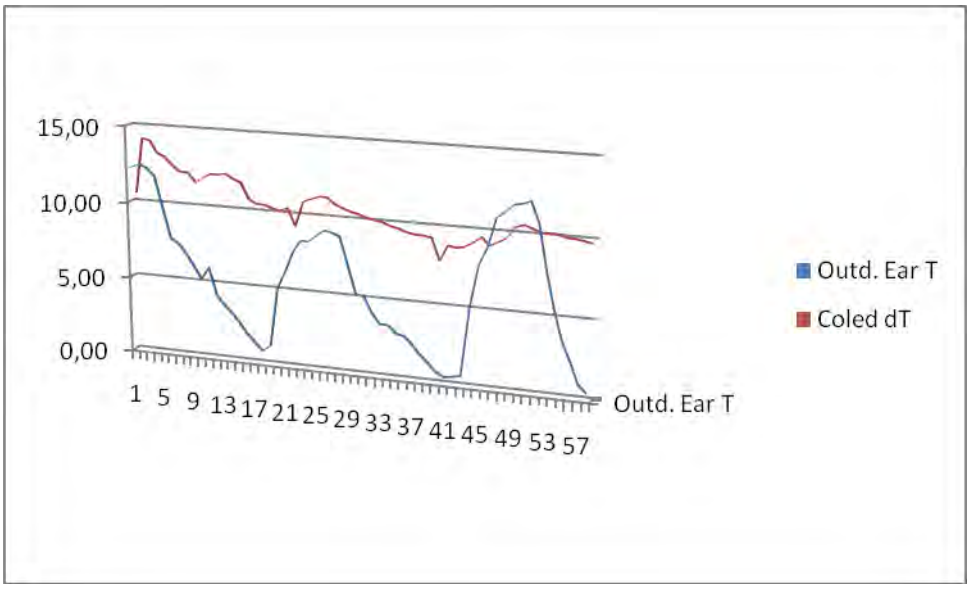

Fig. 4. *Outdoor air temperature impact on the cooling basin properties*

Heating element: a heating element is placed inside the pool, adapting it to the shape and area of the pool – in any case, the configuration of the heating element must be selected so as to create maximum heat carrier resistance and heat loss both as radiation and as hydraulic loss. The pool in question is connected to the boiler room's heat exchanger, which allows adjustment of heat carrier input temperature as well as heat carrier throughput.

The purpose of the heat evaporation pool is to retain the installed cooling parameters regardless of fluctuating external conditions.

Thermal cooling basin exploration for thermal calculations:

- Basin size $S = 11\text{m}^2$;
- Basin volume $v = 22\text{m}^3$;
- Basin temperature Schedule 35° – 29°C;
- Basin heat input $Q = 3.20\ \text{m}^3/\text{h}$;
- Circulation pump yield $Q = 8\ \text{m}^3/\text{h}$;
- Heat transition coefficient K kJ/m^2;
- Spray jet yield V m^3/s;
- Spray jet diameter $F = 0{,}001$m;
- Relative water weight $\alpha_p = 1\text{kg/m}^3$;
- Yield coefficient η - (0,6 – 0,75)
- Nozzle pressure drop $\Delta P = 0{,}00032$ kg/m^2
- Gravitational force $g = 9{,}8$ m/s^2;
- Pressure supply in lines 3,2 atm, 324240Pa;
- Relative air pressure P_g, Pa;
- Outdoor air temperature T_a, °C;
- Air relative moisture d, %;
- Wind speed v, m/s;

Water loss, depending on the outdoor temperature, coefficient k values shown in Table 1.

$$\Delta = k \cdot \Delta T, \% \qquad (1.)$$

Table 1. Coefficient k value depends on air temperature [2]

Air temperature, °C	0°	10°	20°	30°	35°
Coefficient *k*	0,10	0,12	0,14	0,16	0,17

Guided thermal basin volume:

$Q_{heat}=M\cdot C\cdot(T1 - T2)$; [3] (2.)

$Q_{heat}=22.34$ kW/h ;

Heat transition coefficient:

$K = Q/S \cdot \Delta T$; [3] (3.)

K= 0,33kW/m^2;

Sprayed water volume, changes depending on weather conditions:

$V = \eta \cdot F \cdot \sqrt{(2g)} \cdot \Delta P / \alpha_p$; [1] (4.)

$V = 1.5\cdot10^{-6}$ m^3/s;

3. Conclusions

Experimented will be repeated and basins cooling properties measured according with whether when the cooling is necessary – in summer.

Graf shoes there is minor influence on the basins cooling properties by wind speed, there must be assurance that fluctuating is insubstantial in suitable weather conditions.

Water jets and fountains musts be located to exclude terrorism danger.

There is a slight difference between the first and second thermometer readings, but significant deferent's with third thermometer readings because its located above ear and water contact area, but the deferent's between first and second thermometer is called by location, first thermometer located 0.3m above the heater and readings are 0.2-0.5°C higher, but when the heater is shut down readings shift and the second thermometer shoes 0.1-0.2°C higher temperature, this indicates heat flow change and basin heats from the outdoor ear and sunlight when the heater switched on basins heat potential is higher and heat flow changes.

The sprinkling intensity is determined and the heat transfer ratio is adjusted depending on external air parameter fluctuations in order to keep the Δ T value above the installed minimum.

The influence of external air parameters on Δ T changes must be determined during the study.

The most profitable sprinkling intensity must be determined considering the results.

Water volume has properties for heat accumulation, that's why after water jets are shouted down basins retains its cooling properties, for a while.

There musts be investigation before adapt thermal cooling basin to certain system, basins cooling properties changes depending on weather conditions.

Thermal cooling basin could be combined with equipment with absorption and compression cycles, solar collectors, PV and PVT solar cells.

Experiment will be continued and the results will be published.

Abstract: A new tool is presented in this article. The main objective is the improvement of the small and medium companies' energy management systems in order to obtain energy savings and the adaptation of the organizations according to the recognized standard UNE-*EN* 16001:2010. The application of the tool lets companies reduce their energy consumption and improve their processes in an energy efficiency perspective. The methodology is based in questionnaires and tests which will report information in order to identify all standard requirements. In a near future, the expected benefits are going to be a knowledge about the companies' EMS situation, information to prioritize actions to improve, identification of critical areas, comparison between different EMS evaluation results (for example: company' EMS with industry average, etc.), improve companies knowledge about energy, energy efficiency, etc.

Keywords: *Energy, Management, System, software, companies.*

Nomenclature

EMS Energy Management System
SME: Small and medium enterprise
IAT: Instituto Andaluz de Tecnología (Andalusia Institute of Technology: company name).

1. Introduction

In the last few years, society, governments and companies have changed their philosophy in order to protect and preserve the environment. Nowadays, instead of being watched as an economical consumption, this philosophy has become in a competitive factor.

At the same time, laws have included topics related to environment which gives an answer to the general interest.

The purpose of this paper is to introduce a tool (named EVALENER) that offers companies the possibility of evaluating the management system focused on energy efficiency according to the recognized standard UNE-EN 16001:2010 "Energy Management System – Requirements with guidance for use´" (Spanish version of EN 16001:2009).

UNE-EN 16001:2010 [1] standard just became an European standard, so not many other evaluating software has been developed to help companies and no relevant result have been set. Even more so for SMEs. In Spain only few companies has got its EMS certified and most of them are big organizations.

The use of this tool will let companies reach both environmental and business benefits. Regarding environmental benefits the following goals could be achieved: CO2 emissions, global warming and climate change impact and exterior energetic dependence could be reduced. According to business benefits, companies will obtain financial savings (energy bills reduction), achieve legal requirements, social responsibility and corporate image improvement.

Another important aspect is the fact that the tool is focused to be applied in small and medium enterprises (SMEs) since they do not have as much economical resources as big companies have. So the tool's main objective is helping SMEs to achieve an effective EMS carrying out their own evaluations and measuring the impact of the development improvements in the organizations.

2. Methodology

EVALENER has been based in recognized standard UNE-*EN 16001:2010 'Energy Management Systems - Requirements with guidance for use'* that provided a model of excellent energy management to the organization to compare their energy management system with the model one.

The methodology for developing EVALENER has been the same following for the Instituto Andaluz de Tecnología (www.iat.es) to develop other evaluating tools that exist in its organization. IAT has wanted to provide companies (emphasized in small and medium companies) with a set of tools to evaluate different aspects into the organization with the same aspect and the same operation. The results are shown in the same way as well to help companies understand the results.

The methodology for developing the tool in order to evaluate the Energy Management System (EMS in advance) has been the following:

1.- A questionnaire has been developed to cover all standard requirements.

This questionnaire has several questions for each UNE-EN 16001 aspect. Each question is accompanied for evidences examples to help the evaluator to find into his/her organization what they are doing to compliance the aspect asked.

2.- Question weighting has been developed to reach a value for each standard requirement.

The evaluator will have to mark each question between 1 and 5 to show the maturity level as shown in Table 1.

Table 1:Marking of every Maturity level and sub-level for standard aspects

Maturity Level	Marking (Maturity sub level)		
	Basic	High	Advanced
1	1	1,4	1,7
2	2	2,4	2,7
3	3	3,4	3,7
4	4	4,4	4,7
5	5	5	5

To choose the value in this table 1, the evaluator will use first Table 2

Table 2:Maturity Level of every standard aspect

Maturity level	Approach	Performance	Improvement
1	It isn't very sound	It isn't done systematically and not always as planning.	It is done just to repair problems
2	It is sound and it is based in a recognized standard, model, etc.	It is done systematically and not always as planning.	Non conformities are detected in order to plan and to star improvement actions
3	It support the management policy and established targets	It is done regularly and in many relevant areas	Improvement actions are set to avoid future problems. Effectiveness of these actions is measured
4	It consider the influence of all management areas and relevant stakeholders.	It is done in nearly all relevant areas	Results are analyzed and compared with company targets in order to get information to improve activities, process, etc.
5	It is done considered internal and external data	It is done in all relevant areas to guarantee good results for all stakeholders	Best practices and comparison with other companies results are taken into account to set up improvement plans.

This table may be used to set the Maturity Level: The user will mark approach, performance and improvement levels (one mark in each columns). Maturity base level will be given by the lower value.

To find the maturity sub-level (Table 1) the following criteria are considered:

- Basic: the 3 marks in the array have the same level.
- High: one of the mark (approach, performance or improvement) is above the basic level.
- Advanced: 2 of the 3 marks are above the basic level.

By using both tables above, it can be obtained a value between 1 and 5 for each question. In an example both tables will be used as follows:

Set the maturity level: user will mark with a cross the maturity level of approach, performance and improvement (each column in Table 2). The maturity level will be the lower of these three values.

Table3:E.g. of setting Maturity level.

Maturity level	Approach	Performance	Improvement
1			
2		**X**	**X**
3	**X**		
4			
5			

Maturity level will be 2 in this example

Set the maturity sub-level: In the above example: sub-level is "high", therefore this question points with a value of 2,4 (Fig.1) using Table 1 to set it.

Maturity Level	Marking (Maturity sub level)		
	Basic	High	Advanced
1	1	1,4	1,7
2	2	2,4	2,7
3	3	3,4	3,7
4	4	4,4	4,7
5	5	5	5

Fig.1. Example of setting the question value

Thus, for each question the user get a value between 1 and 5.

3.- Some tests have been passed to the tool in order to identify errors and to check the smooth running of it.

4.- The tool has been validated in 15 real cases to assure it provides companies key focus areas and the possibility to compare its EMS evolution throughout the time.

EMS EVALUATION

User, during the evaluation, will answer several questions within each part of the standard. The screen layout of the tool for each question is the following (Fig. 2):

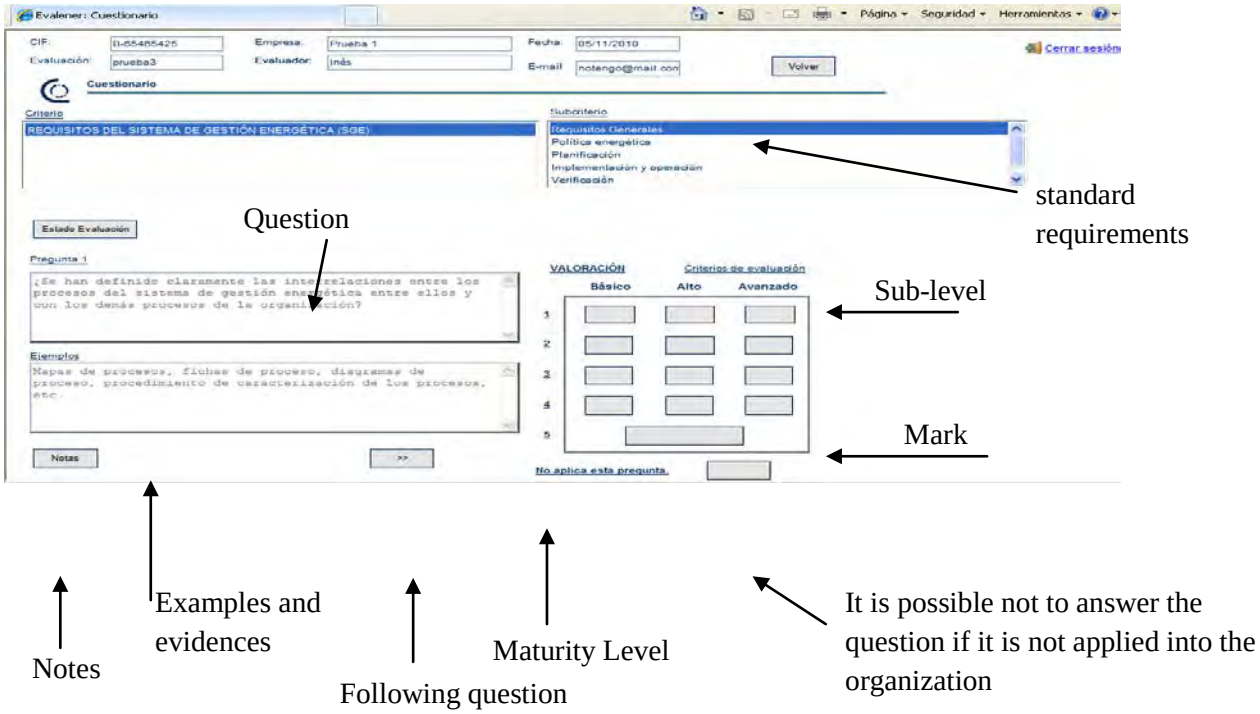

Fig.2. Screen layout of EVALENER

Furthermore, the user could highlight strengths and improvement areas by clicking the Notes button (Fig. 2), which will help detecting during the global analysis the most important areas to be improved. All this information will be shown in a report named “evaluator's notebook” (Fig. 3)

Fig.3. Example of Evaluator’s Notebook report

At the end of the evaluation, EVALENER offers a report with the obtained scores and the evolution from previous evaluations (if exist) as shown in Fig. 4.

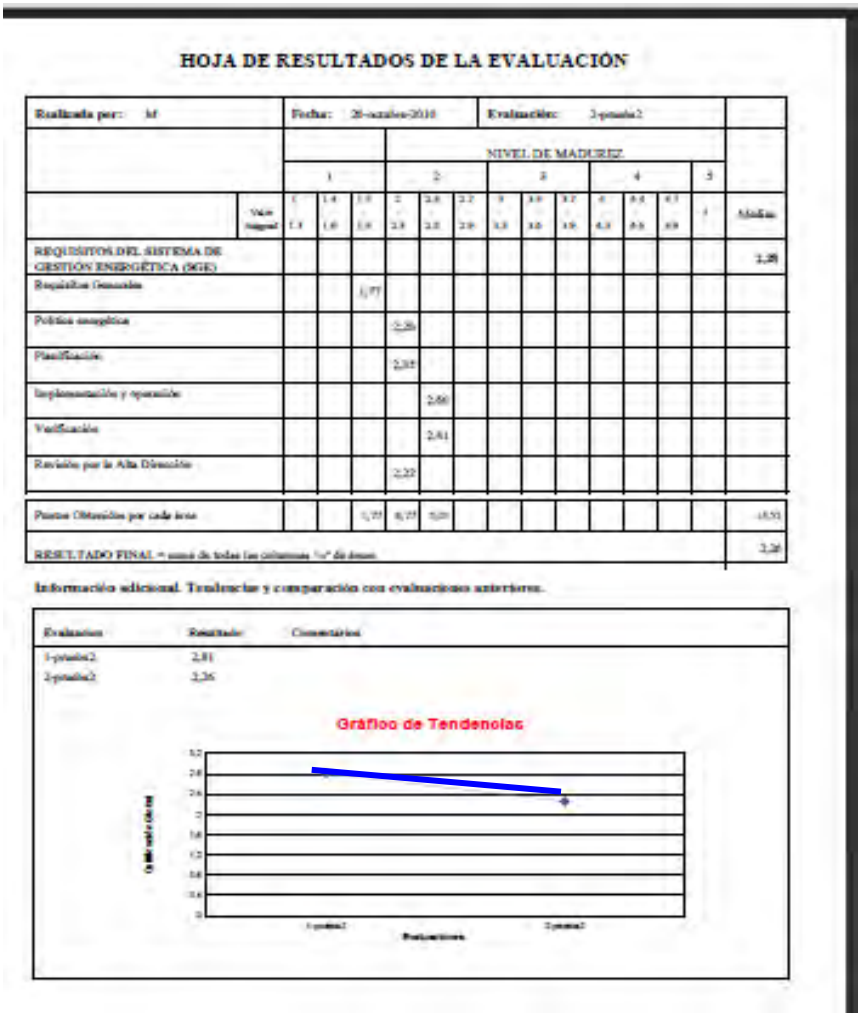

Fig.4. Example of Evaluation Report

3. Results

Companies that took part in this project were SMEs. Some of them have set their own environment management systems (according ISO 14001) but some others don't. None of them have got EMS, although some would consider its use in a future.

A varied set of companies participated during the tool's validation process, companies like a pharmacy, manufactures, or a health care company.

Those companies that have decided to become certified according to UNE-EN 16001:2010 standard want to show customers that these companies are consistent with their business (for example engineering and/or architecting firms that works with energy efficiencies) and others to get more points going to qualify for government public tenders.

Those which are using an environment management system have achieved better scores and found easier during the evaluation understanding the question and evidences compared to those companies that don't use any environment management system. The companies that don't use it even found hard to understand concepts like operational control and significant energetic aspects, besides they achieved low scores in the auto evaluation.

All of the participants used the experience to think about their use of energy, considering new metrics and, the most important, improvement areas in the aspects that they could afford given the current economical circumstances (change machines to other that consume less energy, change to LED technology, used better enclosures, changes in human behavior…)

4. Conclusions

SMEs in Andalusia are currently passing through an economical delicate moment, as in the rest of Spain but increased by a weakest regional and local industry.

In this scenario, an efficient energy management is a must in order of reducing costs and looking after the environment, taking part of the European compromises for reducing the greenhouse effect, consumption, etc.

The main obstacle for these SMEs is the access to information related with energy management, contracting experts to help with it or even economically afford some of the improvement options available in the market.

Because of the mentioned reasons, this tool tries to help small companies that cannot make use of any EMS because of a lack of resources. The software has been organized following the standard requirements with the purpose of helping companies approach to the standard and it has been adopted the question-evidences formula to ease its understanding.

The option of evaluator's notebook makes considerably easy bringing up improvement areas after finishing auto-evaluation as well as highlighting the strengths of the company.

Beside of evaluator's notebook, EVALENER offers the chance to de companies to compare evaluations and see the EMS evolution. This information will be useful to know how efficient were the improvement actions undertaken by the company and will help with the continuous improvement of the organization.

In any case, the system has to be improved because it has been revealed as not very flexible (it doesn't allow weighting each question or section) and not very intuitive in the use of both tables (Tables 1 and 2). The way of looking for the score for every question (Table 2) requires using an auxiliary paper sheet as it is not automated in the software, and makes it hard until further practice had been acquired. For this reason, this functionality should be improved in a second version of the tool (now developing by IAT and to be integrated with other evaluation tools that have been developed by IAT).

The software could be enhanced by adding help tags and screens to let the evaluator a better understanding of each question or standard aspect.

Despite all, the goal of approaching EMS to SMEs and letting them, in an affordable way, analyze and reflect on their way of use of energy and consider actions for improvement has been achieved.

The main advantage of this methodology is the used of a questionnaire to analyze that companies done about their EMS and to be able to get a goal easily to compare different situations (with other companies, with the own company after to carry out improvement actions, etc.). That is easy to use for SMEs and not require a lot of knowledge or experience.

"Uncovering Industrial Symbiosis in Sweden" -exploring a possible approach

Sofia Persson [1,*], Jenny Ivner[1]

Linköping University, Linköping, Sweden
** Corresponding author: Sofia Persson. Tel: +46 13285613, Fax: +46 13149403, E-mail: sofia.persson@liu.se*

Abstract: Industrial Ecology (IE) is a relatively new field that is based on the ideology of nature. IE uses nature as a "reference" to study resource productivity and environmental burdens of industrial and consumer products and their production and consumption systems.

Industrial Symbiosis (IS) is a subset of Industrial Ecology with a particular focus on cyclical flows of resources through networks of businesses. One definition is that IS "engages traditionally separate businesses in a collective approach to competitive advantage involving physical exchange of materials, energy, water and/or byproducts. "The keys to IS are collaboration and the synergistic possibilities offered by geographic proximity" [1].

This paper presents a methodology that aims at developing a method for uncovering IS in the Swedish energy sector. The method is exemplified by district heating and consists of data collection of the occurring resource and energy flows to and from district heating plants in three different Swedish regions. The results show that the method presented in this article can be used in future and more comprehensive "uncovering" studies. The material from a broader, nationwide study is expected to make it possible to develop tools to facilitate the conditions for IS to be developed.

Keywords: *Industrial Symbiosis, Methodology, Uncovering*

1. Introduction

Industrial symbiosis (IS) has been defined as "engaging traditionally separate industries in a collective approach to competitive advantage involving physical exchange of materials, energy, water, and by-products"[1]. IS emerge as a self-organizing business strategy among firms that are willing to cooperate to improve their economic and environmental performance [2]. According to Chertow [1] "The keys to IS are collaboration and the synergistic possibilities offered by geographic proximity". Businesses that are collocated can, in accordance to IS, reach environmental benefits and competitive advantages by physical exchange of resources with each other or with residential areas [3]. In Sweden, the occurring identified cases of IS show fruitful collaboration and integration from the companies´ point of view as well as increased environmental performance [4, 5]. However, there is a gap of knowledge when it comes to an overview of the occurring IS in Sweden. It is currently not known how common these kinds of mutual exchanges and collaborations are.

In the United States Chertow [6] conducted an uncovering study that investigated IS in a broader perspective. In Sweden there have previously been single case studies of IS. Therefore there is both a knowledge gap about the occurrence of IS in Sweden and also when it comes to methodologies to systematically gather data in order to analyze whether IS occur or not.

1.1. Aim and research questions

This article presents a method for uncovering Industrial Symbiosis and how this method can be applied to the Swedish energy sector. The method is exemplified by district heating. The

aim is to illustrate and explain a method used to conduct an uncovering study of IS in Sweden and to discuss how the method can be used to create more in-depth knowledge about IS in Sweden when it comes to the extent of collaboration and mutual exchanges. The discussions are based on a pre-study where the method is tested on three Swedish regions.

2. Background

Efforts to understand and replicate Industrial Symbiosis in the form of inter-firm resource sharing like what was largely self-organizing in Kalundborg, Denmark have since 1989 followed many paths. The success has varied, some of the efforts have been very successful and some have not [6]. Chertow [6] describes the year of 1989 as "an inspirational year for industry and environment". The main reason behind the success is described as two key events following the Bruntland Commission report in 1987. The first was a seminal article in Scientific American illustrating "industrial ecosystems" in which "the consumption of energy and materials is optimized and the effluents of one process serve as the raw material for another process." The article was written by Frosch and Gallopoulos [7]. That same year the Industrial Symbiosis in Kalundborg was discovered as a concrete realization of the theory described by Frosch and Gallopoulos [7]. The cluster of intensively resource sharing companies from different industries in Kalundborg, Denmark was uncovered unexpectedly [6].

Previous research shows many, both public and private, benefits of IS as a result of "spontaneously co-location" of different businesses in industrial areas. Duranaton and Puga [8] describe these benefits as labor availability, access to capital, technological innovation and infrastructure efficiency. Key rationales for advancing IS projects as a way of trying to recreate the same types of collaboration and mutual exchanges include economic development, remediation of pollution associated with heavy industry, water and land savings, and greenhouse gas reductions [9]. Another reason for collaboration around energy savings and greenhouse gas reduction is the construction of shared visions and goal, which also makes projects less vulnerable [10].

Examples from previous research from Sweden and the Swedish forest industry show that there are several occurring cases of IS and that the conditions for implementing IS varies [5]. Also, these studies indicate that IS can have advantages both from an economic and environmental perspective [4]. Mapping these existing cases of symbiotic activity makes it possible to use the knowledge in the IS field to study and develop the partnerships further.

3. Method

As mentioned above, this article presents an approach to uncover industrial symbiosis in Sweden. The overall approach to these uncovering activities is data collection from several sources to obtain triangulation of data for each found case. This is an approach that strengthens the validity and to facilitate deeper analyses [11].

Yin [11] recommends four methods of analysis: Explanation–Building, Pattern–Matching, Time–Series Analysis and Program Logic Models. For this type of study, with large amounts of data, it is of great importance to have a fully functional database. In this case the database is designed to show the different flows that occur, as well as between which actors the flows occur. This gives a good overview and understanding of the situation within the studied regions.

Explanation–Building can mean two things: according to Yin [11] it primarily means building an explanatory narrative, which shows the causal relationship, it also can be about creating a coherent and credible overall picture of a phenomenon [12].

Pattern-Matching means that patterns that can be observed are compared to patterns that have been predicted or known from other cases. To analyse the cooperation and mutual exchanges between the studied district heating plants and related, nearby industries and companies within a specific cluster, comparison with previously known cases of similar character as an ideal type is a form of Pattern-Matching.

In the next step the various actors involved in the symbiosis cluster is studied deeper to understand the sequence in which the development of the cooperation and exchanges develop. Time–Series Analysis means clarifying the order in which events or actions occur, with what intensity they vary over time or how far they are in time.

As a last step the Program Logic Models is used to analyse the assumptions about the connections. In this case, the previous knowledge will enhance the understanding and of the elementary conditions for IS.

4. Methodology

To be able to map ongoing cases of IS empirical data about occurring collaboration and mutual exchanges needed to be collected. In order to test if the chosen approach to uncover IS is appropriate a diversity of empirical material is needed. Therefore three geographically diverse regions with different types of industrial conditions were selected for this study; one region with dominating forest industry, one with a dominating agricultural sector, and one with a diverse industrial sector including food industry, manufacturing as well as pulp and paper industry.

Investigating every single industry in these regions was not feasible for this pre-study, therefore district heating industry was chosen as the main actor to start empirical research from. The motive to choose district heating plants in order to uncover IS was that district heating occur in more or less all Swedish municipalities. In addition, activities from the business of district heating generate large flows of material and energy which are important prerequisites for IS.

The first step in process is to collect data of the occurring resource and energy flows to and from the different district heating plants within the three different regions. All of the district heating plants are also studied more in detail, one plant at a time, based on information from websites and additional interviews. All interviews were conducted via telephone and in semi-structured format, which means that the same question guide was used for all interviews, but the interviewer had the opportunity to ask supplementary questions. This type of interview is recommended since it helps structuring the interview [13]. However, this interview method also allows new and unforeseen issues to arise during the interview and hence is an effective tool for gathering information that is difficult to obtain otherwise [14].This method is expected to provide data that will show which of the studied district heating plants who has some kind of collaboration or mutual exchanges with other nearby business or industries.

To be able to identify and classify occurring cases of IS there is a need of a consequent definition with clear criterions. This study will use the same criterions as the previous study

"Uncovering Industrial Symbioses" made by Chertow [6]. Chertow defines the minimum criterion of IS as "3–2 heuristic". This means that at least three different entities must be involved in exchanging at least two different resources. An example of a 3–2 heuristic relationship within this study is industry 1 providing industry 2 with a flow of resource and industry 2, in turn, provides industry 3 with another flow of resource, figure 1.

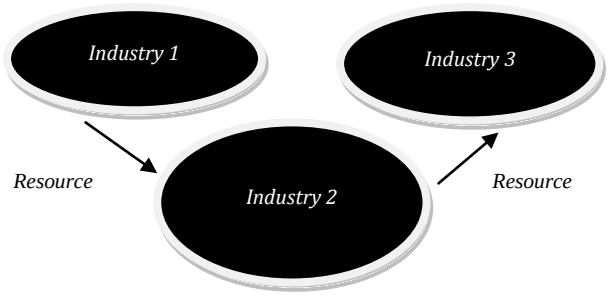

Figure 1. Example of a "3-2 heuristic" relationship. Inspired by Chertow [6].

4.1. Structuring the empirical data

The results from this study are stored in a database designed to address the collected data and to demonstrate the flows of different resources that occur between the actors involved in the detected clusters of symbiotic activity. The structure of the database is built on a model that makes it possible to link "plants" with different "flows" of resources in several steps. The database is also designed to be able to store specific information about the different flows of resources as well as the different plants involved. The information of the plants regards what type of plant it is, the size of the plant, the occurring ownership and the location of the plant. When it comes to the flows, the additional information regards what type of resource it is and of what amount, origin- and destination pant and if the specific resource is used as resource in the industrial process or functions as a utility, see figure 2. It is also possible to specify whether the resource originates as a main product (on which production the industry is based) or a byproduct (waste) from the industry. This information about each resource flow opens up for analyses about for example which kinds of exchanges are more common in relation to different kinds of plants. Martin [15] mean, for instance that by-product synergies are the most abundant type of synergies and that utility synergies in the form of shared use of energy and utilities are not as common.

The implementation of the data is done by two different formulas created in the database. The first formula manages data for each "plant" and the second formula manages data for each "flow" of a specific resource. The formulas are based on the tables within the database where the data is stored and they are created to facilitate the implementation of the collected data. Figure 2 shows the model and how the different data are related.

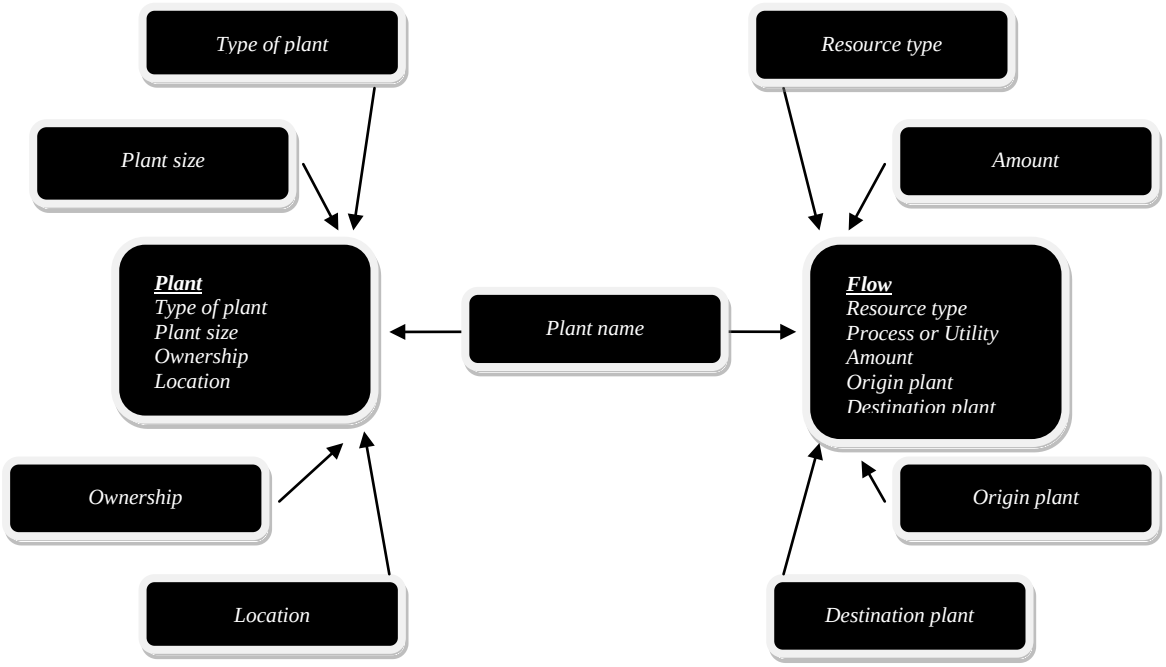

Figure 2. A model of an extract from the database demonstrating how the different data in the database are related.

5. Expected results

The collected data from the three different regions indicate that there is occurring cases of IS within these regions. The most common forms of collaboration is in the form of "3-2 heuristic" relationships, especially in the smaller municipalities. In some of the larger medium size municipalities, where the conditions of collaborations are better, the results show more complex ongoing cases of IS. One example is a forest industry and energy plant co-location, Figure 3. In this (fictional) case it is possible to define five different flows: wood, wood chips, sawdust, process steam and nutrients (ashes). Forestry, the sawmill and the district heating plants all pose as both origin and destination plants, depending on which resource flow is described. It is also possible to define both main products and by-products: wood is a main product from forest industry and ashes are by-products from incineration plants. Furthermore there are resources that pose as both process input and utilities to the destinations plants: sawdust goes into the main process at the main pellet producer and process stem is used as a utility. It is however too soon to draw general conclusions about the data material.

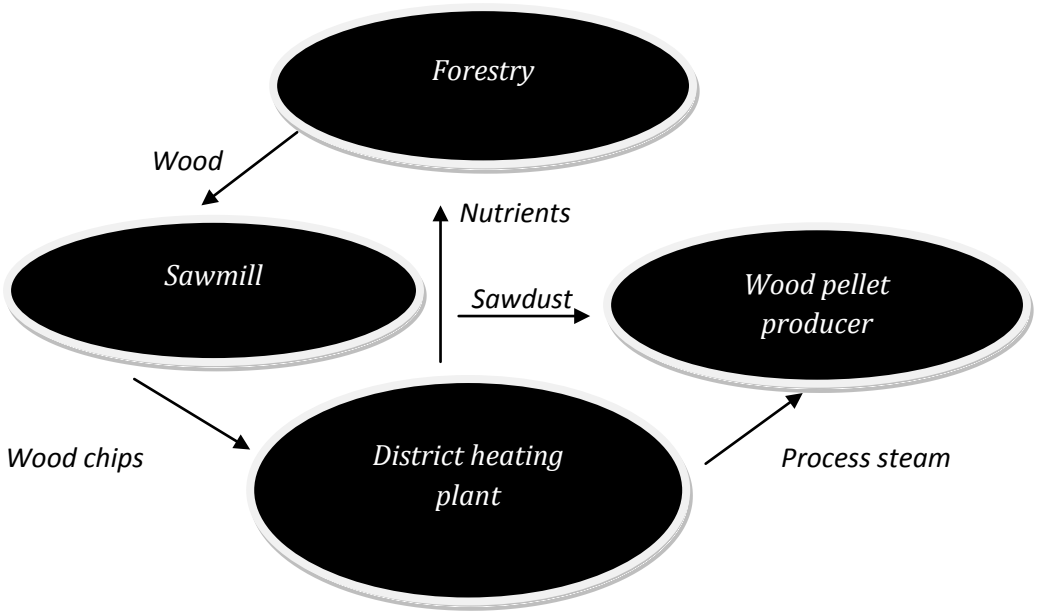

Figure 3. Example of resource flows that can be mapped in the described approach to uncovering industrial symbiosis.

The four methods of analysis described in the methods section can be used to analyze the collected data. This way of arranging the data creates a coherent and credible overall picture of the flows connecting the plants. When mapping the relationships between resource flows and plants is made for a whole region, it will be possible to analyze patterns of occurring collaborations. Thereafter observed patters can be compared to previous research but also to other regions or businesses. In this sense this will function in accordance to the Pattern-Matching as described by Yin [11]. As a continuation of the analysis, Time-Series Analysis can be used to clarify the order in which the different steps in the Symbiotic process occur, to understand the sequence in which the development of the cooperation an exchanges develop. This kind of analysis would however need additional empirical data.

When a deeper understanding of the development of discovered symbiotic activity has been created, it may be used to develop proposals on measures to improve the conditions and the facilitation of the implementation of IS in the future analogous to Yin's [11]the Program Logic Models.

6. Concluding discussion

This article has presented a method for uncovering Industrial Symbiosis and how it can be applied to the Swedish energy sector. Experiences so far have shown that the method for collecting data an organizing them in a database functions well. This method is probably suitable for uncovering IS, however it may be too demanding if it comes to cover large areas, for example the whole of Sweden. A broader, nation wide, study like that with more and broader data would probably need a less personnel intense method than semi-structured interviews with all actors. It is therefore a need to further develop the methods for uncovering industrial symbiosis to be able to expand the studies.

According to Chertow [6] the "Uncovering" of existing kernels of symbiotic exchanges has led to more sustainable development and designing of eco industrial parks. Knowledge about the occurring and ongoing cases of IS in Sweden is expected to provide the basis for more in-

depth knowledge of how these collaborations and mutual exchange evolved and what the important elements for them to arise and function are. Therefore it would be of great interest to develop the methods for uncovering industrial symbiosis in Sweden. This would help to create more in-depth knowledge about IS in Sweden when it comes to the extent of collaboration and mutual exchanges and subsequently the prerequisites for such collaboration. Such knowledge in turn can contribute to develop more efficient, environmentally adapted and prosperous business.

Abstract: Industry is one of the major users of fossils fuels resulting in emissions of GHG (Green House Gases), leading to global climate change. One means of promoting energy efficiency in industry is energy management. The aim of this paper is to outline a number of energy management related factors which affects energy management in industry positively. The paper is a result of collaboration between industry professionals and researchers within an ongoing research project and addresses the issue using a bottom-up energy management perspective. Results indicate that that the "soft" issues of energy management play a crucial role in the success (or not) of energy management in industry, e.g. the manager's role and attitude towards the employees cannot be understated. Instead it addresses that implementation is not only about technology but equally or even more important, concerns the diffusion and adoption of energy management practices and principals.

Keywords: *Industrial energy management, Organizational change, Industrial energy efficiency*

1. Introduction

Research indicates that global climate change resulting from the use of fossil fuels is one of the major challenges for future decision makers worldwide. Industry is one of the major users of fossils fuels resulting in emissions of GHG (Green House Gases), leading to global climate change. EU and other regions are now working proactively to reduce GHG emissions resulting from use of energy. One example is the 20-20-20-targets within the EU which in relation to energy means that each EU Member States should reduce the use of energy with 20% by reducing energy intensity with 3.3 % annually from 2005 to 2020. Industrial energy efficiency is one of the most efficient means of reducing GHG [1]. However, a number of barriers to energy efficiency exist in industry which inhibits adoption of energy efficient technologies and energy conservation [2-4]. One means of promoting energy efficiency in industry overcoming a number of barriers to energy efficiency is energy management [5-6]. Even though the potential is vast, research in the area is scarce [7]. One reason for this is its interdisciplinary character calling for interdisciplinary methods such as collaboration between researchers and industry professionals. The aim of this paper is to outline a number of energy management related factors which affects energy management in industry positively. The paper is a result of collaboration between industry professionals and researchers within an ongoing research project within Swedish industry and addresses the issue of promoting energy efficiency using a bottom-up energy management perspective. This paper is unique in the sense that is leaves the realm of focusing solely on energy efficient technologies when studying industrial energy efficiency.

2. Methodology

Previously, research has focused on energy management practices using questionnaires and in-depth interviews, e.g. [5] and [7]. In this study, the scope is to try to take the research on energy management in industry a leap further. Moving beyond questionnaire and in-depth interviews, an attempt is made to incorporate the manager's own ideas and concepts, not merely study an array of factors (using a questionnaire) or respondents' views and opinions (using interviews) on various themes or topics. As the applied method is narrowed down to

fewer respondents, it naturally may be more difficult to generalize results from this type of research, see Fig 1. A previous literature review on energy management [7], shows that this research, so far is lacking in the academic literature, as well as clear results on how to apply successful energy management practices. We therefore conclude that this type of methodological approach is needed.

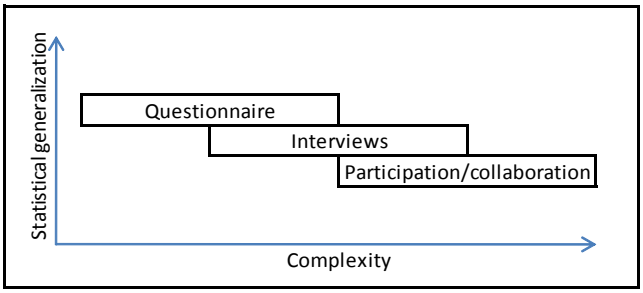

Fig. 1: Differences between participation/collaboration and interviews and questionnaires (Inspired by [8].

According to [8], systems may be categorized depending on degree of complexity. [8] state nine levels and write that research concerning social interaction, i.e. interaction between two individuals is the most complex system to study. He moreover criticizes management research for not moving beyond the lower system levels. In response to [8]'s critique on management research, we aim to move beyond the more common methodological approaches using questionnaires and interviews applying participation/collaboration. Naturally, this limits the ability to generalize results, compared with questionnaires and interviews, as these methods cover several respondents. On the contrary, participation/collaboration methodology enables research to move into the more complex levels of (energy) management. This paper has applied a participation/collaboration methodology where the researchers have collected the manager's ideas and philosophies of successful energy management practices, based on more than 20 years of experience in the field. In doing so, it is evident that this relies on relatively a few cases, and naturally faces an increased risk of being biased, compared with questionnaires and interviews. When analyzing results from this paper, it is therefore important to keep in mind the statement by [5] *"there is no one size fits all"* when it comes to energy management.

3. Results - driving forces for successful energy management practices

In the following section, a number of important factor for successful organizational change related to energy management practices are presented. The stated factors come from the participation/collaboration approach, i.e. a bottom-up energy manager's perspective, a perspective which is derived from the truck manufacturer Scania's more than 20 years of successful energy management practices.

3.1. Culture

An organization has its own culture which is created by a number of factors, such as individuals own values [4]. Culture is an important factor when striving to change an organization, as culture governs the behavior of the individuals of the group, and it is their behavior that creates the organization's results. If any major changes are to take place within the organization, the behavior among the individuals has to change. In the long run, this will change the organizational culture, a change which is needed, if the individuals within the organization are to maintain their changed behavior.

3.2. Will

The second factor of importance is that normally, people want to change things they are not satisfied with, while maintain that which one is satisfied with. The will to change is thus dependent on how dissatisfied a person is, and also how risk averse a person is. The importance for those who lead the change is to perceive that the challenge lies in that person's want the change to take place in their own way.

3.3. Acceptance and recognition

The third factor of importance is that people in general wants attention and positive recognition from personal achievements, from other persons. Many people can go a long way to receive recognition and acceptance. It can range anywhere from fame and compensation in the form of money for the effort one has made, to encouragement and a "thank you" for a good result that the person has accomplished. The former can never replace the encouragement from a manager, thanking the employee for good work. This holds in particular if the manager is also the informal leader, i.e. someone the employees look up to.

In general, people go to their work with a goal to be part of it as they wants to do a good job. If not, this creates discomfort, discouragement and frustration that often take the expression in unwillingness to cooperate, or an unwillingness to change situations at work. Paradoxically, people tend to do exactly the opposite of what it takes to get what one really wants. What this behavior gives in return is attention and an opportunity to be seen in the absence of recognition. Reasons why such an individual have lost sight can be, e.g. lack of attention, challenge or admission from those who are managers. It may also be due to an inadequate role and mission in the group the individual belong to. One may call this a deficiency in the organization caused by poor leadership.

The above three factors, culture, will and acceptance and recognition interact between each other and create the conditions one have in an organization, department and group. It is these challenges that the leader has to work with in order to achieve the expected results.

3.4. Establishing change within an organization

When a manager is leading a change in the organization, he or she can choose one of two main roads or paths. The difference between these two paths can be described by the following: To get from location A to B can be done in two principally different ways. The first option is to run in the sand at the water's edge. Although the road is long, it goes relatively quickly. The tracks in the sand are washed away rapidly and soon, no one else can, by the help of the first person's achievement, manage the very same way. Instead, each one has to take its own way to position B. The load to be moved from A to B depends on the individual's capacity and external conditions and circumstances. In summary, the first path is that of individuality, a path which does not help or support the persons that later wants to take the same path.

The second option is to build a road. It will take much more time, demands much more resources and effort, but when it is finished, there are clearly more people being able to travel from position A to position B. Moreover, people can get more loads with them on the road. The modes of transport can also be developed so that more cargo than was previously possible to carry can be included in each trip. The time to carry out the shipment may eventually be reduced. The load to be moved from A to B is through a road much less dependent on the individual's capacity and external conditions. In summary, the second path is that of the

standardization and continuous improvement, a path which help and support the persons that later wants to take the same path.

Road number one may be stated as to govern by results. This is a road which with the right leadership often creates positive results relatively quickly, but the lasting result is often not maintained. The way to influence behavior is by getting members of the group to do what they request. As the manager does not require how results are achieved, solutions often rely upon individual solutions, i.e. the employees own way. Moreover, duplication of these individual solutions is generally not possible. This, in turn, leads to the fact that structural capital is not being built up within the organization, department or group. The culture is affected only to a limited extent and the impact it does create takes time. There is great risks that if the leader loses focus, or change job, the good results will not last.

Road number two is to use what we define as method governing. This is about influencing the behavior by using good methods and approaches. The modified behavior provides better results both in the economic sense, but also regarding the conditions to do a good job of maintaining or improving quality and work environment. The positive change one gains may be linked to the group and the positive spiral which then creates the opportunity to influence the culture of the group. As method governing focuses on how the work is done, conditions for working with continuous improvement are established.

Things which can be improved are the methods, routines and instructions. These are always the same; everyone in the group performs the operations in a similar way and can contribute to the improvement of the method. This will benefit both the individual and the group, even if the work and the physical and psychological conditions of the work are continuously changing. Method governing thus, and unlike the first road, builds structure capital, and with the right leadership, in the long run, an improvement in the culture of the group is achieved. This also reduces the risk of a manager changing job. However, and this must not be understated, bad leadership will always be able to bring down an organization, independent on which road that is taken.

3.5. Successful organizational change

Fig. 2. displays how an organization may successfully be transitioned by the second road, method governing. If one choose to work after the second road, there are some fundamental principles that should be followed, e.g. focus on the organization's value stream and continuous improvements. These are presented in the coming sections.

3.6. Basis – the organization's value stream

Start from the company's product's value stream and the company's services and do not view energy management as a means which creates value by itself. All work which is done in the organization (be it external or internal) must be valued based on the product's value stream. This provides the ability to sort and evaluate, not based on function, but on value. What is waste and what is value? Waste can also be divided into that which is necessary but not value-adding and that which is simply waste. What is value adding is often of no reason to attack first. It only involves the risk of new losses.

That which is necessary but not value adding should be minimized. That which is solely waste must be eliminated as quickly and smoothly as possible. It usually does not cost so much, it is often achieved relatively quickly, and the risk is often low.

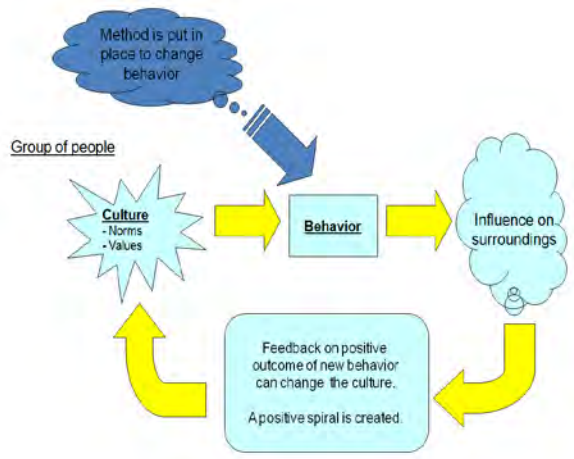

Fig. 2. Example of how an organization may be transitioned successfully based on method governing.

If the organization is a manufacturing company, it is important to understand how the production technologies, maintenance and energy management work is related. Increasing process efficiency is an effective way to reduce energy use for the product. To have a system perspective is necessary when improvements are carried out.

Moreover, aiming to achieve stable systems is of great importance. If for example, the shutdown of a machine or a process, leads to problems when the machine or process is being started, i.e. it may not work properly after shutting it down, employees may be unwilling to shutdown equipment. The root cause to this is not a system which is impossible to change, but rather an unstable system.

The eight types of waste which are relevant also in terms of industrial energy efficiency are: overproduction, unnecessary operations, transportation, discards, waiting, unnecessary movement, storage, and unused skills. Working to minimize and eliminate these both in the organization's value stream, but also in regard to the organizations energy use.

3.7. Basis – continuous improvements

The basis for long-term success is to work according to the principles of continuous improvement. This means that the leader must create an improvement culture within the group/company. The engine in the process of improvement is improvement groups and a systematic work with deviation.

To create an organization in which the principles of continuous improvement are used, and create a continuous improvement cycle, will not be made without effort. It demands leadership in order to be formed, kept active, and further developed. Fig. 3. visualize the above presented approach.

Work with improvement in small steps is of great importance, and one should aim to use all the tools for continuous improvement at disposal, such as deviation control. In order to be able to improve a system, one must be able to describe what the normal state or level is. If one does not know what the normal level is, improvements are not likely to take place. What is described and perceived as normal in the organization is what one can expect. When the outcome deviates from the expected normal state, the organization receives a signal that something has gone wrong. Detecing deviations may be achieved from, e.g. deviation management methods, the use of standards and routines etc. When a deviation from the

normal state has been detected, the system can be improved in small steps, which in turn slowly increase the normal state level.

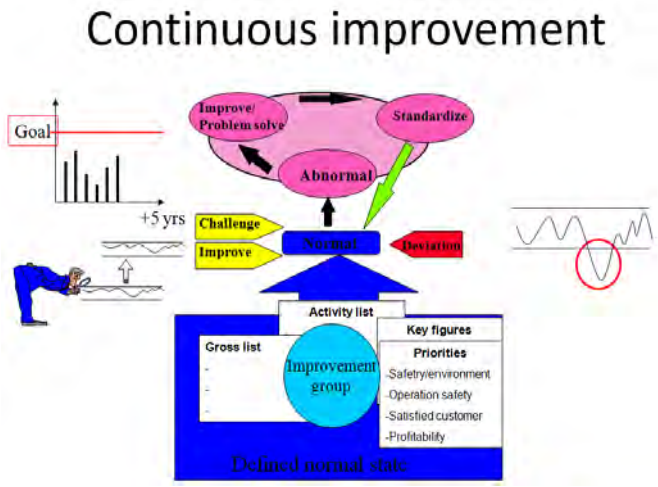

Fig. 3: Principles for continuous improvement in regard to energy efficiency.

Identify where the organization stand in terms of the performance it delivers. All phases have different needs for improvement. Improve from the defined normal state, do it with small steps but take steps often. Fig. 4. visualize the above presented approach.

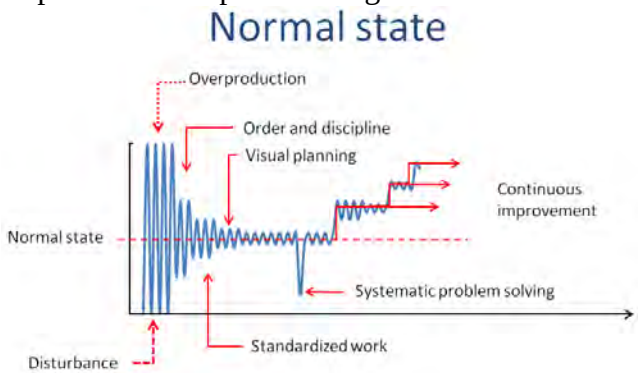

Fig. 4: Principles of defining and working with continuous improvement based on a normal state.

Ending improvement is as important as initiating them. Aim to try to find effective methods to evaluate when an improvement is "effective enough". Describe the new normal mode, implement it, and move on to the next improvement that gives the best effect on the overall efficiency.

Moreover, one should put focus on the flow (creating smooth flows, governed by demand, be sure to reduce the variance). Also, do not forget the work- and information flow. Otherwise, adequate conditions for improvements will not be established. Furthermore, one should focus on quality and time, and make sure to keep the correct delivery parameters, i.e. avoid variation and overproduction. Make sure to deliver on time and let demand govern as much as possible. By describing what is normal, delivery can be assessed, and the root cause for the deviation can be corrected.

Some general issues related to successful energy management practices are similar, no matter which one of the two main roads one chooses for implementing change. These are presented in the coming sections.

3.8. The role of leadership

The role of leadership is independent of which main road one chooses to take. Leaders must lead through visions and overall goals. The larger the group/organization is, the more important it becomes. One of the reasons that this is so universal is that it provides space for the group and its members to use their individual creativity to solve the tasks. It uses the collective expertise of the group. However, it requires that the leader, e.g.:

- Is willing to join and show how tasks must be carried out (if required). Moreover, the leader has to be so knowledgeable that he or she, if needed, can act as a role model. Notably, this does not mean that the leader should do all the work for the employees.
- Serve as the creator of contacts, not as problem solver.
- Work with the monitoring of agreed activities and targets. Send feedback and let the person who made the job receive recognition for the accomplishment. Focus on those in the group who have the ability to influence.
- Work with action plans developed by those who must do the job. Do not let the action plans run over a too long period of time. Half a year may often be a good time horizon. Make sure to keep activity plans short and prioritize what is most important. Working with gross list and make decisions on new items on the list if space is available. Follow up about this on a regular basis, e.g twice a month: provide support, feedback and encouragement when the data is completed. Be sure that the agreements on completion dates are kept. Measure and visualize the number of items completed on time. If events are "slipping", find the root cause to this. In principal, this is a leadership issue. However, it may also be due to that the employee does not fit for the specific assignment or lacks time. In general, it is not due to unwillingness from the employee.
- Create conditions for a rapid feedback of the key indicators chosen to measure. Use them to guide and evaluate the work. The feedback often needs to be done weekly or whether it is possible, in real time.
- Try to create a positive atmosphere where “anything is possible”. A positive spiral. It is therefore important to ensure that "easy victories", particularly early in the process, are achieved.
- When one set goals and prioritize activities always base this on the organization’s value stream flow. It is the value stream which should be improved and not primarily single processes. It is only from the basis of the organization’s value flow, ones effort can be measured correctly. Working with energy in general may not provide much value, but rather to be effective in reducing waste.
- Put effort into understanding the system links. There is always a larger improvement potential in a system than in a single component or process. Let the need control demand.
- Develops a strategy for how the plant should be operated in the long run. Do this in terms of the desired operational strategy, and the desired technology strategy, and how the desired system strategy should look like. When done, one can be flexible, and make changes when available opportunities occur in the business. Streamlining systems and components are not so costly when a major change is to be made but may be very costly if done as an operational acticity, e.g. lead to production disruptions.

4. Conclusion

This paper addresses that increasing industrial energy efficiency is not only about technology, but equally important concerns the diffusion and adoption of energy management practices. In particular, the three factors, *culture*, *will* and *acceptance and recognition* interact between each other and create the conditions one has in an organization, department and group. It is these challenges that the leader has to work with to achieve the expected results. Moreover, results may be achieved in principally two different ways, where method governing is the way advocated for in this paper as it builds structural capital in the organization. If one choose to work with method governing, there are some fundamental principles that should be followed, e.g. focus on the organization's value stream, normal situation, standardization and continuous improvements. It is also of importance to define the system's normal state. From that position, improvements may be carried out in small steps. If a manager follows these basic recommendations outlined in this paper, and allows employees to understand and see the connections, improved results are achieved in the long run. Energy management practices using these principals may lead to employees showing improvements far above what the manager or organization thought was possible.

The applied methodology was shown to contribute with increased knowledge on how energy management practices successfully can be carried. Further research in the field using the applied methodology is suggested.

In conclusion, a fully successful in-house management program is dependent on both sound leadership and adoption of sounds methods. If either one is lacking, the full embodied (energy efficiency) potential in the organization is not released.

Comparison of repowering by STIG combined cycle and full repowering based on exergy and exergoeconomic analysis

Mohammad Baghestani[1], Masoud Ziabasharhagh [1*], Mohammad Hasan Khoshgoftar Manesh[1]

[1]Mechanical Engineering Faculty K.N.Toosi University of Technology, Tehran, Iran
** Corresponding author. Tel: +982184063255, E-mail: mzia@kntu.ac.ir*

Abstract: Nowadays, repowering is considered as the most common methods for improving status of current power plants. Repowering is the transformation of an existing steam power plant into a combined cycle system by adding one or more gas turbines and heat recovery capacity. It is a cost-effective way to improve performance and extended unit lifetime while adding capacity, reducing emissions and lowering heat rejection and water usage per kW generated. Each methods of repowering from "para repowering" to "full repowering" shall probably be the best choice for special national and economical power plant. In this paper different repowering methods have been introduced. The design concept consists in adding a gas turbine to the combined cycle, integrated by steam injection into the existing gas turbine. The steam is produced in a simplified heat recovery steam generator fed by the additional turbine's exhaust gas.
A 156MW steam cycle power plant has been chosen as a case study. Two repowering scenarios have been utilized for this case. Thermodynamics code has been supplied for combined cycle and STIG combined cycle and compare with each others. The exergy and exergoeconomic analysis method was applied in order to evaluate the proposed repowered plant. Also, computer code has been developed for exergy and exergoeconomic analysis. It is anticipated that the results provide insights useful to designers into the relations between the thermodynamic losses and capital costs, it also helps to demonstrate the merits of second law analysis over the more conventional first law analysis techniques.The efficiency of the STIG repowered plant compares favourably with repowered combined cycle.

1. Introduction

The country of Iran is experiencing in all fronts and areas and thus, consumption of electrical power is on the increase on a daily basis. Based on the ever increasing electrical energy consumption, changes in generating system load requirements, lower allowable plant emissions and changes in fuel availability, steam power plants repowering has been investigated much more as a method for energy conservation. Considering the increased electrical energy consumption and annual growth rate of 4.5 percent and according to the end of existing steam power plants life in Iran(like Montazer Ghaem power plant), repowering could be used as an economical method for increasing the output power with less investment than building a new power plant. Repowering of steam power plant can be achieved in several ways. In a full repowering, several gas turbines (GT) and heat recovery steam generators (HRSG) are installed in a parallel arrangement dispensing with the conventional boiler. Live steam from HRSG is used in the original steam turbine [1]. Industrial gas turbines are one of the well established technologies for power generation. Various additional cycle configurations such as reheating, regeneration, intercooling and steam injection have been

suggested [2, 3]. All of them offer increased performance and increased output compared to a dry gas turbine cycle. Several types of water or steam injection gas turbine cycle (STIG) have been proposed in previous studies and the performance characteristics of them investigated [4]. The exhaust gas from the turbine is used as an energy source in a heat recovery steam generator (HRSG) where energy is transferred from the exhaust gases to the boiler feed water. The high pressure steam is generated from HRSG. The steam is then injected into the combustor. Injection of steam increases the mass flow rate through the expander and so the power output and the efficiency of the turbine increase. Steam injection also helps in reducing the NOx emissions from the gas turbine [5]. Exergy analysis usually predicts the thermodynamic performance of an energy system and the efficiency of the system components by accurately quantifying the entropy-generation of the components [6]. Furthermore, exergoeconomic analysis estimates the unit cost of products such as electricity, steam and quantifies monetary loss due to irreversibility. Also, this analysis provides a tool for the optimum design and operation of complex thermal systems [7]. Combined and steam injected gas turbine cycle power plants are being installed all over the world as compared to other plants. The current emphasis is on increasing the plant efficiency and specific work while minimizing the cost of power production per kW and emission. In this paper, simple repowered combined cycle and combined cycle with added steam injected gas turbine have been modeled as a repowering design for 156MW steam power plant. For each cases exergy and exergoeconomic analysis has been studied and compared as a economical analysis for product cost estimation.

2. Process description

In this paper, 156MW steam cycle power plant has been selected as a case study for exploring two repowering methods and comparing with each other. The steam cycle power plant encompasses three turbines, that work with three different pressures and 6 feed water heaters. The Steam cycle has been modeled by MATLAB code and STEAM PRO (THERMOFLOW). Results of modeling steam cycle have been introduced and compared with real data in table.1.

Table1. Compare result of modeling steam cycle

	THERMOFLOW	Simulation code	Real
Plant Gross power(kW)	156300	156305	156294
Plant Gross Heat Rate(kJ/kWh)	9010	9120	8976
Plant Gross Efficiency (LHV)	39.9%	39.4%	40.1%
Superheater Capacity(kg/s)	133	130	136
Reheater Capacity(kg/s)	115	114	117

3. Repowering

There are several alternatives to combine and integrate a gas turbine into an existing steam power plant. As a result of ending boiler life time and exploring another aspect for this case, the best alternative is full repowering. Full repowering is defined as complete replacement of the original boiler with a combination of one or more gas turbines (GT) and heat-recovery steam generators (HRSG), and is widely used with very old plants with boilers at the end of their lifetime. It is considered as one of the simplest ways of repowering for existing plant.
For this power plant, Full Repowering with SGT5-4000F (formerly known as CC 2.V94.3A) with triple pressure reheat cycle has been considered as a first method for repowering old steam cycle power plant. Schematic flow diagram of combined cycle with the components is shown in Fig. 1. The gas cycle is selected as a topping cycle.

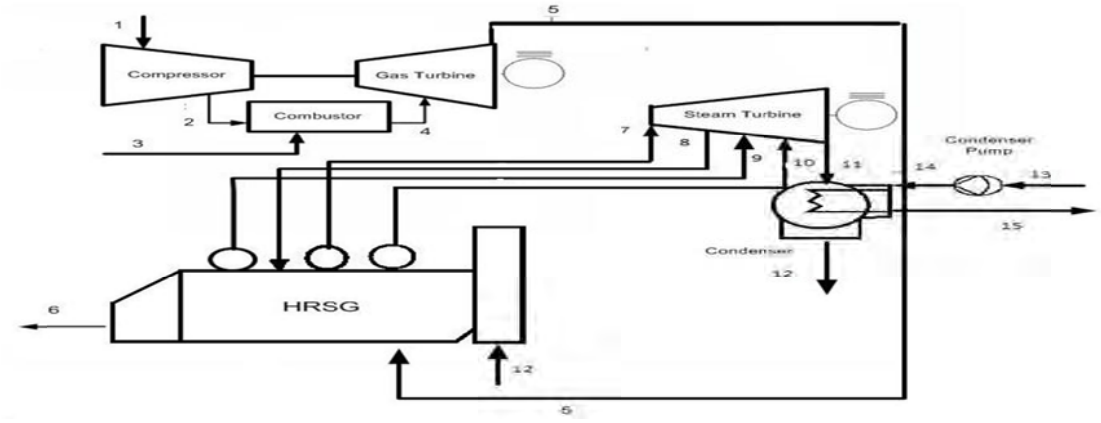

Fig 1. Combined cycle power plant (Repowering 1)

Second repowering scheme is based on the addition of a gas turbine and of a HRSG to a baseline of combined cycle. This method includes two main parts, the first part is combined cycle and the second part is a small gas turbine with a single pressure HRSG. These new components are integrated within the existing plant by injecting the steam produced by the additional HRSG into the existing gas turbine. The second part generates needed steam for injecting into main gas turbine of combined cycle in addition of producing extra power. In this way, the original turbine is transformed into a STIG (steam injected gas turbine), thereby increasing power. CC power augmentation is, thus, the sum of the power generated by the new gas turbine and the additional power of the original plant, comprising both the gas turbine and steam cycle. This scheme figure is shown in Fig.2.

As can be seen, the steam line feeding the original gas turbine connects the plant to the added section that comprises a gas turbine and a heat recovery steam generator. However, many other subsystems may be shared to reduce the repowering cost such as, for examples, flue gas treatment, electric power conditioning etc. One major addition to the plant is the water flow entering the new HRSG, which is inevitably lost at the stack. This can be a major drawback in certain situations and limits the applicability of the present scheme to sites with large fresh water availability, though the specific water requirements are fairly low, as will be shown later. If a low temperature thermal load is available nearby the power plant, the steam in the exhaust could eventually be condensed and the water could be recovered. Obviously, the very large size and the very low temperature level of such a heat sink restrict this option to quite uncommon cases, and its feasibility has to be carefully evaluated. Another significant feature of the proposed repowering scheme is its operational flexibility. Because of the inherent flexibility of the gas turbine, the entire additional section can be switched off in a short time, yielding part load efficiency equal to that of the original plant. At full load, the efficiency does not differ substantially, as will be demonstrated by the thermodynamic simulation. Fitting both the new and original gas turbines with variable intake guide vanes (IGVs) should provide a fairly wide operating range with efficiency close to rated.

4. Exergoeconomics analyses

All costs due to owning and operating a plant depend on the type of financing, the required capital, the expected life of a component, and so on. The annualized (levelized) cost method of Moran [9] was used to estimate the capital cost of system components in this study. The amortization cost for a particular plant component may be written as:

$$PW = C_i - S_n PWF(i,n) \quad (1)$$

$$\dot{C}(\$ / year) = PW \times CRF(i,n) \quad (2)$$

The present worth of the component is converted to annualized cost by using the capital recovery factor CRF (*i*,*n*), i.e [7]. Dividing the levelized cost by 8000 annual operating hours, We obtain the following capital cost for the *k*th component of the plant.

$$Z_k = \Phi_k \dot{C}_k / (3600 \times 8000) \quad (3)$$

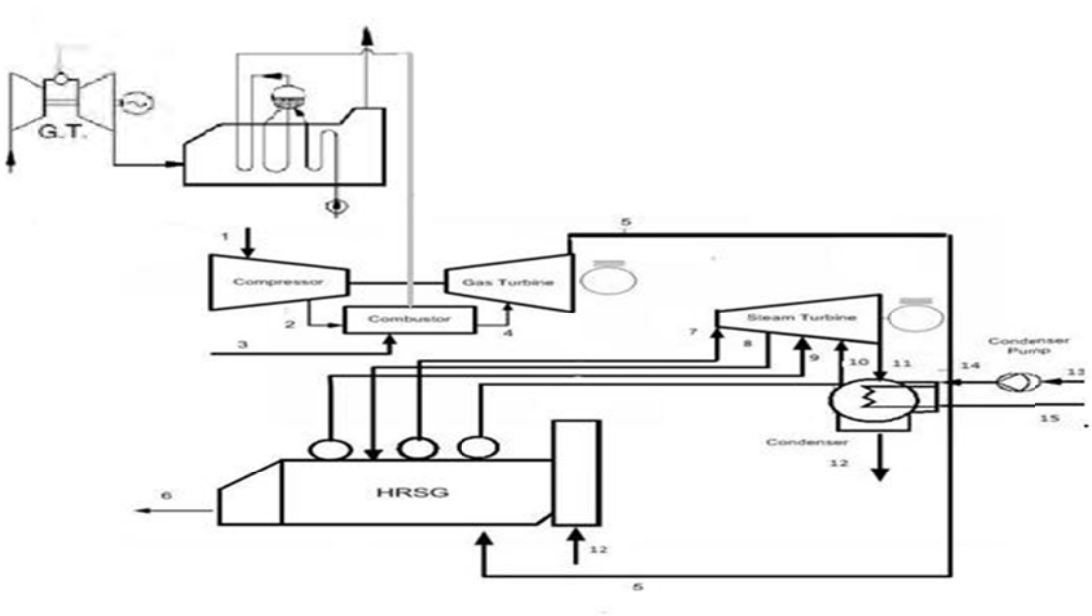

Fig 2. Combined cycle with STIG power plant (repowering2)

The maintenance cost is taken into consideration through the factor $\Phi_k = 1.06$ for each plant component whose expected life is assumed to be 15 years [9].

4.1. Thermoeconomic Modeling

The results from an exergy analysis constitute a unique base for exergoeconomics, an exergy-aided cost reduction method. A general exergy-balance equation, applicable to any component of a thermal system may be formulated by utilizing the first and second law of thermodynamics [10].

The cost balance expresses that the cost rate associated with the product of the system (C_P), the cost rates equals the total rate of expenditure made to generate the product, namely the fuel cost rate (C_F), the cost rates associated with capital investment (Z^{CI}), operating and maintenance (Z^{OM}) [12].

In a conventional economic analysis, a cost balance is usually formulated for the overall system (subscript tot) operating at steady state [12]:

$$C_{P,tot} = C_{F,tot} + Z_{tot} \quad (4)$$

Accordingly, for a component receiving a heat transfer and generating power, we would write [4]:

$$\sum_e \dot{C}_{e,k} + \dot{C}_{w,k} = \dot{C}_{q,k} - \sum_i \dot{C}_{i,k} + Z_k \quad (5)$$

To solve for the unknown variables, it is necessary to develop a system of equations applying Eq. (6) to each component, and it some cases we need to apply some additional equations, to fit the number of unknown variables with the number of equations [11].

A general exergy-balance equation, able to any component of a thermal system may be formulated by utilizing the first and second law of thermodynamics. In a conventional economic analysis a cost balance is usually formulated for the overall system operating at steady state. To derive the cost balance equation for each component, we assigned a unit cost to the principal product for each component. Depending on the type of fuel consumed in the production process different unit cost of product should be assigned [11].

5. Result and discussion

In this paper full repowering method for 156MW steam power plant has been applied. Table 1 indicates specification of repowered plant. It shows that, 68% of total power is produced by gas turbine cycle with 39% efficiency, in addition remained power are produced by steam cycle with 34% overall efficiency.

Repowered cycle produces 250MW more than old power plant. Heat rate in repowering power plant is 6500(KJ/KWh) and 1500(KJ/KWh) more than old power plant. Efficiency increases 15% for repowering model more than old power plant.

Table 2- combined cycle results

	Repowering
Gas Turbine(kW)	278041
Steam Turbine(kW)	125655
Plant Total (kW)	403695
Plant net LHV efficiency (%)	55.27
Plant net LHV heat rate(kJ/kWh)	6514
Gas turbine LHV efficiency (%)	39.05
Steam turbine efficiency (%)	34.59

Second proposed method uses STIG and adds a small gas turbine with single pressure HRSG. Result of this method with three model of gas turbine for producing steam injected, is shown in Table 2. For each three gas turbine model efficiency and exergy efficiency has been calculated. These results show that, increasing amount of injected steam mass flow can improve efficiency, but obviously only a limited amount of steam can be injected into the original gas turbine. This method can improve efficiency also increasing net power. In second stage, exergy and exergeoconimcs analyses are studied for both repowering method as an economical analyses. Table 3 and 4 show Exergy destruction and cost fuel and product rates of exergy with and without considering capital investment for each component in both repowered power plants.

Table 3- combined STIG cycle results

	V64.3A	V84.2	V84.3
Injected steam mass flow (kg/s)	26.2	49.2	53.2
added gas turbine power (MW)	68.7	108.2	138.2
Gas turbine power (MW)	306.1	330	334.5
Steam turbine power (MW)	123.8	140.2	142.1
Added gas turbine efficiency (%)	37.2	33.7	35.9
Gas turbine efficiency (%)	48.8	52.6	53.3
Steam turbine efficiency (%)	32.8	36.6	36.5
Net power (MW)	498.7	578.8	615
Efficiency (%)	61.2	60.32	60.8
Exergy efficiency (%)	59.6	58.6	59.1

Table 4-Exergy destruction and cost fuel and product rates of exergy with and without considering capital investment for each component in combined cycle

Component	Exergy Destruction(MW)	CF0 ($/MW)	CP0 ($/MW)	CD0 ($.s)	CF ($/MW)	CP ($/MW)	CD ($/s)
COMP	46.2489	0.0061	0.0073	0.2821	0.0064	0.0078	0.2959
COMB	152.5663	0.0049	0.0059	0.7475	0.0051	0.0061	0.7780
GT	17.0101	0.0059	0.0061	0.1003	0.0061	0.0064	0.1037
ST	36.2881	0.0083	0.0092	0.3011	0.0089	0.0101	0.3229
HRSG	38.6824	0.0063	0.0073	0.2436	0.0065	0.0078	0.2514
COND	4.8385	0.0083	0.2376	0.0401	0.0083	0.2603	0.0401
FWP	0.0236	0.0064	0.0113	0.0001	0.0064	0.0177	0.0001
CWP	0.6226	0.0064	0.0006	0.0039	0.0064	0.0007	0.0039

These results represented that combustion chamber and heat recovery steam generator in repowered combined cycle has most exergy and exergy cost destruction due to nature of combustion; however combustor in combined cycle plant shares about 51% TED, 44% TCD0 and 43% TCD. In next steps, compressor and steam generator have most exergy and exergy cost destruction.

Comparison of cost fuel and product of turbine for both schemes is shown in table 5. Gas turbine produce major of net power therefore cost product of gas turbine has important role in whole cost product. Gas turbine cost product for STIG combined cycle is less than ordinary combined cycle. However Cp of HPST in STIG cycle is more than ordinary combined cycle, HPST power is not as much important as other power product utility such as GT, LPST and IPST. Rate of total cost exergy destruction is specified in table 6.As shown, second repowering method can decrease TCD and TCD0 and therefore this scheme is more economical. Although exergy destruction increases in this method, ratio of exergy destruction to net power improves appreciably. Combined cycle with STIG can produce 498MW net power and has 356 MW exergy destruction but ordinary combined cycle produce 400MW net power with 346MW exergy destruction.

6. Conclusions

In this paper an old steam cycle has been chosen as a model for repowering. At first full repowering has been examined for this model and it changed into combined cycle that has 400MW net power. This repowering increases net power and improves efficiency. As a result of old boiler and power capacity for this model, full repowering is one of the useful an economical method. After that, a gas turbine and a single pressure HRSG added to combined cycle and it has been changed into STIG combined cycle. Net power increases with adding

new gas turbine and using STIG in this method. However increasing amount of mass flow steam injected can heighten net power, there is limitation for mass flow. Exergy and exergoeconomic methods have been applied for analysis and comparison both repowering method. An exergy-costing method has been applied to both cases to estimate the unit costs of electricity produced from steam turbines. The computer program that was developed which shows that the exergy and the thermoeconomic analysis presented here can be applied to any energy system systematically and elegantly. If correct information on the initial investments, salvage values and maintenance costs for each component can be supplied, the unit cost of products can be evaluated. These analyses shows that cost product of combined cycle with STIG is less than ordinary combined cycle. Also net power and efficiency of combined cycle with STIG is more than ordinary combined cycle. Although using water for steam injection is the most problem of this new method, there are some suggestions to recycle water and reused in the cycle.

Abstract: Steelmaking is an energy intensive industry. Much development work has been accomplished during the past years to make the processes more efficient. Process integration has come to play an important role for identifying efficiency measures, using mathematical programming as general tool. So far only a few minor process integration studies using pinch analysis have been made in this type of industry, and only on smaller sub-systems. This paper presents the results of a pinch targeting study that was conducted at the Swedish steel making company SSAB EMEA in Luleå. The pinch analysis methodology was originally developed to study heating, cooling and heat exchange in process systems with many streams. In the steel industry there are relatively few streams that are appropriate for heat exchange. This limits the use of pinch analysis. However, this study demonstrates that pinch analysis is a powerful tool for certain subsystems, especially the gas cleaning unit of the coke plant. The paper includes several suggestions for improved energy efficiency in this section of the steel plant.

Keywords: *Pinch analysis, Energy efficiency, Steel industry, Process integration*

1. Introduction

1.1. The steel industry

The steel industry sector is the second largest industrial user of energy in the world. In 2007 it used 24 EJ or 6700 TWh according to IEA [1]. Steel is an important construction material and the production has increased with the growth of the world economy. The development of the world production of steel is shown in Fig. 1.

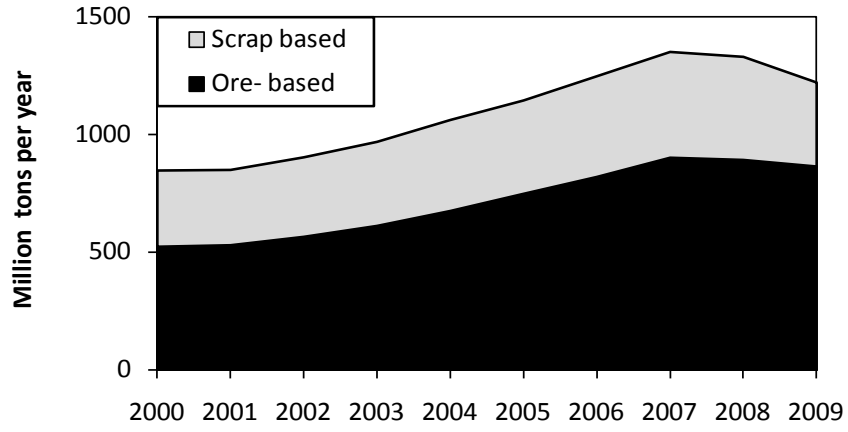

Fig. 1 Development of world steel production from ore and scrap based route[2]

The diagram shows a steady growth except from the recession years 2008-2009. A considerable part of reactants and fuels that are used in the processes are of fossil origin. The combination of production increase and use of fossil energy puts an emphasis on work to decrease energy consumption. One road to achieve this is to improve the processes to decrease their consumption. A large amount of work is and has been carried out in this area. It is, however, considered out of scope for this paper and not described here. A second road is to

improve the system efficiency, with process integration as one important tool. That type of work is the subject of this paper.

Steel is produced using two alternative routes: an ore based route where primary steel is produced from iron ore and a scrap based route where recycled steel (scrap) is re-melted (Fig. 2).

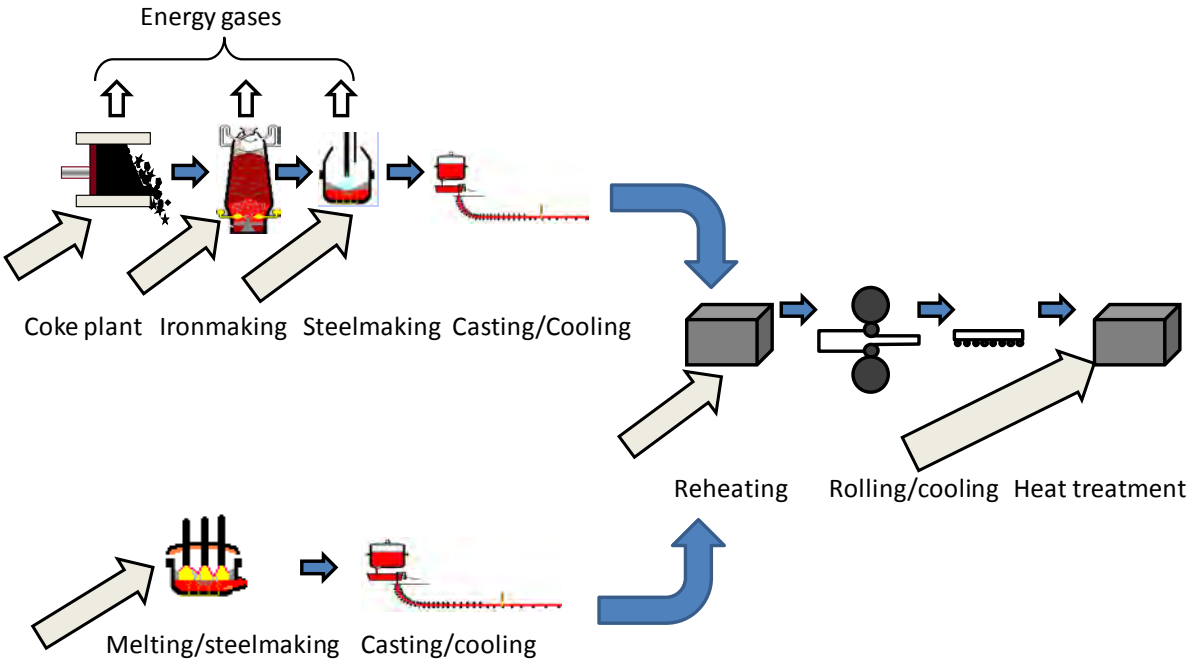

Fig. 2 Process route for ore and scrap based steel production

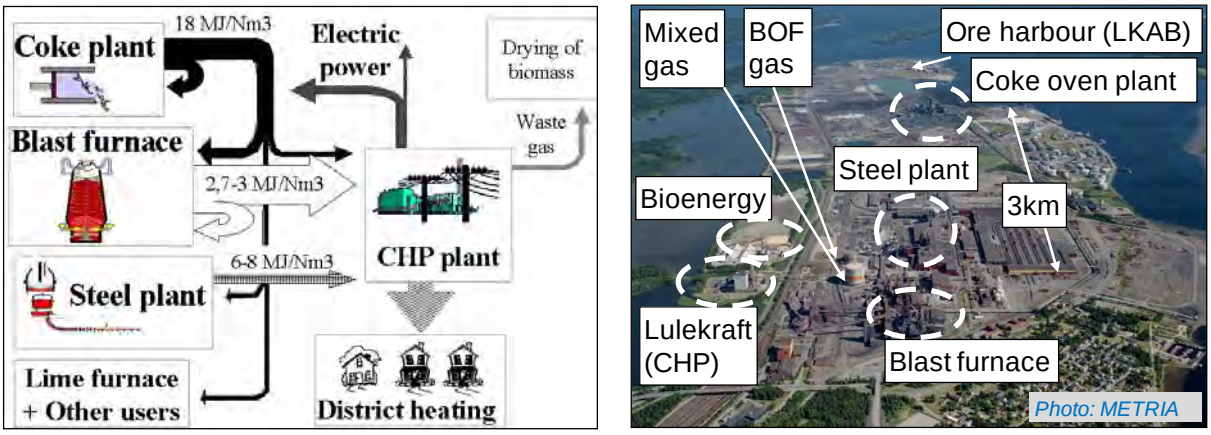
The upper branch in Fig. 2 illustrates the ore-based route. The production is based on coal and ore (mainly iron oxide). The coal is converted to coke by dry distillation in a coking plant. Approximately 25% of the weight is recovered as energy rich gas, tar and chemical products. The ore, e.g. in the form of pellets, is fed into the blast furnace along with coke and preheated blast air. The blast furnace produces a hot liquid metal with high carbon content. A combustible gas is obtained as a by-product. The hot metal is transformed into steel in an oxygen converter (BOF). An energy-rich gas is obtained as a by-product. After ladle treatment the steel is cast in a continuous casting machine. The semi-finished cast steel is cooled and transported to a rolling mill where it is heated to rolling temperature and rolled (or forged) into products and cooled on a cooling bed. Depending on the product, there may be additional treatment, such as heat treatment, cold rolling and metal coating (e.g. zinc). In most cases by-product energy gases from iron and steel-making are used in the reheating furnaces.

After some time the steel products are returned as scrap, and converted into new steel using the scrap based route (lower branch in Fig. 2). The scrap is melted and heated, usually in an electric arc furnace. The molten steel is then refined. This post-processing can be carried out in the furnace, in the ladle treatment or in a separate unit, e.g. refining with oxygen in a so-called AOD converter. Then the finished steel is cast and treated in the same way as in the ore-based route. This recirculation is an important part of the steel economy.

The system studied in this work is the SSAB EMEA steel plant in Luleå. This is an ore-based plant. The by-product energy gases cannot be used for preheating as the rolling mill is situated 800 km from the steel plant. Instead they are used in a local CHP plant, which co-produces electricity for the steel plant and district heating for the community (see Fig. 3 a.

1.2. Process integration and Pinch analysis

A typical process industry does not consist of independent process units. Instead, it is a network of units exchanging energy and energy media with each other. Very often the local community is also involved in the network, e.g., through power generation and/or district heating. The flowsheet and photo in Fig. 3 show the network that is studied in this paper.



a) Flow sheet *b) Actual plant*

Fig. 3. Network of the Luleå energy system.

The different units exchange energy and material with each other. Changes in one unit have side effects on the other units. Energy saving in one unit does not necessarily lead to energy saving of the total system. A global approach is needed to avoid sub-optimization. A flowsheet does not tell the whole truth. At the actual plant site there is usually a great distance between some units, in this case up to 2-3 km (see Fig. 3 b). Some connections that would be optimal from an energetic point of view may be impossible from a practical and economic point of view. A good analysis tool should be able to select the solution that is technically and economically most attractive.

A first attempt to make a more systematic analysis of this type of problem using pinch analysis was made at Manchester University in the UK [3]. In this type of analysis, the heat-carrying media are categorized as either cold streams (media that require heating during the process) or hot streams (media that require cooling). Based on this information it is possible to construct *composite curves* in order to determine the minimum energy-consumption target for the process. The curves are profiles of the process' heat availability (hot composite curve) and heat demands (cold composite curve). The degree to which the curves can overlap for a specified value of minimum temperature difference for heat exchanging (ΔT_{min}) is a measure of the potential for heat recovery. The point of closest approach of the composite curves, i.e. where ΔT_{min} is reached, is known as the pinch point. The effect of different operations and/or process modifications can be studied using pinch analysis. The relative position of such operations in the composite curves with respect to the pinch point is often a determining factor. Further details are described in Section 2 (Methodology). Pinch analysis has since then become a wide-spread tool for process integration in many industrial systems. Ref [4] can be seen as an example.

Steel industry energy systems are characterized by large high temperature flows of molten, solid and gaseous materials, as well as by energy intensive chemical reactions. Mathematical programming is considered particularly suitable for optimizing energy flows in this type of system. A specific simulation and optimization tool (reMIND) was developed and

implemented for steel plant applications ([6], [7]) and has reached a position as standard process integration tool for those applications.

Pinch analysis was originally developed for large systems with many streams that require heating and cooling and that are suitable for heat exchanging. This makes implementation in the steel industry somewhat restricted as there are relatively few streams, and the ones with the largest energy content are in the form of molten metal, hot slag or as radiation from slabs, i.e. unsuitable for conventional heat exchanging. Only limited uses of pinch analysis in the steel industry are reported ([8], [9]). However, previously conducted system studies carried out in the steel sector and PRISMA indicate that there are subsystems where pinch analysis could be a powerful tool. The Swedish Energy Agency and the national program for process integration decided to carry out a study on the possibility to use pinch analysis in the steel and mining sector. A major part of that work was a smaller pinch targeting study of the Luleå Steel plant system.

1.3. Scope of paper

The main scope of this study is to describe the above mentioned targeting study and the conclusions on possible use of pinch analysis in the steel industry.

2. Methodology

The analysis procedure for one of the subsystems (the gas cleaning system of the coke oven plant) is described in more detail to illustrate the methodology.

Data was collected together with coke plant staff. The energy streams were compiled and characterized as hot or cold streams. The cold streams, or ”heating loads”, are shown in Table 1. A similar table (not shown here) was made for the hot streams.

Table 1 Heating loads in the coke oven gas cleaning area

Process part	Unit	T_{start} (°C)	T_{end} (°C)	Flow	Load (kW)
Ammonia stripper	DB 602 A/B	MP steam			5 852
	EB 605 cold side	6.8 [1]	63	22 t/h	≈1 500
Benzene stripper	EA 2363	LP steam			42.3
	DB 2362	LP steam			633
	EA 2361	178	178.1		950
	EB 2261 A-D cold side [2]	27	143	51.8 m^3/h	2 620
2nd feed water preheat	FL 1401	63	124	22 t/h	1 566
Sulfur stripper	EB 601 cold side	26	51	61.1 m^3/h	1 770

[1] Yearly average water temperature in Lule River

[2] Heat capacity of 2.13 kJ/kg K is used for the circulating oil (petroleum) Density = 881 kg/m^3. The load is the average value of the two streams: (3132 kW + 2108 kW)/2

Composite curves (CC) were constructed for the gas cleaning section of the coking plant, shown in Fig. 4, using the stream data. The minimum distance between the curves is set by ΔT_{min}, set at 10 K in this study. Internal heat recovery is theoretically possible where the curves overlap (shaded area). A larger ΔT_{min} would push the curves further apart, thus decreasing the overlap and cause an increasing demand for heating and cooling media ($Q_{H,minimum}$ and $Q_{C,minimum}$).

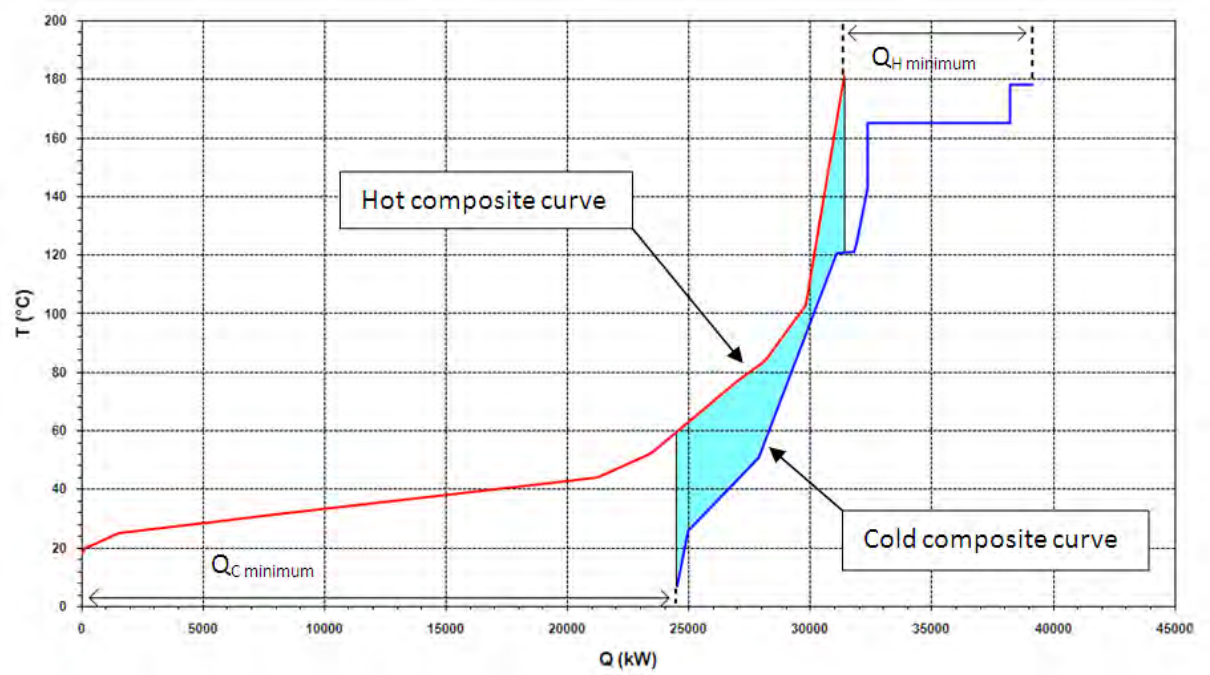


Fig. 4 Composite curves (CC) for the coking plant's gas cleaning area

The CC establish the energy targets (minimum hot and cold utility demand), but are not suitable for identifying appropriate utility steam levels and loads, or whether excess process heat can be used for hot water production instead of using cooling water. The Grand Composite Curve (GCC) is more appropriate for analyzing the interaction between the process and the utility system. Therefore a GCC was constructed for the gas cleaning area. To visualize the correspondence between CC and GCC, these are put next to each other in Fig. 5. The hot and cold composite curves are merged into one curve, i.e. the GCC, by calculating the net heat load in each temperature interval. A new interval can often be identified by a gradient change in the curve.

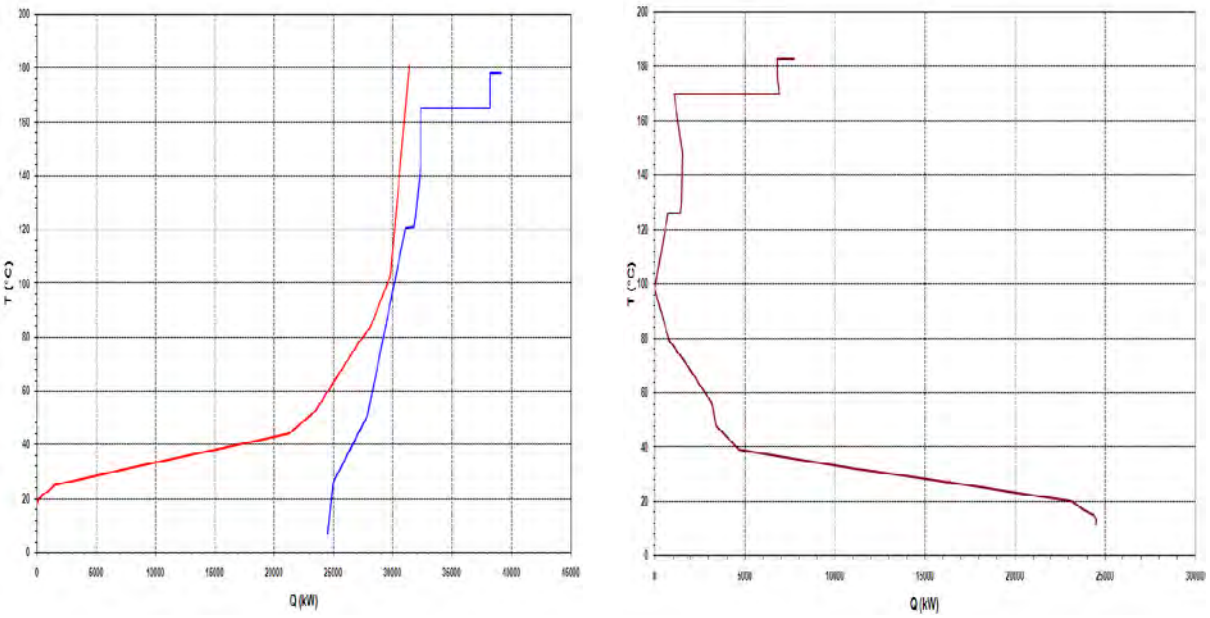

Fig. 5 Composite curves (CC) and corresponding grand composite curve (GCC) for the coking plant's gas cleaning area

A more detailed view of the GCC is shown in Fig. 6, enabling an analysis of different possible utility level setups.

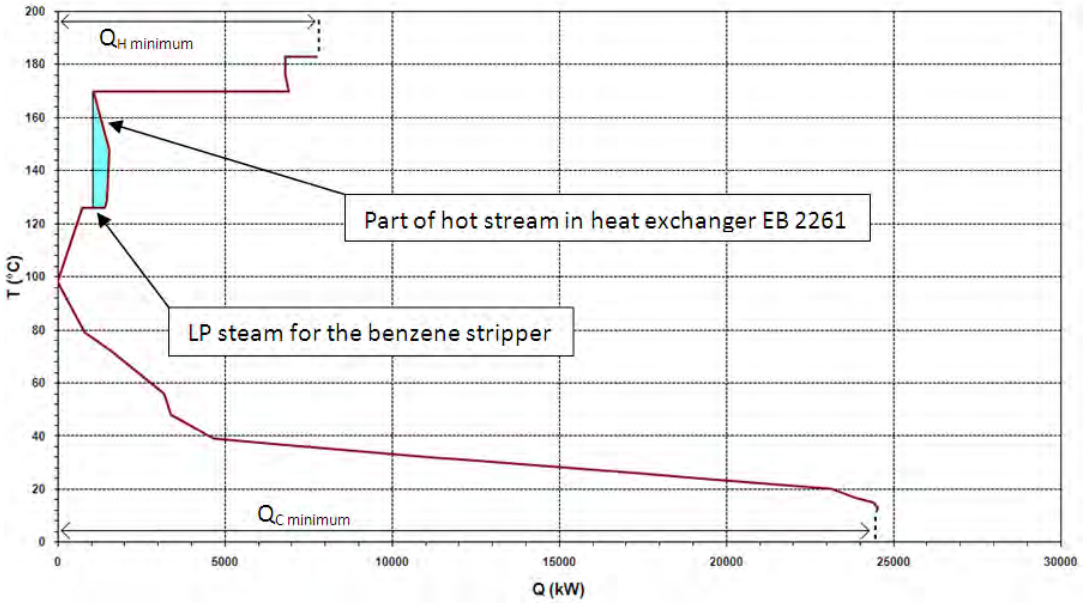

Fig. 6 Grand composite curve for the coking plant's gas cleaning area

One can for example examine whether there is any heat surplus (below the pinch) at useful levels, which could be used for steam generation, district heating, electricity production in a Rankine cycle, etc. The shaded part shows where internal heat exchange between temperature intervals is possible, i.e. a so-called pocket. The curve shows that part of the hot stream in EB 2261 is used to generate LP steam for the benzene stripper. The same methodology was used to analyze the other subsystems and the total plant.

3. Results

3.1. Coke plant

The analysis of the gas cleaning section of the coking plant (Fig. 4) shows that the demand for feed water preheating will decrease since less steam is needed in the process. The current preheating load is approximately 1500 kW in heat exchanger EB 605 and 1566 kW in FL 1401 (Current preheating load ≈3066 kW). The minimum preheating requirement turned out to be 2779 kW in total in this first step of the analysis of the coking plant. The horizontal parts of the lower line represent the demand for condensing steam in the strippers. The slope is determined by the flow multiplied by the heat capacity [kJ/°C] in each temperature interval. In all, the gas cleaning area currently uses 25.7 MW of cooling water whereas the minimum cooling demand, determined by pinch analysis, is 24.5 MW ($Q_{C,minimum}$ in Fig. 4). The process uses 9 MW of external heat, compared to 7.7 MW ($Q_{H,minimum}$.). This means that there is a 14% steam savings potential if a maximum energy recovery heat exchanger network were to be built, assuming ΔT_{min} = 10 K. The pinch temperature is 103°C for hot streams and 93°C for cold streams. That tells us, for example, that external heating media has to be at least 103°C and that the cooling media can be 93°C at the most, in order not to violate the ΔT_{min} of 10 K for heat exchange between utility and process streams.

An extended study (diagram not shown) was carried out to study the effect on heating and cooling loads in the total coking plant area assuming that steam is used at as low pressure as possible. This is particularly important if the steam is extracted from a turbine, in order to maximize electricity production. This showed a 1290 kW steam saving potential. The main

reason was elimination of the use of LP steam for feed water heating and avoiding heat exchange through the pinch.

A lot of heat at high temperature is wasted when washing water at around 70°C is used to cool the hot coke oven gas directly after it leaves the ovens. It should be possible to heat exchange the gas down to the tar dew point. A study was made to study what could be gained from such an arrangement. The dew point is between 350 and 150°C. An inlet temperature at a temperature of 450°C (i.e. significantly above the dew point) was assumed to give a safety margin. A gain of 9 MW was indicated if the heat is used to replace steam from the boiler.

3.2. Blast furnace and steel plant

A first attempt was made with separate studies of the blast furnace, the steelmaking converter plant, the ladle metallurgy and the continuous casting. However, limited availability of cold streams limited meaningful implementation of process integration based on pinch analysis. Since the distance between the units was not very large, a merged study of the Blast Furnace-Steel Plant system was tried. The analysis showed a potential hot utility savings of 2.7 MW that could be accomplished by using BOF steam for preheating the inlet gas to the cowper. This is further commented in the discussion chapter.

3.3. Total system

The study indicated that there actually is a match between the two sites, where the steel plant fits in the coking plant's "pocket". Flue gases and hot coke oven gas are in that case used to heat the blast air and steam from the BOF converters is used to run the strippers in the coking plant. There is a difference in load magnitude between the two sites, where the blast furnace and steel plant demand lots of external utility.

4. Discussion

4.1. General results

The expected result was that many sources of excess heat at hot water temperature level would be found. However, that is not the case assuming that this study shows the whole picture. Excess heat is available either at low temperatures, where utilization is more or less impossible, or at levels where steam could be generated. The dominating energy carrier suggested in this study is steam at fairly moderate pressure and temperature (below 200°C). Before heat recovery of that kind is realized, there must be heat sinks where the steam can be utilized. Several options are available but the simplest solution appears to be a steam turbine for electricity production.

4.2. System blast furnace + steel plant

The study in section 3.2 suggested that BOF steam should be used to preheat input cowper gas. For different reasons this is not technically feasible. However, it indicates another option that was not visible with the available stream data. A solution that has been used in some plants is preheating of the combustion air using a heat exchanger with the off-gas from those burners. The results confirm that this is interesting, although a different technical solution was suggested due to lack of detailed data regarding internal cowper streams.

4.3. Analysis of the total system

The analysis shows a large energetic gain by transportation of flue gases and steam between the sites. However, under present conditions this can be judged as less realistic due to the transport distances. Combining the two sites does not seem to be a feasible option just by

investigating integration possibilities. It would, however, add a degree of flexibility to have a common steam net.

4.4. Effect of process integration on sustainability

The effect is usually indirect, energy that would otherwise have gone to waste is used elsewhere, e.g. to replace consumption of fuel. Pinch analysis is useful where matches can be found at proper temperature between heat sinks and excess heat.

4.5. Future work

It would be interesting to carry out further studies at other plants. It is suggested that this is done as integrated projects where Pinch analysis is used together with other methods. Commonly available software and educational tools could increase industrial general awareness about pinch analysis.

5. Acknowledgments

The authors of this paper would like to thank Ida Engström and Rickard Broström at SSAB in Luleå, for guidance about the processes and for providing data to this work, and Chuan Wang, MEFOS, for valuable comments. We also would like to thank the Swedish Energy Agency for financing the study.

Abstract: Sustainable manufacturing claims for more energy efficient operations in warehouse management. In AS/RSs they can be pursued by optimizing storage and retrieval cycles so that the least energy is required to move the crane. While picking operations have been traditionally optimized in order to minimize picking times directly linked to the service level perceived by customers, a sustainable approach leads to change this perspective by optimizing storage and retrieval cycles to lower energy requirements. In this paper we propose an energy-based heuristic to re-sequence retrievals in order to perform dual command cycles with the least energy requirements. Impact on both energy savings and round trip times is assessed when moving from single command to dual command cycles, if storage and retrieval operations are combined by the common first-come first-served policy. Further improvements on energy and time performances achievable by adopting different re-sequencing heuristics are then investigated. Factors affecting energy consumption and round trip times such as the storage allocation strategy, the re-sequencing time-based or energy-based policies, the demand distribution, and the shape of the rack, are analyzed by a 2^4 factorial design of experiments.

Keywords: *energy efficiency, Automated Storage and Retrieval Systems, dual command cycles.*

1. Introduction

An automated storage and retrieval system (AS/RS) is a fully automated facility, where cranes running on rails between fixed storage racks pick up and drop off unit loads without the need of human operators.

AS/RSs have been recognized as sustainable facilities [1]. Since they allow to store inventory more densely and vertically than traditional warehouses, they reduce, in facts, energy consumptions to heat, cool, light and ventilate excess square footage. Furthermore, allowing storage of the same number of units in a smaller footprint, AS/RSs require less concrete, reducing carbon dioxide emissions.

From an operations management point of view, energy efficiency can be pursued in AS/RSs by optimizing also their storage and retrieval cycles, so that the least motion energy consumption can be achieved [2]. While picking operations have been traditionally optimized in order to minimize picking times directly linked to the service level perceived by customers [3], a sustainable approach leads to change this perspective by matching time performances with energy efficiency ones.

Dual command cycles couple a storage operation to a retrieval one into the same trip, in order to avoid idle travels of the AS/RS machine to/from the I/O station as in single command cycles, where only one operation (storage or retrieval) is performed at a time. In a dual command cycle, therefore, the AS/RS machine departs from the I/O station with a load on board and reaches the desired storage location, then it moves directly towards the selected retrieval location where the load is picked up, and then it comes back to the I/O station. The possibility of performing dual command cycles depends on the simultaneous availability of both storage and retrieval requests. When this occurs, dual command cycles have been recognized by literature to lead to significant time savings if compared to traditional single command ones in the order of 30% [4]. Adopting a sustainable perspective, the first question

to be addressed is therefore how much energy consumption can be reduced by adopting dual command cycles with respect single command ones.
Time savings are strictly related to the storage assignment policy adopted. Graves et al. [4] demonstrated by both analytical and enumeration analysis that maximum time savings are achieved by mandatory interleaving, that means performing dual command cycles whenever possible, with a full turnover strategy rather then the common random allocation. The full turnover strategy is a dedicated assignment policy, which exclusively assigns a given number of locations to a product, on the basis of its demand rate sorted by decreasing order. In this way the most frequently moved items are located to the most convenient positions with respect to the I/O station and maximum improvement on the selected performance is achieved. From the traditional time-based perspective convenience has been read in terms of minimum picking time, which has been the performance to be enhanced. Since it was found that interleaving time accounts for 30% of the total round trip time (equal to the sum of the travel time from the I/O station to the storage location + interleaving time from storage to the retrieval location + time to travel from the retrieval location to the I/O station), the time-based full turnover strategy allows to minimize the one-way travel component from/to the I/O station of a dual command cycle, thus is able to affect the 70% of total time.

In our opinion, when a sustainable perspective is adopted convenience should be read in terms of energy efficiency. Therefore, in order to assess the maximum energy savings achievable by dual command cycles, we introduce a full turnover strategy based on the least motion energy, that means assigning high turnover items to locations requiring the least energy to be served. Energy performance achievable by the energy-based full turnover policy can therefore be considered as upper bounds of energy savings achievable with other less performing but more easy to apply storage policies, such as the random allocation (i.e. each open location can be occupied by every item) or the class-based storage allocation. It was already shown in our previous work [2] how energy-based dedicated zones differs from time-based ones; from the traditional rectangular or L shapes of time-based approach, in fact, step-wise zones are identified by the energy-based one, with a general shift towards upper levels of the rack, due to exploitation of gravity.

Performance improvement gained by dual command cycles depends also on the capability of optimally combining storage and retrieval requests in order to optimize the interleaving phase. A common practice is to adopt a First-Come First-Served (FCFS) policy, which means processing storage requests in the exact sequence they arrive and combining each storage with the first available retrieval request respecting the order it has been inserted into the information system. While processing storage in FCFS order reflects the fact that in general input unit loads are moved by a conveyor to the I/O station of the AS/RS and therefore their sequence is fixed, retrieval requests can be considered as electronic messages, which can be rearranged in any desired sequence.

When a random allocation is performed, and only one open location is available at a time, Bozer et al. [5] explained that the dual command scheduling of AS/RSs can be formulated as a Chebyshev travelling salesman problem, which is known to be NP complete. When multiple open locations are available for storage, the problem involves finding the best storage locations other than coupling storage and retrieval requests and it is in general NP-hard [6]. This is the reason why several heuristics were developed to overcome such complexity. By analytical analysis, Han et al. argued that in order to gain an improvement in throughput greater than 10%, travel-between (i.e. interleaving time from storage locations to the retrieval ones under the hypothesis of rectilinear constant speed motion) must be reduced by over 50%

with respect to FCFS retrievals as it is achievable by the Nearest-Neighbor Heuristic [6]. The overall performance of this heuristic can be enhanced by adopting a class-based storage policy rather than a random one [7]. Near-optimal solutions can be achieved under random storage by the ε-optimum algorithm proposed by Lee and Schaefer [8]. An $O(n^3)$ heuristic for dedicated storage with one open location at a time (meaning that storage locations have been previously identified and no storage choice has to be performed) was also proposed by authors [9] with very good performance with respect to the optimal solution.

In this paper, a heuristic approach to couple storage and retrieval requests within a given time period aiming at minimizing motion energy requirements rather than picking time is proposed for the energy-based full turnover strategy. Time and energy are related by power, but it should be considered that due to simultaneity of movements along vertical and horizontal axes the Chebyshev metric applies to travel time (i.e. machine travel time is the maximum between x-time and y-time), while energy is the sum of the requirements of both the x motor and the y motor installed in the crane. This is the reason why energy savings potential could be different from time savings potential gained by dual command cycles and should be analyzed. Furthermore one can wonder to what extent energy-based dual command cycles overcome time-based ones as regards energy saving if compared to single command cycles and FCFS dual command ones.

Therefore, picking time and energy performances of dual command cycles identified by the proposed heuristic are compared to the commonly use First Come First Served combination approach and Lee Schafer time-based heuristic's one by simulation. Energy saving potential related to dual command cycle optimization is assessed as well as the impact of a sustainable approach on client service levels. Factors such as the shape of the rack affecting motion energy, the ABC demand curves affecting the turnover frequency or the type of full turnover strategy (time-based versus energy-based heuristics) are considered in other to analyze the amount of energy savings obtainable by optimizing both location assignment and picking cycles.

The paper is organized as following. In par. 2.1 the energy model developed in order to compute energy required for crane movements is described. In par. 2.2 an energy-based heuristic for combining storage and retrieval requests is proposed, while in par. 2.3 the design of simulation experiments is described. In par. 3 results are analyzed and conclusions on energy saving potential are collected in par. 4.

2. Methodology

To adopt the new perspective aiming at energy efficient manufacturing, new models and performance measures should be introduced in order to assess energy saving potential of different operation policies.

The first step is the development of an energy model so that motion energy required by the crane to reach each storage location of the AS/RS rack can be estimated. The second step is therefore an energy-based heuristic to combine storage and retrieval requests into dual command cycles. Finally, factors which are expected to affect energy efficiency performance of dual command cycles should be identified and a factorial design of simulation experiments provided. In the following subsections previously described steps are discussed.

2.1. The energy model

The crane movements along the horizontal axis (namely x) and the vertical one (namely y) are described as a rectilinear motion with constant acceleration. A trapezium speed profile is adopted, where three phases can be recognized: acceleration until the maximum speed is reached, constant speed motion, and deceleration in order to stop at the desired location in the rack. When the shift to be performed by the AS/RS machine isn't great enough to reach the maximum speed, a triangular speed profile with only symmetric acceleration and deceleration phases is adopted. The AS/RS machine movements are characterized by their simultaneity along the two axes, and therefore the Chebyshev metric has been applied in literature to calculate travel time. As regards energy, the crane in equipped with 3 independent motors per axis. Since fork cycle to insert and/or drop off unit loads from the rack is independent from their location and can be considered a fixed component of energy requirements, energy for the z axis is neglected in our model. New generation crane are controlled so that their movements along x and y axes not only start simultaneously, but also end at the same time. This allows to avoid the additional torque needed to maintain the load in position while completing the slowest movement as in traditional cranes. To adhere to market behavior, we slow down the fastest motion by decreasing the acceleration/deceleration times so that the maximum speed value achievable is lower than the nominal one, while keeping acceleration at nominal value, as described in [2].

Energy is then computed per axis on the basis of the torque provided at the motor shaft, supposed constant during acceleration due to A.C. 3-phase inverter duty motors. Torque has to counterbalance inertia of load and masses (motor + crane), friction and gravity (for the y-axis). It was so possible to assign to each location in the rack the value of energy required to store into or retrieve from by departing/arriving from/to the I/O station supposed at the lower left corner of the rack. Furthermore, the model allows to dynamically compute energy for interleaving between any pairs of locations in a dual command cycle.

2.2. The energy-based dual command cycle heuristic

We imagine to process storage requests in the same order they arrive, since unit loads are supposed to be moved to the I/O station of the AS/RS by a loop conveyor. Retrieval requests, instead, are re-sequenced in order to save motion energy. In order to limit computational time but also to adhere to a dynamic environment, the list of available retrievals requests is commonly split into blocks which are sequenced one at time [3]. We adopt blocks of 15 storages and 15 retrievals to be combined into N = 15 dual command cycles at time. In our computation we considered unchanged each block until all the pairs have been identified, thus adopting a static approach. In a very turbulent environment, however, it is possible to adopt a dynamic approach by updating the block with new retrievals requests at each iteration before selecting the successive pair of operations.

Let be L_S the list of N storage requests and L_R the list of N retrievals requests in the analyzed block. The energy-based heuristic consists of the following steps.

1. Assign to each element in L_S the open location with the lowest energy required to store the load moving from the I/O station. Let S the set of such locations.
2. Assign to each element in L_R the retrieval location among the available with the lowest energy required to pick the load to the I/O station. Let R the set of such locations.
3. For each pair (s, r) with $s \in S$, $r \in R$, compute energy requirements for moving from storage location s to retrieval location r;

4. Select the pair (s^*, r^*) $s^* \in S$, $r^* \in R$ with the minimum energy requirement and perform the related dual command cycle;
5. Set $S = S - \{s^*\}$, $R = R - \{r^*\}$;
6. Go to step 4 until $S = \varnothing$ and $R = \varnothing$.

The rationale of steps 1 and 2 is attempting to positively affect the one way travels from and to the I/O of a dual command cycle, so that the minimum energy is consumed for them. Steps 3-5 try to minimize energy required by interleaving, which is the only energy component that can be changed with a different combination of storage and retrievals requests. As it has been already assessed [4], in fact, given a block of N storage locations to be served and N retrieval ones, one-way travels from/to the I/O station are fixed both in terms of time and energy, since all the selected locations must be served anyway. The variable component remains the travel between a storage position and the coupled retrieval one in a dual command cycle, that strictly depends on how retrievals are re-sequenced. The above heuristic has a $O(N^2 \log_2 N)$ complexity, as shown in Appendix.

2.3. Simulation

By simulation experiments we compare energy consumption and round trip times of dual command cycles with single command cycles under different re-sequencing policies, namely FCFS, time-based, and energy-based ones. We consider only one side rack and one crane per aisle, since results can be modularly extended to all the fronts of an AS/RS. A reorder point replenishment policy is adopted and the size of each dedicated zone corresponds to the Economic Order Quantity (EOQ) of a given items. According to Graves et al. [4] EOQ is calculated assuming an equal ratio of inventory to order costs, so that the introduction of disturbing factors such as the supply policy can be avoided. In this way, zone size and frequency of access to a given location are affected only by demand distribution, as required by the full turnover strategy. Since the storage location policy has been showed in literature to significantly affect picking performances, we apply both the time-based full turnover strategy and the energy-based one. In this way we analyze whether adopting a sustainable perspective even when establishing dedicated zones could lead to significant energy savings with respect to the traditional time-based allocation.

In order to apply Lee-Schaefer heuristic to identify time-based dual command cycles, we need to first select storage and retrieval locations, since this heuristic applies only to re-sequencing of retrievals when locations involved in the decision process have been already established. We introduce a rule similar to step 1 of our energy-based heuristic, that is sorting all open locations dedicated to a given item by their one-way travel time from the I/O station and selecting at each iteration the position with the lowest time to be reached. Similarly to step 2 of the energy heuristic, all occupied locations of a given item are sorted by their one-way travel time to the I/O station and the position with minimum required time is selected for retrieval.

Since the adopted storage policy is strictly related to the ABC demand distribution curve of items stored in the analyzed AS/RS, we consider the ABC shape as a main factor in our analysis and select two levels: a 20-50 curve, meaning that the 20% of items account for the 50% of picking operations, and a more skewed one such as the 20-80 curve.

Nominal speed and acceleration of the crane, angular speed and inertia of motors etc. and shifts to be performed in order to serve locations are related to the shape of the AS/RS rack. Since all these quantities represent an input of the energy model as described in par. 2.1 and in previous research [2], we select also the shape of the rack as a factor of analysis. In particular

we compare a horizontally laid AS/RS with 99 columns and 10 levels to a more vertically developed one, characterized by 45 columns and 22 levels for a total amount of 990 available locations in both cases. We used actual data provided by System Logistics SpA, an international manufacturer of AS/RSs, to properly select a crane for each rack.

We first compare single command performances to First-Come First-Served dual command ones by a 2^4 factorial design, including the storage policy, the movement strategy, the ABC distribution and the rack shape as main factors to be analyzed, each at the two levels previously described. The rationale is to assess if dual command cycles can contribute to energy efficiency so significantly as they were proven to do for time reduction. This is the reason why the most actually used policy for re-sequencing retrievals, the FCFS one, is initially adopted. As regards the movement strategy, we mean how storage and retrieval locations to be served are selected before the coupling process based on the FCFS policy is performed. Empty locations for storages as well as available location for retrievals basically depend on the position of dedicated zones established by the storage strategy, but among these the selection of the order by which they will be served depends if movements are optimized by the time-based perspective or by the energy-based perspective. By the former, the location with the minimum one-way time from/to the I/O station is selected among the available, by the latter, instead, the location with the minimum motion energy requirement for the one-way travel from/to the I/O station is identified.

Once established if and how much FCFS dual command cycles overcome single command ones, an analysis on further improvements achievable by dual command cycles when replacing FCFS re-sequencing policy with time-based and energy-based heuristics is performed. A 2^4 factorial design of experiments with 4 factors (storage policy, re-sequencing policy, demand curve, and rack shape) at two levels is selected again. Main factors and related levels are summarized in Table 1.

Table 1.Factors and levels of the 2^4 design of experiments

Factors	**Low Level**	**High Level**
Re-sequencing policy	Time-based heuristic	Energy-based heuristic
Storage strategy	Time-based full turnover	Energy-based full turnover
Demand distribution	20-50 ABC curve	20-80 ABC curve
Rack shape	99×10	45×22

Simulation of 450 storage operations plus 450 retrievals is therefore performed. It is supposed that storage and retrievals operations can be always coupled, meaning that requests for both operations are available when planning the AS/RS machine cycles. Heuristics for re-sequencing retrievals are applied to block of 15 storage operations and 15 picking operations at time, for a total amount of 30 blocks to be analyzed. The size of the block is selected as a reasonable trade-off between opposite patterns. On one hand, in fact, computational effort increases as the block size is increased. Furthermore, if a dynamic approach should be adopted, meaning that the list of retrieval requests is updated as much frequently as possible to be aligned with client requirements, then the size of the block should be kept small in order to reduce the frozen window in the planning process. On the other hand, the capacity of really optimizing cycles in the whole planning horizon increases as the block size increases, since more operations are involved in the optimization process.

3. Results

Results from simulation runs show how dual command cycles gain significant performance improvements in comparison to single command cycles.
The average round trip time decreases of 29.7% when moving from single command to First-Come First-Served dual command cycles, in line with well-known results reported in literature.

Energy consumption to move the crane towards the desired storage and retrieval locations is lowered by a 26.6% on average, when storage and retrieval operations are combined into dual command cycles. Thus, dual command cycles are showed to be an effective operative mean to foster energy efficiency in warehouse management other than improve the service level perceived by client, for which they have been traditionally conceived. Main effects of the identified factors on lowering energy requirements are positive, but of limited importance. It comes that deleting one-way idle travels to/from the I/O station and replacing them with interleaving from a storage location to the coupled retrieval one leads itself to a significant improvement, which can be weakly affected by other characteristics of the system.

When replacing FCFS policy with heuristics to combine storage and retrieval requests into dual command cycles, a little improvement on the desire performance can be further achieved. Simulations analysis highlights how a 32.4% of improvement on round trip times is gained on average, and a 30.11% of energy savings can be obtained on average. As concern factorial analysis, the major effect on round trip time reduction if compared to FCFS policy is played by the time-based heuristic, whose implementation gains a 2.4% improvement with respect to the energy-based one. Concerning factorial analysis on motion energy savings when applying heuristics, instead, the major effect is achieved by applying the energy-based full turnover storage policy rather than the traditional time-based one, with a 1.7% increase. This confirms how the storage policy affects results obtainable successively by a proper management of AS/RS machine operations.

It is worthwhile to notice how adopting a full energy-based management of the AS/RS, meaning that both storage and re-sequencing are based on the least motion energy, leads to an energy saving increase of 30.77% with respect to single command cycles, but a time decrease of 30.78%. When a full time-based management is selected, instead, we obtain a 33.2% improvement of round trip times in comparison to single command cycles, and 29.61% improvement of energy requirements. It comes that if the most critical performance for a company is energy consumption, then an energy-based approach leads to the maximum benefit in terms of energy consumption, but renouncing to a 2.4% of improvement in times and the associated service level perceived by customers.

4. Conclusions

Sustainable manufacturing claims for more energy efficient operations in warehouse management. While AS/RS operations have been traditionally optimized in order to minimize picking times directly linked to the service level perceived by customers, a sustainable approach leads to change this perspective by optimizing storage and retrieval cycles so that the least motion energy is required to perform them.

Adopting dual command cycles instead of the more common single ones leads not only to reduce picking time, as traditionally expected, but also to strongly increase energy saving. Comparing single command cycles to dual command ones obtained by coupling storage and retrieval requests by the easy-to-use and largely applied First-Come First-Served policy, a

26.6% of energy saving was found on average. Further improvement of about 3.5% on energy saving can be achieved by implementing heuristics to optimize dual command cycles. In this case, current results show how the major benefit can be gained by a full energy-based approach, thus adopting both an energy-based full turnover storage strategy and an energy-based re-sequencing heuristic.

Appendix

For implementing step 3 of the energy-based heuristic described in par. 2.2, one can compute the N^2 energy values related to all the N^2 possible couples (s, r) and then choose the minimum. However, if an ordering of this N^2 length list is made, the following steps can be implemented faster.

Therefore, let E the ordered list of N^2 tuples (s, r, En(s, r)), where En is the interleaving energy requirement associated to (s, r). It can be computed in time $O(N^2\log_2 N^2) = O(N^2\log_2 N)$.

For each $s \in S$ we build a list L(s) pointing to those elements concerning s and a list L(r) pointing to $r \in R$. Then step 4 can be executed in constant time (the first cell of the list stores the minimum). We use the lists L(s) and L(r) for accessing E and remove the cells of the kind (s,..,...) or (..,r,…). This can be done in time $O(N)$. The loop is repeated N times, therefore the overall complexity is $O(N^2\log_2 N + 2N^2) = O(N^2\log_2 N)$.

Abstract: In this work a mathematic model to simulate and optimize the energy system of a scrap based plant has been developed. Scrap based steelmaking is an energy intense production system. The potential for energy saving by system optimization is therefore high, even if the percentage of saved energy is relatively small. The model includes scrap pre-treatment, electrical arc furnace, ladle furnace and continuous casting units. To estimate the chemical compositions of the scrap charged into the EAF a statistical model based on an existing EAF plant has been used to provide the inputs to the model. Distribution factors have been used to describe the distribution of elements and oxides between the steel, slag and off gas/dust. To calculate the energy consumption in the electrical arc furnace a combination of an empirical and theoretical energy formula has been used. The model represents a general description of the most common process in electric steelmaking. It is suited to be adapted for specific plants with adjustments to the model parameters. The model gives reasonable results which follow the chemical composition of steel and slag and yield. The model can be a powerful tool to optimize the scrap mix and injectants towards energy and costs.

Keywords: *Energy systems, optimization, steelmaking, EAF, MILP, linear programming*

1. Introduction

Energy has been and will always be one of the most important production factors in the iron- and steel industry. In Sweden approximately one third of the total steel production is produced in electrical arc furnaces (EAF) and two thirds in basic oxygen furnaces (BOF) [1].

In the steel industry system, several processes are often connected together. A change in one process unit may result in unpredicted changes in other parts of the system. A literature study has been made of the best available technique and state-of the-art processes to decrease the specific energy consumption in the electrical arc furnace steel making.

The purpose of this work is to create a mathematic model to simulate and optimize the energy system of an EAF plant. In the past similar work has been made on the integrated blast furnace route energy system [2]. It is likely to presume that the scrap based steelmaking will increase in the future and more efforts will be spent to optimize the energy used in this area.

For the scrap based steel plant, it is often difficult to know the exact chemical compositions of the scrap charged into the EAF. In this work a scrap material statistical model based on an existing EAF plant has been used to provide the inputs to the model. The process steps in scrap based steelmaking are raw materials handling, pre-treatment EAF scrap melting, steel and slag tapping, ladle furnace treatments and casting.

1.1. Scraped based steel plant

With respect to the end-products, distinction has to be made between production of ordinary, so-called carbon steel as well as low alloyed steel and high alloyed steel/stainless steel. In the EU, about 88 % of steel production is carbon or low alloyed steel.

1.1.1. Energy consumption in electrical steelmaking

Electric arc furnace steelmaking uses heat supplied from electricity that arc from graphite electrodes to the metal bath to melt the solid iron feed materials. Although electricity provides most of the energy for EAF steelmaking, supplemental heating from oxy-fuel burners and oxygen injection is used. To produce EAF steel, scrap is melted and refined, using a strong electric current. Several process variations exist, using either AC or DC currents and fuels can be injected to reduce electricity use.

EAF steelmaking can use a wide range of scrap types, as well as pig iron, direct reduced iron (DRI/HBI) and hot metal. The EAF operates as a batch melting process, producing heats of molten steel with tap-to-tap times for modern furnaces of 30 minutes [3]. Current on-going EAF steelmaking research includes reducing electricity requirement per ton of steel, modifying equipment and practices to minimize consumption of the graphite electrodes, and improving the quality and range of steel produced from low quality and low cost scrap.

The best practice EAF plant is state-of-the-art facility with eccentric bottom tapping, ultra high power transformers, oxygen blowing, and carbon injection. The “best practice” is to use as much scrap as possible, as melting of DRI/HBI requires more energy. An efficient electric steelmaking plant with 100 % scrap as iron bearers has an electrical energy consumption of 409 kWh/t liquid steel for the EAF and 65 kWh/t liquid steel for gas cleaning and ladle refining, as well as 42 kWh/ton liquid steel of natural gas and 8 kg/t liquid steel of carbon [4].

There are various techniques to decrease the energy consumption for scrap based steelmaking. The Best Available Technique (BAT) to consider is to preheat the scrap and to replace the continuous casting, hot rolling, cold rolling and finishing with thin slab casting, also called near net shape strip casting [5]. The two most common methods to preheat steel are the CONSTEEL process and the post combustion shaft furnace (FUCHS). The electricity savings reported are 60 and 100 kWh/t liquid steel respectively [6]. An example of a thin slab casting technique is the Castrip® process. Potential energy savings are estimated to be 80 to 90% over conventional slab casting and hot rolling methods [7].

2. Methodology

The method used in this work is a model for industrial systems where the process is described as a network of nodes (sub-processes) which are connected by energy and material flows. The potential of this method is that it enables a simultaneous representation of the total industrial system, and that it makes it possible to optimize the whole system, in contrast to the optimization of each sub-process individually. The method is described by Nilsson [8], and later developed for complex material production systems by others [9]-[11].

The method is based on Mixed Integer Linear Programming (MILP). The model described in this paper contains no integers. There are four main nodes that symbolize the different processes in the system. These are a pre-treatment node, an electric arc furnace node, a ladle furnace node and a continuous casting node. There are nodes that provide the main processes with resources such as raw material, slag formers, alloys, energy sources and destination nodes for products and by-products.

2.1. Scrap pre-treatment

The scrap pre-treatment nodes main function is to summarize the different ingoing elements and oxides from each scrap grade and slag former, and transport them to the EAF node. There

is one flow for each element or oxide. There is also a possibility to restrict the amount of each scrap grade or slag former going into the EAF. As well as it is possible to set boundaries on each scrap grade it is also possible to set a fixed scrap recipe. Fig. 1 describes the ingoing and outgoing flows for the scrap pre-treatment node.

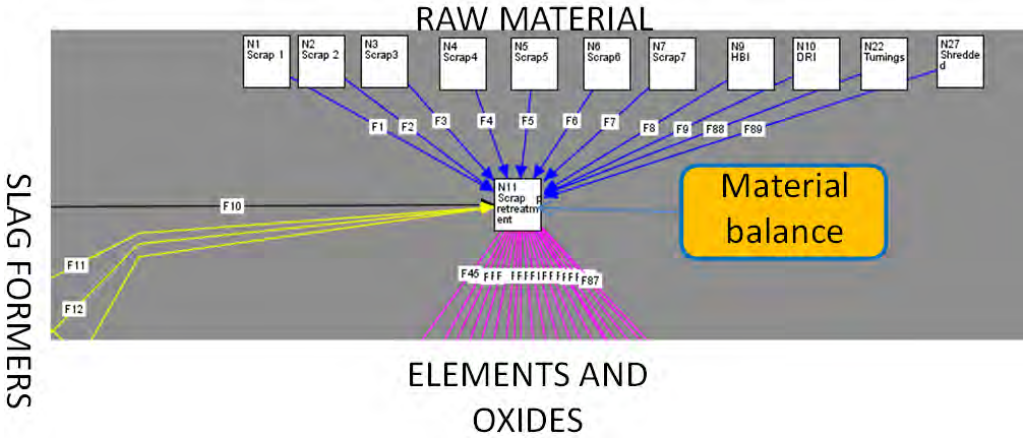

Fig. 1. Ingoing and outgoing flows for the scrap pre-treatment node

The chemical composition of scrap grades have a tendency to vary over a period of time as well as from heat to heat. For the raw material with well-known chemical composition the content are written according to that [12]-[14]. For scrap grades that have a more uncertain chemical composition the values have been estimated with multiple linear regression (OLS – Ordinary Least Squares) or "by hand".

Process data from approximately 1400 melts have been used in the OLS regression analysis. The data contained information about both scrap mix and steel analysis and an assumed distribution factor for each element/oxide to steel in the EAF for each element. From this information a material balance was made. The outgoing flows from the pre-treatment node represent the weight of each element and oxide and total weight of charged material.

2.2. Electric arc furnace

Ingoing raw material to the EAF node is the different amount of each element and oxide that is determined in the pre-treatment node. As ingoing material there are also three types of slag formers. Carbon and fuels in form of natural gas, LPG and oil are represented. The electrode consumption is also represented as an ingoing flow. The ingoing gases are nitrogen for stirring, oxygen from lance and air leakage from slag door and from off-gas duct opening after the 4th hole. There are three different flows for by-products; flue-gas, slag and dust. Fig. 2 describes the ingoing and outgoing flows for the electrical arc furnace.

All incoming elements and oxides from all sources are treated in a material balance. A very central part of this node is the distribution factor table between steel, slag and off-gas/dust. This table decides how much of each element that remains in the steel and how much that are transferred to the slag or off-gas. The distribution factor for an element/oxide applies for the sum of that element/oxide for all incoming flows. The distribution coefficients have been determined statistically by calculation of average weights and concentration of elements and oxides in steel, slag, dust and off-gas.

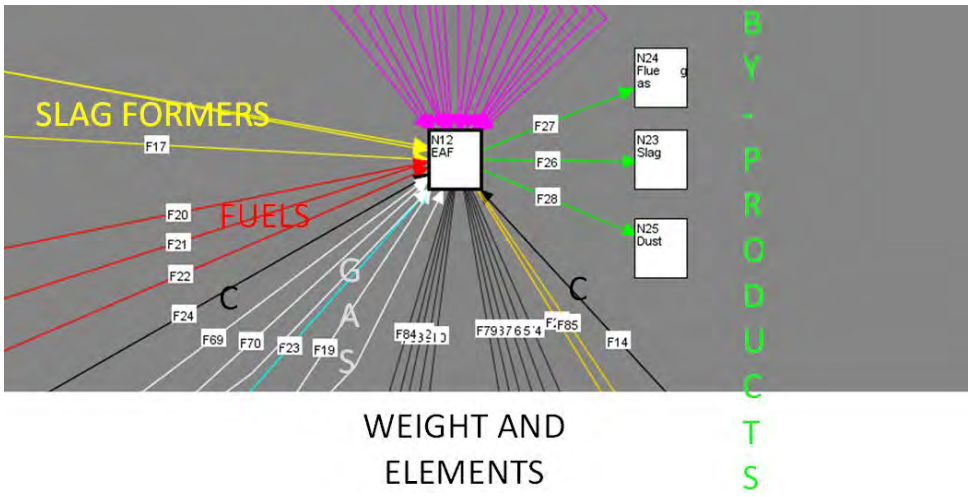

Fig. 2. Ingoing and outgoing flows for the EAF node

2.2.1. Energy calculation

For calculations regarding energy consumption for the electric arc furnace one empirical formula (Köhle-Formula) [3, 15] and a theoretical formula (Adams' formula) [16] has been used. Köhle's formula determines the electrical energy demand based on the use of other energy carriers, added materials, tapping temperature and tap-to-tap time. The Adams' formula determines the total energy consumption where quantities of non-electric energy are converted into kWh. The coefficients in the Adams formula have been used to assign "energy costs" for chemical fuel (kWh/kg or kWh/Nm^3) so that a "cost function" (kWh) for total energy consumption can be defined.

All the values that are needed for the formula are selected from the calculations or flows in the model. The values that are fixed constants are tapping temperature, power on time and power of time. Hot metal is not included in the model but there is a possibility to add it in the pre-treatment node along with the chemical analysis and also include it as a factor in the Köhle formula.

In the EAF-node there is an equation for pre-heating of scrap. The user can choose the preferred pre-heating end temperature of the charged scrap. If this function is activated this will also affect the electric consumption that is calculated. The energy added to the scrap is calculated with a fixed heating value (Cp) for the scrap mix. The Cp value has been estimated as the average value in the temperature range of 0 to 500 °C [17]. The reduced electric energy is calculated from the added energy value multiplied by the efficiency factor of the electric arc furnace.

2.2.2. Assumptions

It should be noted that factors for Oil and LPG are included in the Adams formula but not in the Köhle formula. Factors for Oil and LPG were therefore added to the Köhle formula as well. For calculation of these additional factors to the Köhle formula it was assumed that the heat transfer efficiency to the scrap/steel is the same for all kinds of chemical fuel (natural gas, oil and LPG). Then the factors for oil and LPG in the Köhle formula can be estimated as the factor for natural gas in the Köhle formula multiplied by the ratio of the factors for oil/LPG and natural gas in the Adams formula (11/10.5 for oil and 8/10.5 for LPG).

It is possible to set specifications for the steel chemistry. This is made by restricting the calculations to fit the minimum and/or maximum allowed concentrations of each element in

the steel. The slag weight must be greater than 7% of the steel weight and the amount of MgO in the slag must be greater than 8% of the slag weight. The slag basicity (CaO/SiO_2) is restricted to a constant that is determined by the user.

There are calculations regarding the off gas in two stages of the process, one calculation at the so called 4th hole and the other after the slip gap of the off gas duct. The calculations have been made in this way to show the post combustion energy potential of the off-gas before the air leakage in the slip gap. The calculations of the flue gas are depending on a number of assumptions. All C and H from the incoming flows leave the steel bath as CO and H_2 except the contribution from the burner fuel, which is completely combusted to CO_2 and H_2O. All Zn from ingoing flows that ends up in the dust leave the steel bath as Zn(g). These gases react with the air coming from the slag door and with the post combustion oxygen from the burners. At this point all the Zn(g) is oxidized to ZnO and the O_2 that is left reacts with CO and H_2 and generates CO_2 and H_2O. This reaction occurs according to a fixed distribution where a defined percentage of the remaining oxygen after Zn oxidation reacts with the CO and the rest with H_2. At the slip gap at the off gas duct it is assumed that there will be enough air flow for a complete combustion of the remaining CO and the H_2 in the off gas. The amount of excess oxygen in the flue gas after the slip gap is set to a constant.

2.3. Ladle furnace

The steel is going into the ladle furnace node with one flow for each element represented in the liquid steel. In this node there is a function where the user specifies the final steel weight. If a specified scrap weight and scrap mix is used there is a need to disable this function for the model to work properly. There is the opportunity to use the three slag formers that are used in the EAF node as well as a synthetic slag former. The model offers the user to add different kinds of alloys to the steel. The most common alloys that are available have been added but it is possible to add additional ones if that is needed. The chemical composition of the included alloys can also be changed. Fig. 3 describes the ingoing and outgoing flows for the ladle furnace.

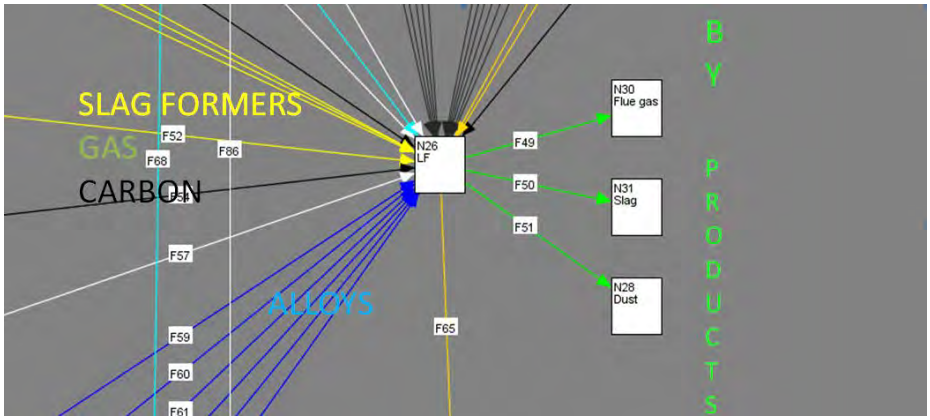

Fig. 3. Ingoing and outgoing flows for the LF node

The material balance in this node is as in the EAF node based on a distribution table between steel, slag and off gas/dust. The distribution coefficients have been estimated by empirical knowledge. The distribution coefficients refer to the materials that are added in the node. The contents of the ingoing steel are therefore not affected by any distribution factor. The exception from this is sulfur that has distribution coefficients also for the amount that is transferred with the steel into the ladle furnace node.

The ingoing temperature of the liquid steel to the ladle furnace is decided by the tapping temperature from the EAF which is reduced by a constant factor due to temperature loss during tapping of the EAF. The final temperature is decided by the demands of the following operation. It is also assumed that an average amount of slag is transferred along with the liquid steel from the EAF to the LF during tapping. There is a calculation of the electrode consumption that is based on a constant amount of electrode per kWh.

In the model it is assumed that argon is used for stirring the melt during the ladle furnace operation. The consumption is based on a fixed volume per ton of steel. This assumption is made from an average calculation from the process data. The amount of air that leaks into the system is also a constant per ton of steel.

2.3.1. Energy calculation

The electric energy consumption in the ladle furnace is based on the amount of steel and the increase in steel temperature needed to reach the final temperature. At first there is the difference between the ingoing temperature and the final temperature. But also the effect of the added material will contribute to a temperature drop. The temperature drop caused by each added material is based on an individual material constant. This constant determines how large the temperature drop, or in some cases a temperature raise, will be depending on the percentage of material added to the liquid steel. The temperature drop constants have been estimated by empirical knowledge.

2.3.2. Assumptions

It is possible to set specifications for the steel chemistry. This is made by restricting the calculations to fit the minimum and/or maximum allowed concentrations (wt. %) of each element in the steel. This is also possible in the EAF node so the user can choose if the specification is to be set at the LF or both. The slag weight is set to be greater than 2% of the steel weight and the slag basicity (CaO/SiO2) is restricted to a constant. The amount of elements and oxides in the off gas/dust that leaves the steel bath is calculated according to the same principles as the off gas in the EAF node. However, the reactions with infiltrated air are not considered.

2.4. Continuous casting

The continuous casting (CC) unit is treated in a simple way in the model. For the material flow, a material loss in percentage based on the total liquid steel amount from the LF unit is assumed when casting. A specific oxygen consumption (Nm^3 O_2/ton-slab) based on the final product (slab in this case) is assumed to calculate the total oxygen consumption. The oxygen is needed when cutting the slabs. For the electricity consumption in CC, it is based on assumed specific electricity consumption (MWh/ton slab).

3. Results

Simulations have been run in CPLEX with three different scrap mixes corresponding to average mixes for three different steel grades at Höganäs AB EAF plant in Halmstad. The model calculations in terms of chemical analysis of steel and slag and metallic yield have been compared with real data from Halmstad. The model calculates reasonable results which correspond well to real data.

An optimization test with the objective to minimize the total energy consumption (kWh) in the system (for a given quantity of a specific steel grade at Halmstad) was performed. During

the optimization scrap preheating function was turned off and the EAF tapping temperature was constant.

In the optimized solution, the use of shredded scrap is maximized because of the lower specific energy consumption for this scrap grade (-50 kWh/ton compared to "normal" scrap) in the Köhle formula [3]. The maximum amount of shredded scrap is limited by the quality restrictions (chemical analysis) of the steel grade. The use of HBI/DRI is minimized (zero consumption) because of their higher specific energy consumption (+80 kWh/ton compared to "normal" scrap) in the Köhle formula [5].

For all chemical fuels (oil, natural gas and LPG), the optimizer chooses zero consumption in the EAF This is because the energy content according to Adams [16] for natural gas (10.5 kWh/Nm^3) is higher than the reduction of electrical energy consumption it gives according to the Köhle formula (-8 kWh/ Nm^3) [3]. As the efficiency of oil and LPG in the EAF burners are assumed to be the same as for natural gas it follows that the energy content of all chemical fuels are higher than their reduction of electrical energy consumption in the EAF.

The optimizer chooses to add as much post combustion (PC) oxygen through the burners in the EAF as possible, because burner PC oxygen has zero energy content and will reduce the electrical energy consumption (-2.8 kWh/Nm^3) according to the Köhle formula. The limit of PC oxygen is set by the available amounts of post-combustible gases (H_2, CO and Zn) in the furnace, as the amount of these substances in the 4^{th} hole off-gas must be zero or higher. The amounts of post-combustible gases in turn are determined by the charge material mix and the amount of air leakage through the slag door.

The lance oxygen consumption is minimized in the optimized solution. This is because the energy development for oxygen injection (5.2 kWh/Nm^3) according to Adams [16] is higher than the reduction of electrical energy consumption that it gives according to the Köhle formula (-4.3 kWh/Nm^3) [3].

4. Concluding remarks

Scrap based steel plants around the world differs a lot in terms of scrap mixes and final products. The model described in this paper represents a general description which shall be adapted for specific cases. The model is built up to easy adjust to the processes of interest. To use the model correctly the incoming data needs to be correct and the model parameters (raw material analysis, slag basicity, air leakage, etc.) must be adjusted to represent the conditions of the specific plant. Then the model can be a powerful tool to optimize the scrap mix and injectants towards minimized energy consumption or production cost. In upcoming work the model will be used to optimize specific processes and plants.

The future work will also include further development of the scrap preheating function and move it to a separate node. A cost function for monetary units for all incoming flows will be added so that the total production cost can be optimized. Nodes for alternative solidification processes such as ingot casting and atomization will be considered and coefficients for specific energy consumption for different scrap grades in the EAF will be adjusted and added. Interaction with external systems like district heating can also be added.

Moreover different feeding and charging systems and a water cooling system for EAF are planned to be implemented and the processes after casting such as transport, heating and metalworking processes needs to added to complete the system.

Environmental system effects when including scrap preheating and surface cleaning in steel making routes

Abstract: The main part of the steel manufactures producing alloyed steel use scrap as an essential raw material. To increase the corrosion resistance of steel a coating is often applied. The share of steel being coated and galvanized is today globally increasing, which is resulting that the amount of scrap with different types of coatings are increasing. This result in that more of the scrap used in steel making is contaminated with for example Zinc and organics. Scrap preheating is a known method for reduction of energy use in steelmaking. However due to environmental restrictions a widespread implementation of scrap preheating have not been achieved in the steel industry. Combined surface cleaning and scrap preheating is a way to handle the problem that coatings give rise to in the melting cycle and is a new concept suggested and developed at Swerea MEFOS. The pre-treated scrap (cleaned and preheated) is charged hot into the oxygen converters with direct savings of energy, as the demand of hot metal from the blast furnace decreases. The method opens for the possibility to widen the scrap base and to melt complicated scrap. Since the preheating process is a standalone solution, a large number of unwanted chemical components are removed prior melting resulting in that the dust generated from the melting process is easier to recover. In this paper the system effect of introducing a preheating and surface cleaning process for scrap in a Blast Furnace (BF) and oxygen converter (BOF) steelmaking route is analyzed according to energy and CO_2 emissions. The system analysis shows that surface cleaning of scrap makes it possible to use shredded scrap and ASR (automotive shredder residue) or other combustible waste to replace fossil fuels. The results from the analysis demonstrates that implementing surface cleaning leads to increased possibilities for recycling of otherwise non-recyclable material. The system model shows the interaction between different processes, which gives an overview picture including the whole steel making route. The model is used to investigate changes in process conditions from making use of shredded scrap and ASR as input material in the steel making process. The implementation of surface cleaning and preheating lead to both increased possibilities for recycling of scrap, and more efficient energy use in the steelmaking routes.

1. Introduction

Currently, the blast furnace (BF), basic oxygen furnace (BOF) route is the dominating processes for iron ore steel making. The steel is produced from the hot metal produced in the BF by treatment in a BOF converter. In the converter process a surplus heat is generated during the oxygen blowing which is utilized for scrap melting. 15-20 % of the iron raw material input to the BOF is originated from scrap. Liquid steel (LS) from the converter is sent to an after-treatment station where the final adjustment of the steel analysis and temperature is performed before the casting procedure. Energy and material efficiency in a process system is closely linked together. A higher recycling rate and a minimization of landfill is energy efficient, since it decreases the demand of virgin materials.

The main part of the steel manufactures producing alloyed steel use scrap as an essential raw material. To increase the corrosion resistance of steel a coating is often applied. The share of steel being coated and galvanized is today globally increasing, which is resulting that the amount of scrap with different types of coatings are increasing. This result in that more of the scrap used in steel making is contaminated with for example Zinc and organics. In this paper the system effect of introducing a preheating and surface cleaning process for scrap in a Blast Furnace and oxygen converter (BOF) steelmaking route is analyzed according to energy and CO_2 emissions.

Scrap preheating is a known method for reduction of energy consumption for melting. However due to hazardous components generated in the exhaust, a widespread implementation of scrap preheating have been interfered due to the costly treatment required. A standalone combined surface cleaning and scrap preheating is a way to handle the problem that coatings on the scrap give rise to. This is a new concept suggested and developed at Swerea MEFOS [1]. The pre-treated scrap (cleaned and preheated) is charged hot into the oxygen converters with direct savings of energy, as the demand of hot metal from the blast furnace decreases. The method opens for the possibility to widen the scrap base and to melt complicated scrap. Since the preheating process also applies surface cleaning a large number of unwanted chemical components are removed prior melting resulting in that the dust generated from the melting process is easier to recover. [1-2]

1.1. Objective of the study

This study analyzes the system effect of introducing surface cleaning of scrap in a BF-BOF steel making route. An optimization model highlights the possibilities regarding cost and CO_2 emission. The model is used to do analysis on operation practice, scrap usage and cost. The intention of the study is to investigate the changes in the process system, when using shredded scrap in the scrap mix.

2. Methodology

The method used in this work is based on the MIND method [3]. The study is made in an optimization model of an integrated steel mill, where the process is described as a network of nodes (sub-processes) which are connected by energy and material flows. The potential of this method is that is enables a simultaneous representation of the total industrial system, and that is makes it possible to optimize the whole system, in contrast to the optimization of each sub-process individually. The optimization model of one integrated steel plant has been further developed with the requirements for scrap preheating [4-5]. The model used in this work is based on an existing energy optimization model designed for the iron and steel industry [6-8].

2.1. The optimization model

2.1.1. Objective function

This study uses two objective functions which are defined in the model as raw material and energy costs and CO_2 emission. Generally the objective function is imbedded within the optimization model but can in mathematical terms be written as follows.

$$\min z = \sum_{i=1}^{n} c_i x_i \qquad (1)$$

where z is the objective function for the minimization problem. It could be CO_2 emission and cost, depending on what objective is set for the optimization. x is studied variables and c is coefficients set for the corresponding objective function and depends on which objective function. The coefficients set for the corresponding objective functions are shown in Table 1.

Table 1. Coefficients used for different objective functions.

	Unit	Cost (SEK)	CO_2 emission (ton)
Iron ore pellet	ton	675	0.051
Lime stone (wet)	ton	128	0.856
Mn ore	ton	488	-
Quartz	ton	180	-
Lime stone	ton	124	0.856
Dolomite Lime	ton	600	0.466
Raw Dolomite Lime	ton	263	0.931
FeSi	ton/ton RS	4875	-
CaC_2	ton	3225	-
Coal and coke	ton	293-331	2.492-3.064
External coke	ton	1950	3.744
Pulverized coal injection	ton	205-525	2.488-2.916
External scrap	ton	2300	-
Shredded scrap	ton	2000	-
BOF sludge	ton	-	-
Oil	MWh	5550	3.126
External energy	MWh	-	0.6
Excess coke	ton	-1950	-3.744
Benzene	ton	-1600	-3.287
Sulphur	ton	-40	-
Tar	ton	-1300	-3.349

In Table 1, the costs analysis is limited to raw material and energy and thereby not including the cost for energy and landfill of material. Furthermore credits are made in the model for by-products. Market values for the different raw materials and energy sources fluctuate whereby the costs for raw materials and energy used in the model is mean values calculated over a conjuncture cycle. Values of costs are estimations based on figures from The London Bullion Market Association.

2.1.2. Boundary conditions and limitations

To make sure to get reasonable results, some necessary boundary are introduced. The boundary conditions, which can describe variations in the system, maximum and minimum for various variables can be expressed as follows.

$$x_i \le b_i, \quad i = 1,...,n \tag{2}$$

where the x_i variable could be the corresponding flow variables, and the boundaries b_i, are the corresponding restrictions. As a boundary condition the production of prime slabs is fixed in the model. The BOF charges has limitations, such as hot metal, pig iron, slag binders and scrap are set to the production parameters of liquid steel, to ensure the right quality for the final products.

2.2. Model description

In the iron and steel industry optimization models considering effects on the entire production process chain have been used for investigations of performance of different aspects like energy consumption, CO_2 emission, costs and environmental issues [4-8]. The system boundary of the whole system is to casted steel slab, the boundary of this study is to RS (Raw

Steel) from the BOF converter. The process units included are coking plant, blast furnace (BF), basic oxygen furnace (BOF), and continuous casting (CC), oxygen plant, and lime furnace, etc. [9]

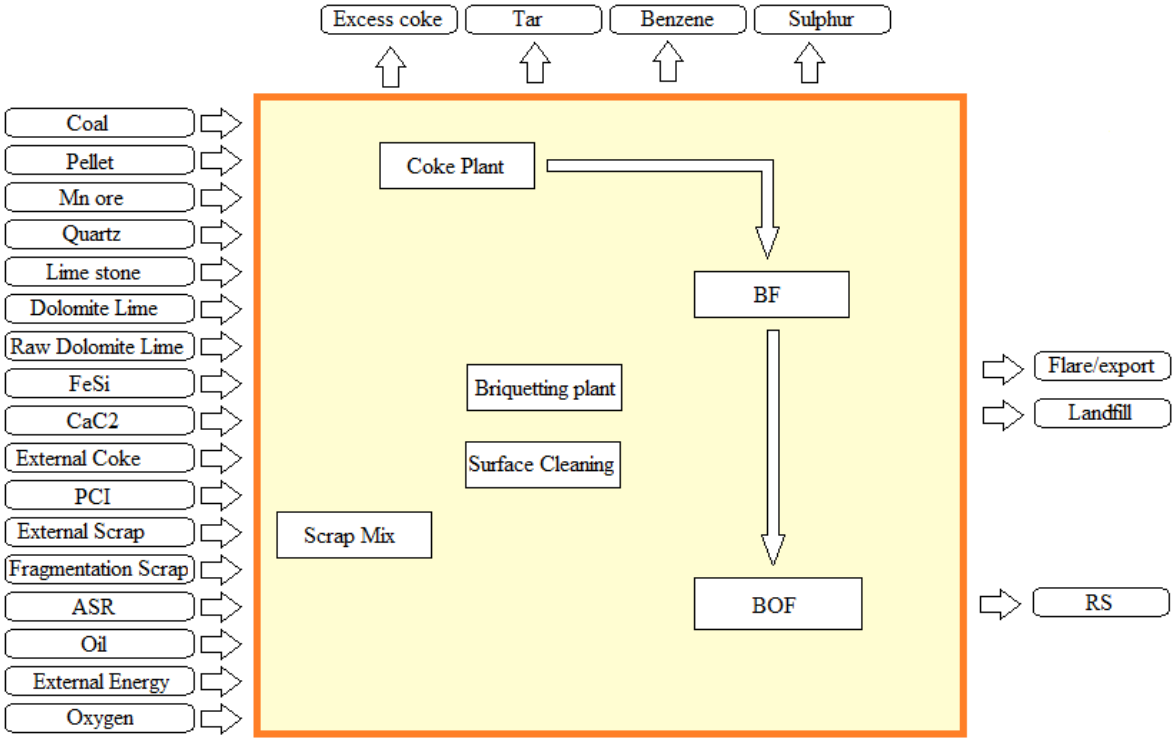

Fig. 1. Schematic outline of the modeled system.

The blast furnace is a very complex process and thus difficult to model. In this study different operational conditions for the blast furnace, which are feasible are defined. The model chooses and combines between these to overcome this problem. The prepared model is consisting of modules of process steps connected by mass and energy balances.

2.2.1. Operating conditions and modeling cases

The BF module is simulating the hot metal production in a Swedish BF with potential changes in briquette recipe and charged amounts. The BOF production process is described in the model by the mass and energy balance of the process. Different options can be optimized regarding the raw materials used due to the chemical composition. The coarse fraction of the generated BOF sludge is recycled through briquettes charged into the BF. The fine fraction of sludge from the BOF is normally land filled however it may be recycled in briquettes provided the zinc content is reduced sufficiently [10]. Including the scrap preheating unit in the system contributes to the scrap usage efficiency by the charging of preheated scrap. The introduction of the scrap surface cleaning unit in the model makes the use of shredded scrap as a scrap source to the BOF viable as it reduces the Zinc content in the scrap input to the BOF to zero. Scrap cleaning and preheating is performed on all the scrap charged to the BOF when the pre-treatment operation is implemented. Since the exhaust problem with the pre-treatment of scrap roughly identical with the combustion of many types of polluted fuels, Therefore the preheating process needs an advanced gas cleaning facility which gives that fossil fuel could be replaced with organic rest material. In this study ASR (automotive shredder residue) has been chosen as fuel in the preheating process since it has a good heating value and can be delivered in enough quantity to be interested for industrial use. Zinc sources

to the BOF sludge and dust in the model is the external scrap and the shredded scrap. Sources of Zinc to the BF come from the iron ore pellets and briquettes. The possible integration and effect of the preheating and surface cleaning operation is analyzed in five cases compared against a reference case, Table 2. The input of scrap to the BOF is limited to 17 % in the reference case, case 1 and 2, since it is a reasonable amount. To ensure that the use of internal scarp is preferred, the external scrap use is limited to maximum 5 % of the scrap charge into the BOF. The optimization cases have a higher degree of freedom on the BF operation and on the raw material input in the BOF.

Table 2. Case study.

Case	Comments
Reference Case	BF operation with briquettes
Case 1	BF operation with briquettes, scrap pretreatment implemented, otherwise as the Reference Case
Case 2	BF operation without by-product briquettes, otherwise as the Ref. Case
Case 3	Optimization of cost, Scrap preheating/surface cleaning available
Case 4	Optimization of CO_2, Scrap preheating/surface cleaning available

3. Results

3.1. System optimization

Data from the system modeling of production and differences in the analyzed cases is illustrated in Table 3. Regarding the coke making there are only minor differences between the reference production and the five different cases. The production rate of coke is the same in all five cases. Small change in coal mix volatile matter and ash result in small increase in COG production compared to the reference case. To increase recycling inside the steel plant by-product briquettes are used. Data from the system model of BF operation show that the HM (Hot Metal) production is higher in the reference case and in case 2 which is using no briquettes. Increased use of briquettes is positively affects the cost- and CO2 emission optimized cases by the lower lime stone and pellet consumption in the BF.

3.1.1. Iron ore pellet consumption

The use of iron ore pellets in the analyzed cases vary. Iron ore pellets has a CO_2 emission burden of 0.051 ton, as a comparison to scrap which has zero, se Table 1, since scrap is a recycled material origin from iron ore. In case 2 where no briquettes are produced the major amount of pellets is being utilized due to less recycling of iron bearing by-products. In the case 4, where CO_2 emission is the optimization target, the lowest amounts of pellets are used.

3.1.2. Scrap consumption

Producing steel from scrap is better from an environmental point of view since the energy demand for producing steel from iron ore is more than twice the energy required in scrap based production. Scrap usage for the cases is illustrated in Fig. 2. Shredded scrap may only be utilized in the cases when surface cleaning is implemented. The Reference case, case 1 and 2 has a limitation on the scrap usage to a maximum load of 17 %, where maximum of external scrap is 5 % in the BOF. The largest amount of scrap utilized is in case 4, which is the CO_2 emission optimization case. Since energy use and CO_2 emissions from integrated steelmaking is closely related, increased scrap utilization results in less CO_2 emissions.

Table 3. Optimization results coke making, Blast furnace and BOF route.

4. Discussion and Conclusions

4.1. Results from the objective function analysis

Table 4. Results from the objective functions.

Case	Cost (SEK/t slabs)	CO_2 (t/t slabs)
Reference Case	1409	1.936
Case 1	1365	1.892
Case 2	1461	1.994
Case 3	1357	1.887
Case 4	1359	1.884

Comparison of the different cases with the reference regarding the cost objective is illustrated in Table 4. The results show that the cost optimization case followed by the case 1, where surface cleaning is utilized for the reference case, is generating the lowest production costs. The highest costs are shown to be generated in case 2, where no briquettes are produced. This shows that the use of briquettes and surface cleaning of scrap improves the cost analysis. In Cases 3 and 4, the cost decreases approximately 4 %, compared to the reference case. However the model only considers raw material cost related directly to the process and does not consider investment cost, salary, administration and other external costs. Furthermore no credits are made in the model for decreased landfill costs. Analysis of the results from using CO_2 emission as the object function demonstrates only minor differences between the cases, as seen in Table 4. The case with the highest CO_2 emission is Case 2 where no by-product briquettes are used; consequently an increased pellet and coke consumption generate higher CO_2 emissions.

4.2. Conclusions

The system model shows the interaction between different processes, which gives an overview picture of the whole steel making route. The model is used to investigate changes in process conditions from making use of shredded scrap and ASR as input material in the steel making process. The system analysis shows that surface cleaning of scrap makes it possible to use shredded scrap and ASR or other combustible waste to replace fossil fuels as a cost and environmental efficiency choice. The implementation of surface cleaning and preheating leads to both increased possibilities for recycling materials, which otherwise is difficult to recycle and a more efficient use of energy in the steelmaking routes. Increased recycling of materials is efficient ways to reduce the energy demand, since it often replace virgin materials. The optimization of the model shows that both cost and CO_2 can be decreased when scrap pretreatment is implemented, however none of the analyzed cases is simultaneous minimizing cost and CO_2 emission.

Acknowledgement

This work is part of the ongoing projects in the Centre for Process Integration in Steelmaking (PRISMA) for the possibility to present this work. PRISMA is an Institute Excellence Centre supported by the Swedish Agency for Innovation Systems, the Knowledge Foundation, and eight industrial partners within the iron- and steel industry. This study has also received funding form the SSF ProInstitute programme.

Abstract: Based on statistics about fuel demand in industry sectors a method is developed for the estimation of additional combined heat and power (CHP) potential in the main industry sectors. Electricity generation costs of several CHP technologies are then compared to the purchase of electricity on electricity markets. It is found that additional heat potential for CHP is limited in the chemical industry; additional potential is found in the paper industry, food industry and in the manufacturing industry. Additional electricity potential for CHP can be found in all sectors as electricity to heat share is 0.34 at the moment and can be increased with new installations to more than 0.7. The share of renewable fuels used in CHP is highest in the wood and paper industry, additional potential can be found in several branches, but costs are high at the moment.
Markets can pick up CHP electricity in the short term and installations are profitable when long operating hours can be reached. Looking in electricity markets with a higher share of renewable energy sources (RES), operation become more restricted making new operation strategies necessary. Times with electricity prices below short term generation costs of CHP installations increase in the future, so that operation will be less profitable.
In short term CHP can bring additional CO_2 reduction, specific emissions are below new combined cycle units. In the medium to long term additional use of RES fuels and adapted operation strategies will be necessary to lead to further CO_2 reductions.

Keywords: *Combined Heat and Power, Renewable energy, Electricity market, Industrial applications*

1. Introduction

Reduction of CO_2-emissions in all energy consuming sectors will be necessary to fulfill short and long term goals to stabilize climate change. The usage of combined heat and power technologies (CHP) is promising to provide cheap CO_2 reductions especially in the industry sector, but is questioned to be the right technology option regarding long term goals [1]. The EU commission tries to promote CHP technologies with the CHP directive 2004/08/EC [2]. Various support schemes has been implemented throughout Europe [3] and the member states have to report progress to the EU commission. So far progress in the German industry sector has been limited although potential is expected to be large [4]. The purpose of the work is to identify reduction potential in the German industry sector based on fossil but also on renewable fuels. Furthermore the work analysed the possibilities of selling CHP electricity on future power markets with increasing renewable electricity generation.

2. Methodology

2.1. Approach

Statistics of final energy demand in Germany's industrial sector and estimates of the electricity demand in the future were used as a basis for the identification of the industrial heat demand and industrial CHP potentials [5], [6]. The final energy consumption less electricity demand was applied as an indicator for the heat demand. Sector specific energy intensity and indicators of sectoral economic development served as important influencing factors for the estimation of the future heat demand of the German industry. With the help of estimated heat demand the technical potential which could be covered by CHP was then projected (Fig. 1). In this projection the evaluated distribution of heat demand according to

the temperature levels for different industry sectors and technical assumptions of conversion efficiency and CHP heat coverage were also integrated.

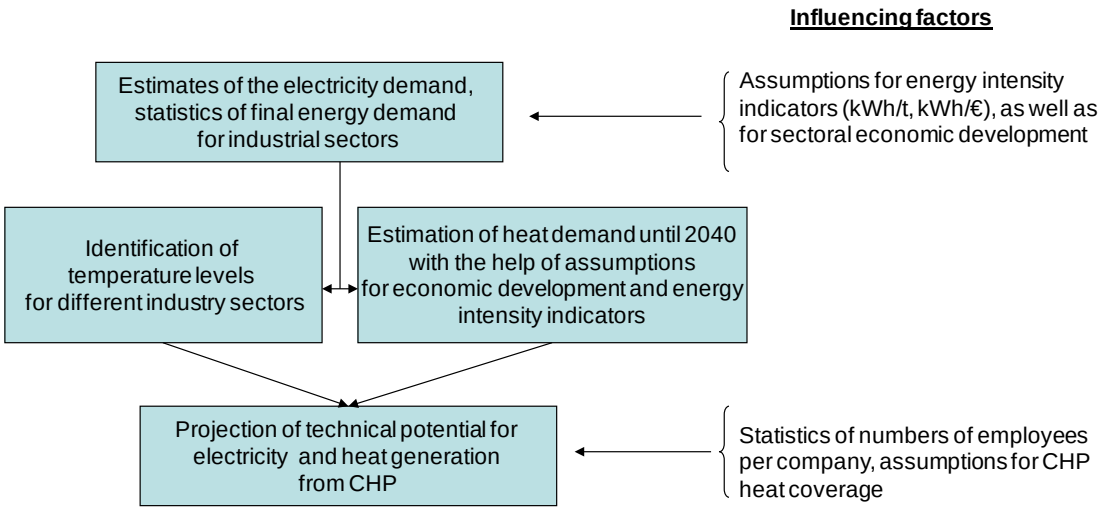

Fig. 1. Methodical approach for estimation of the heat demand in German industry and technical CHP potential.

The evaluation of heat demand according to the temperature distribution for different industry sectors was performed on the basis of previous estimations by Wagner et al. [7] as shown in Fig. 2. As one can see this temperature distribution provides indication for temperature levels of heat demand applicable for possible CHP generation. In this case the process heat at temperature levels lower than 500 °C and heat use for space heating and process water were of high relevance for the identification of the technical CHP potential.

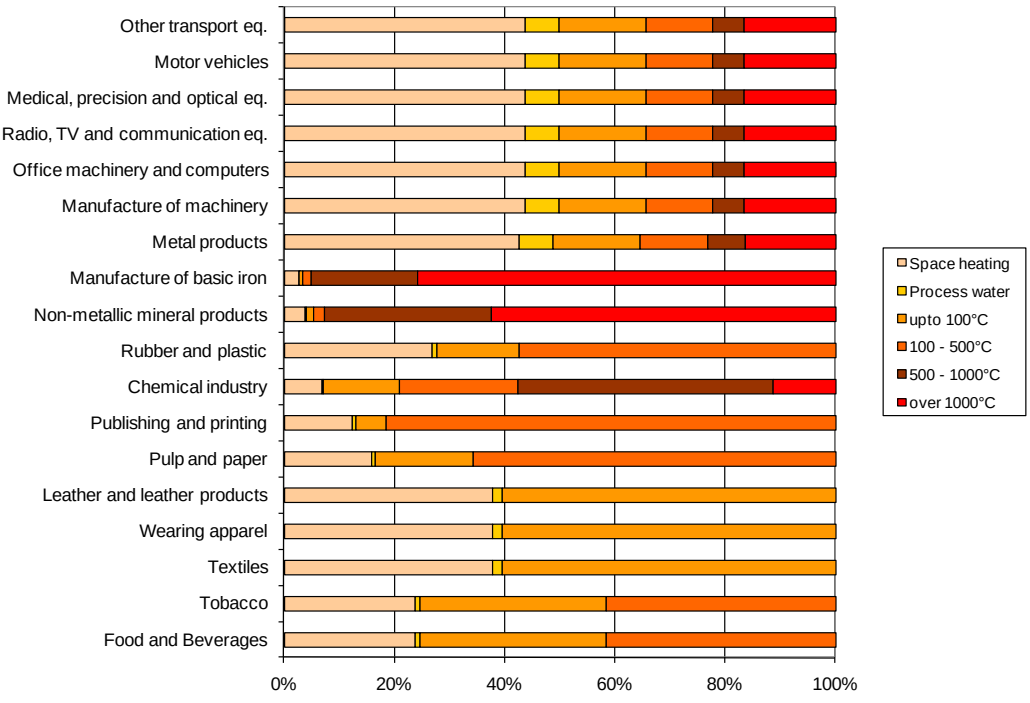

Fig. 2. Distribution of heat demand according to temperature levels and industry sectors in Germany in 2001.

Besides the technical potential also the economic (cost-effective) potential for CHP in the German industry is estimated. The parameters for the technical and economic potentials are defined as follows:

- Technical potential

The technical potential is derived from the useful heat demand applicable for CHP installations (< 500 °C). The conversion from fuel input (final energy) to useful energy is performed with the constant conversion efficiency factor of 90% which corresponds to the boiler efficiency of the separate heat generation. The CHP installation is assumed to apply for 75% of the heat demand. The rest of heat demand will always be generated via a peak load boiler.

- Economic (cost-effective) potential

Economic (cost-effective) potential is defined as a potential that can be supplied more economically attractive via CHP installation than with a separate electricity and heat generation. The base load price on the European Energy Exchange (EEX) served as a reference for electricity generation. The heat generation is considered via a heat bonus. These reference costs were calculated as saved fuel costs in case of separate heat generation. The life cycle of installations was assessed depending on installation type and was defined as 12 years for small installations and up to 20 years for large installations. The interest rate for calculations was set at 10%. Also the financial remuneration of CHP and grid access fees were taken into consideration. In Germany operators of CHP plants get a CHP premium on the electricity production guaranteed by law. The premium is paid to promote new installations of CHP power plants. It is typically between 1.5 and 2 €/MWh and is paid additionally to the revenues for the electricity production. The premium is paid for 4 to 6 years after the installation of the power plant. A comparison of costs and revenues is presented in Table 1.

Table 1. Costs and Revenues for identification of cost-effective CHP potential in the industry.

Costs	Revenues
Investment (life cycle of 12 – 20 years, 10 % real interest rate)	For electricity
Fixed operating costs	For heat
Variable operating costs	CHP premium
Fuel expenses	Avoided grid access fees
CO_2-allowances	

The impacts on the electricity markets are calculated using today's spot market prices from the EEX. Spot market prices for a future scenario with higher RES shares of 40 % have been calculated using the agent based electricity market model PowerACE [8].

2.2. Technical and economic specifications

The spectrum of industrial CHP technologies varies from CHP installations with 1 MW of electric power output to large power plants with several hundred MW of electric power output. In this research the complete spectrum of various CHP technologies available for combined heat and power generation was analysed. For that purpose so called reference installations were defined and their various technical and economic parameters were

described. In Table 2 one can see a clear cost decrease with growing power output of an installation.

Table 2: Parameters of CHP installations for output range from 2 to 220 MW (el).)

Parameters	**Unit**	**CC-GT**	**CC-GT**	**OC-GT**	**CC-GT**	**OC-GT**	**Gas Engine**

3. Results

3.1. Additional technical CHP potential

Today the major industry sectors using CHP power plants are the chemical industry, the paper industry and the food industry in Germany (see Fig. 3). They provide around 74 % or more than 19 TWh of the CHP electricity production in the industry sector in 2009 [6]. Additional electricity generation is possible without an increase of the heat generation as the average electricity to heat factor of the CHP installations is only ca. 0.34. The modernization of old CHP devices can increase the electricity to heat ratio above 0.7 and double the electricity generation.

Next to modernization of old CHP generation units, there is also the possibility to find new heat sinks that can be supplied by CHP units. It is found that additional heat potential for CHP heat generation is limited in the chemical industry, some additional potential is found in the paper and food industry (see Fig. 4). Further additional heat potential is found in the manufacturing industry. Final energy demand in the industry sector has been 700 TWh in 2008 with around 214 TWh of low temperature heat. Around 45 % of this low temperature heat is already supplied by district heating or by CHP auto producers. The technical potential to increase CHP heat production is then around 118 TWh. Only a small part of it is a cost-effective and realizable potential. In some sectors like metal or glass industry a lot of high temperature heat is available that could be used first before new CHP units would be installed. In other sectors with small companies the installation of CHP units might not be profitable as only small units with shorter operation times could be used.

Source: Own figure based on [5, 6, 7]

Fig. 4. Provision of low temperature heat by CHP heat generation, district heating and available CHP heat potential in major industry sectors in 2008

3.2. Renewable fuel use in the industry sector

Until now renewable fuels have only a very limited share of 4 % in the industrial sector corresponding to around 27.5 TWh (final energy demand) in 2008 [5]. It increased from 15.5 TWh in 2003. Most of it is used in the wood and furniture industry followed by the pulp and paper industry (see Table 3). In this figure fuel use for heat production in CHP power plants is included. The fuel use for CHP electricity production is covered by the statistics for the power plant sector. The renewable fuel use for electricity production in industrial power plants was 7.8 TWh in 2008 (with 3 TWh in 2003).

Table 3. Distribution of renewable fuel use in major industry sectors in Germany 2008.

Sector	Wood/ furniture	Paper	Chemistry	Cements	Food	Other
Share [%]	37	27	22	8	3	3
Total [TWh]			27.5			

3.3. Renewable CHP generation

The share of renewable fuels used in CHP power plants is covered in the statistic [6] together with other fuels like waste (refuse-derived fuels, RDF). In the past the use of renewable and RDF fuels has slightly increased from 25.3 TWh in 2003 to 29.8 TWh in 2008 (see Fig. 6). In 2003 around 24 % (6 TWh) of the 25.3 TWh are renewable fuel due to statistics from EUROSTAT [9]. This corresponds to almost 5 % of the fuel used in CHP power plants. For 2008 no statistics are available. Under the assumption that the fuel use in CHP power plants has increased similar to the total renewable fuel use in the industry sector, it should be around 11 TWh in 2008. Progress in the sector is difficult to estimate, but there should have been some in the past.

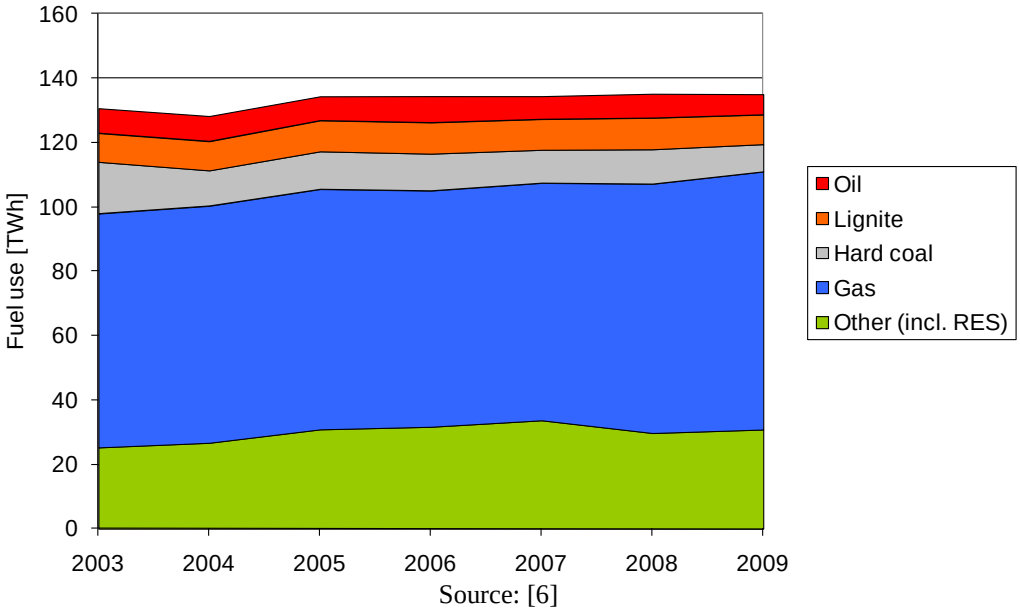

Fig. 5. Fuel use in CHP power plants from 2003 until 2008 in the industry sector in Germany

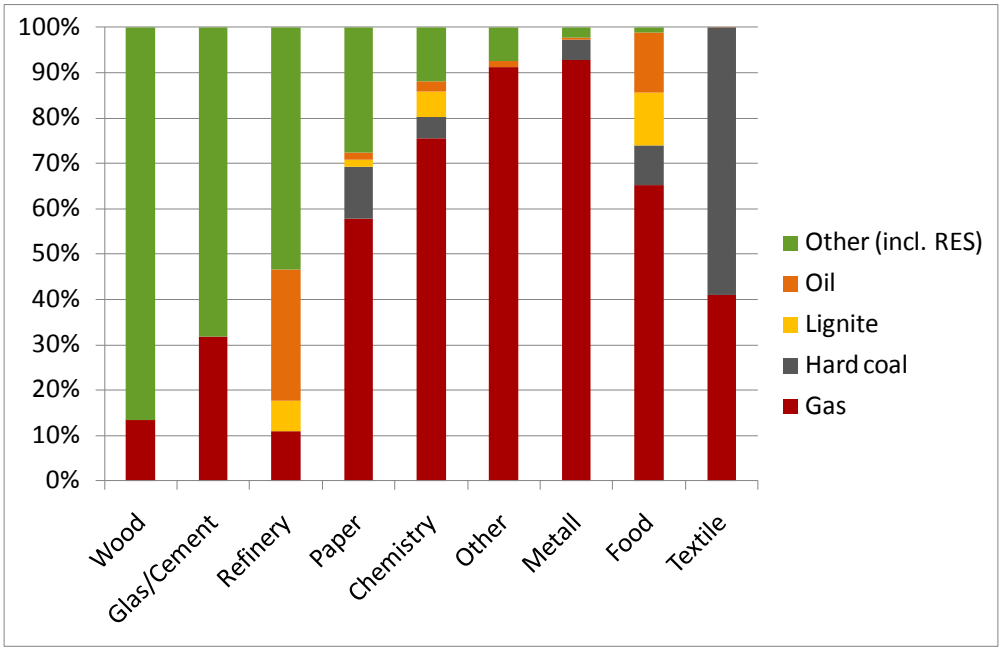
High shares of renewable fuel use in CHP power plants can be found in the wood industry and in the paper industry (see Fig.7). Renewable fuels are also used in the chemical industry. Additional potential in the wood and paper industry is very limited as the major waste material from production processes is already in use [10]. An increase of renewable fuels in CHP power plants can be done with external biomass like wood chips or pellets. Another option is the usage of biogas. Until now this option has not been used as renewable fuel costs were much higher than fossil fuel prices.



Source: [6]

Fig. 6. Share of renewable fuel use in CHP power plants in major industry sectors in Germany 2008

3.4. Economic potential and CO_2 savings

The economic assessment is driven by the size of the CHP units as investment costs typically decreases for larger units. Furthermore utilization decreases costs. Electricity production costs range between 10 Cent/kWh(el) for small CHP units (500 kW) and 6 Cent/kWh for big CHP units (400 MW), when units are in operation for 4000 h/a. If the value of the heat generation is estimated with saved fuel costs then electricity production costs are typically reduced by 2 to 4 Cent/kWh. In this case, CHP units are profitable compared to the electricity purchase. With a higher utilization the benefits typically increase.

Markets can pick up CHP electricity in the short term and installation are profitable when long operating hours can be reached. Profit margins are in the range of 13 to 25 €/MWh for more than 5000 hours per year.

Looking in electricity markets with a higher RES share of 40 %, operation become more restricted making new operation strategies necessary. Times with electricity prices below short term generation costs of CHP installations increase in the future, so that operation will be profitable in fewer hours than today. This is because natural gas and CO_2 allowances will be more expensive. This will be partly compensated by higher revenues for electricity, but the increase of electricity prices will be limited due to wind and solar power production. Typical profit margin increases up to 40 €/MWh, but can be reached only 2500 – 4000 hours per year.

The heat bonus for CO_2 emissions on the CHP heat generation is calculated using a reference heat technology. Assuming gas as fuel and a 90 % efficiency of the heat generation the heat bonus is 223 g CO_2/kWh(heat). Resulting CO_2-Emissions for the electricity generation reach 230 – 280 g CO_2/kWh(el) depending on the CHP technologies. Compared to the German electricity mix with specific emissions of 575 g CO_2/kWh(el) savings up to 60 % can be reached. A comparison with a modern combined cycle power plant, specific emissions are at 340 - 350 g CO_2/kWh(el), leads to a reduction of ca. 35 %.

4. Discussion and conclusions

In short term CHP can bring additional CO_2 reduction in the German industry sector as specific emissions are below the actual electricity mix and also below new combined cycle power plants with no heat or steam generation. As gas is already the dominant fuel source in the industry sector savings in the heat production are limited. Major reductions can be achieved by the substitution of fossil electricity generation outside the industry sector. Renewable fuel use is already done in sectors that have renewable waste from its production process. These potentials within the different sectors are already used today, so that an increase of renewable fuels can be mainly achieved by using additional renewable fuels like wood chips, pellets or biogas from outside the industry sectors. In the medium to long term additional use of RES fuels and adapted operation strategies will be necessary to lead to further CO_2 reductions.

Abstract: A new challenge to reduce energy usage has emerged in Swedish industry because of increasing energy costs. Energy usage in the Swedish powder coating industry is about 525 GWh annually. This industry has a long and successful record of working towards reduced environmental impact. However, they have not given priority to energy saving investments. Electricity and LPG, for which end-user prices are predicted to increase by as much as 50 – 60% by 2020, are the main energy carriers used in the plants. This paper presents the results of two detailed industrial energy audits conducted with the aim of quantifying the energy efficiency potential for the Swedish powder coating industry. Energy auditing and pinch analysis methods were used to identify possible energy housekeeping measures and heat exchanging opportunities. The biggest users of energy within the plants are the cure oven, drying oven and pre-treatment units. The energy use reduction by the housekeeping measures is 8 – 19% and by thermal heat recovery an additional 8 – 13%. These measures result in an average energy cost saving of 25% and reduction of carbon dioxide emissions of 30%. The results indicate that the powder coating industry has a total energy efficiency potential of at least 20%.

Keywords: *Powder coating, energy audit, pinch analysis, energy efficiency*

1. Introduction

The Swedish electricity market was liberalized 1996 in order to increase competition. The European electricity market deregulation was delayed until 2004 before it was liberalized for industrial consumers, which has led to increased electricity prices in Sweden [1]. Industry accounts for 40% of Sweden's total energy use, which is forecasted to increase due to greater industrial demand. Hopefully new eco-efficient technology as well as increased energy efficiency will reduce the rate of increase of energy usage in industry [2].

The 20-20-20-targets have been formulated by the EU commission in order to achieve their energy policy vision: competitiveness, sustainability and security-of supply. The targets represent 20% reduction in energy use and at least 20% share of renewable energy supply based on the 2005-levels and a 20% reduction in greenhouse gas emissions based on the 1990-level. Key areas of the EU targets are in the electricity and gas markets, renewable energy sources, consumer behavior and closer international cooperation. All EU countries are encouraged to act and coordinate activities in order to try to distribute the burden but also its future dividends. Policy instruments have been introduced in Sweden to achieve these goals and guide the energy use in a sustainable direction, and decrease emissions to reduce climate change. The instruments include energy, carbon and sulfur taxes but also the electricity certificate system, program for Energy Efficiency (PFE), the energy audit program, technology procurement, policy instruments for buildings and transport and information [3]. The end user prices of electricity and liquefied petroleum gas (LPG) is predicted to increase by as much as 50 - 60% by 2020 [4]. This is another driving force in implementing energy efficiency measures. Beside the environmental and economical benefits from making industrial energy usage more efficient there are also marketing benefits as customers begin to require energy-efficient production within the powder coating industry [5].

Experience from Swedish research in industry reveals that the energy saving potential among non energy-intensive companies ranges from 15-50% [6-7]. No figures are available for the energy saving potential in the energy-intensive powder coating industry. The aim of this paper is to quantify energy efficiency potential for the Swedish powder coating industry based on two thorough industrial energy audits. The research was conducted using multiple case study analysis, energy audit as well as pinch analysis.

The Swedish powder coating industry includes approximately 350 plants using more than one metric ton of coating powder. These currently accounts for a combined energy usage of 525 GWh/year, corresponding to 1,5 GWh/year per plant [5]. This sector has successfully implemented eco-technology as a result of legal requirements. However, so far they have not given priority to energy saving investments. A powder coating plant usually includes pre-treatment, drying oven, powder box and cure oven, e.g. see Fig. 6. In the pre-treatment unit, the parts that are to be coated are washed in a degreasing step with alkaline washing solution of around 60°C. The pre-treatment also includes a number of rinsing steps. The parts go through a drying oven that has a temperature of around 120–150°C. Then one layer of powder is applied in the powder box and at the end of the conveyor the parts go through a cure oven that has a temperature of 200°C. After the cure oven some plants have a cooling zone where cold air is blown over the parts to make them cool faster [8].

Two companies were selected for this multiple case study analysis [5]. Company A uses LPG as fuel for firing an immersed heater in order to heat their first pre-treatment bath. Company B uses district heating instead. Direct burners using LPG heat the drying ovens to a temperature of 150^{o}C and 120^{o}C respectively. The cure oven is heated by electricity to 200^{o}C at Company A while Company B uses LPG with direct burners. Company B also has a primer box, primer oven and cooling zone while Company A has a liquid finish box between the drying oven and the powder box. All components besides heating accessories are driven by electricity.

2. Methodology

The electricity use is based on instantaneous measurements for the different units of the process as well as on logging of selected components and it was performed during one week for each company. The values from the logging were used to evaluate how many hours the different parts of the process are in use each day as well as to get an average value for the electricity usage. The calculated energy use of electricity was compared with the electricity invoices. This comparison made it possible to extrapolate the logged and instantaneous measurements to the usage of one year. The usage of district heating and LPG was based on the monthly values for the consumption stated on the invoices. Invoices for one year were compared for all three energy carriers.

Pinch analysis is a tool to analyse industrial process systems and determine how much heat that must be added, how much excess heat must be removed and how much heat that can be recovered within the process. Pinch technology is also a useful tool to investigate how to design a heat exchanger network in order to achieve maximum heat recovery. In this project the heat content in the different streams was estimated based on process data and after this different possible options for heat exchange were investigated. The heat usage depends on the different production schemes, when the processes are used, for how long and the distance between them. In the end the options are weighed against each other based on energy cost savings and capital investment required.
The payoff period and the net present value (NPV) method were used to evaluate the investments. The payoff period quantifies the time period necessary for the investment's

energy cost savings to cover the initial investment cost. The net present value method evaluates the viability of an initial investment by comparing it with all future energy related cash flows. All future cash flows are discounted using the interest rate and a reference period of time. The net present value ratio (NPV divided by initial investment) is used to compare different investments. The investment with the maximum ratio is the most attractive. In the base case, the investments are analyzed assuming constant energy prices over the lifetime of the investment. In a sensitivity analysis, the analysis accounts for the development of energy prices during the years 2010 – 2020.

3. Results

The energy audit showed that 77 – 86% of total energy usage occurs in the core production processes, whereas 14 – 23% is connected to the support processes. The first graphs illustrate the electricity use during an average production day. As can be seen in Fig. 1a, company A has two peaks for the production processes during the day. This is because they operate with two shifts and they have a large variation of products. Company B, e.g. Fig. 1b, has a more homogeneous production and single-shift operation. Significant differences can be seen when analysing how the electrical power load is distributed between the process units during operating hours, e.g. Fig. 2. For Company A the cure oven is the largest consumer of electricity and for Company B it is the powder box. For Company A the cure oven can be used at three different temperatures due to combination of liquid finishing and powder coating. The powder box in Company B has a high ventilation requirement because of a more open construction and employees working inside compared to Company A. Figures 1 and 2 are comparable when production is at its full capacity.

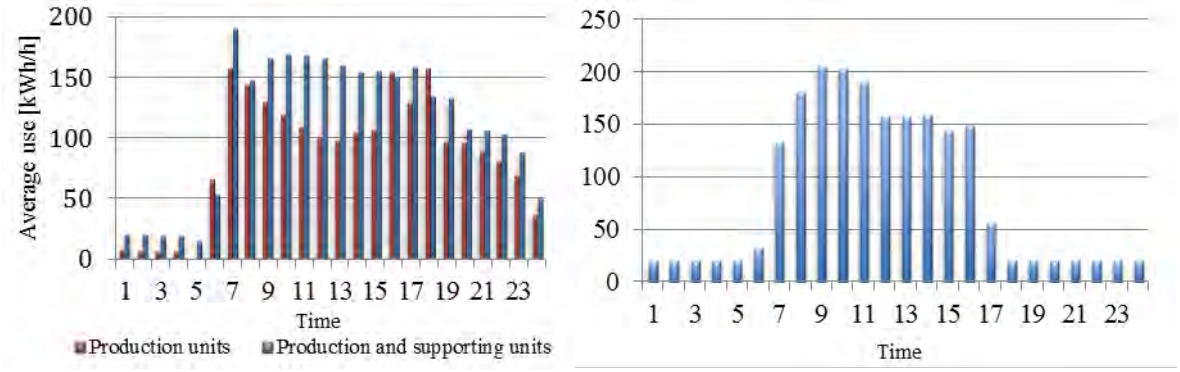

Fig. 1. Electricity use during an average production day for Company A (left) and B (right).

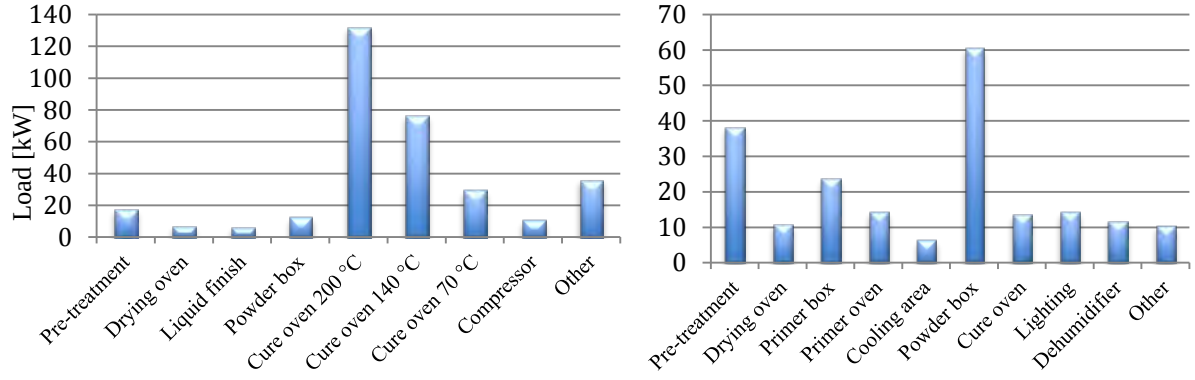

Fig. 2. Load balance for electricity during production for Company A (left) and B (right).

In the energy balance all energy sources are included, i.e. electricity and LPG for Company A and electricity, LPG and district heating for Company B, e.g. Fig. 3. As can be seen it is the pre-treatment, drying oven and cure oven that uses most energy. Together these three units

accounts for about 70% of the total energy supply for both companies. When using liquid finishing (65% of the time) the pre-treatment and drying oven are turned off for company A, which leads to a lower demand for LPG for this company. For company B it is the primer box, primer oven and cooling zone that can be turned off during periods.

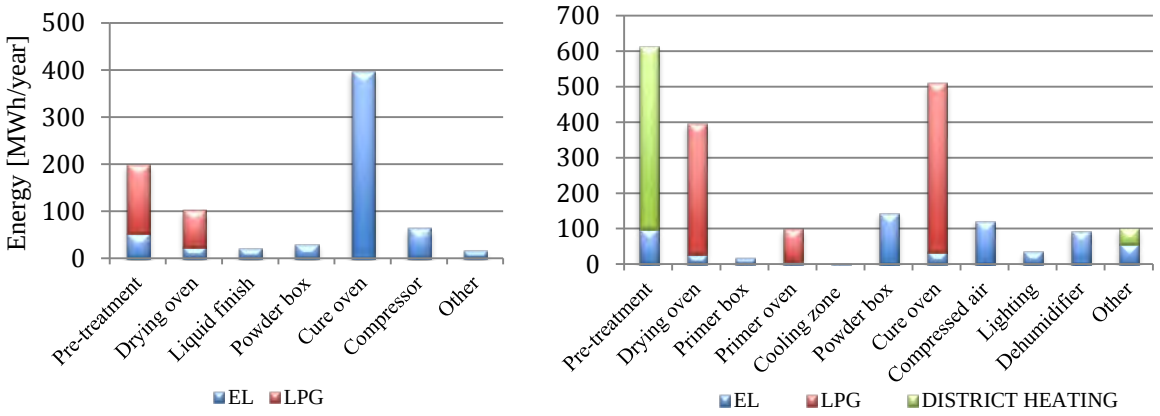

Fig. 3. Energy balance during one year for Company A (left) and B (right).

Figure 4 shows the total energy use for the two companies. Both companies have a significant use of electricity during downtime. This is due to that both have dehumidifiers that are on all the time as well as charging of trucks during the nights.

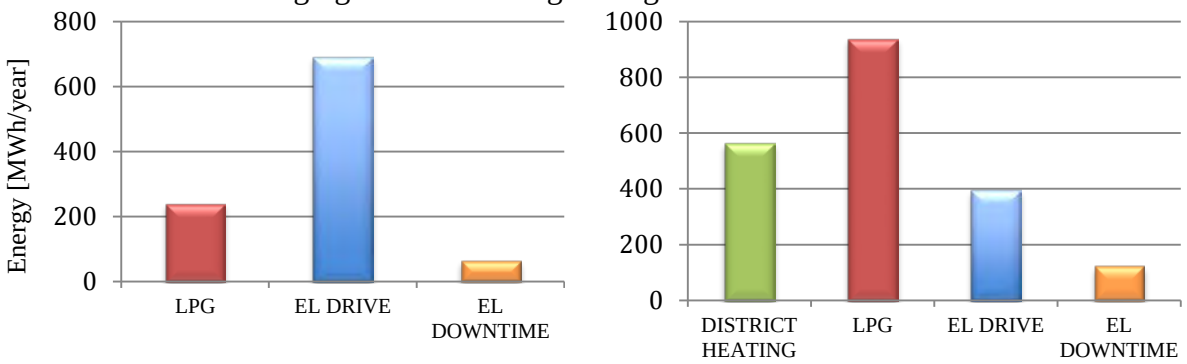

Fig. 4. Total energy use per year for Company A (left) and B (right).

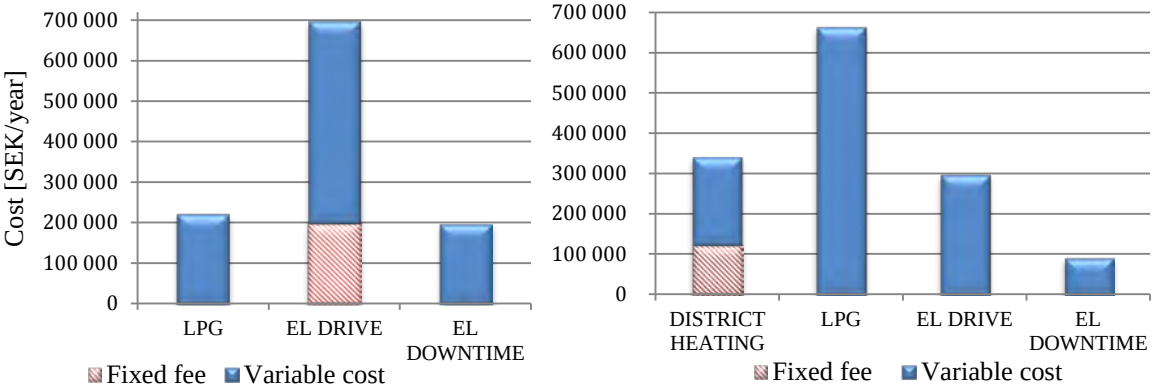

Fig. 5. Energy cost per year for Company A (left) and B (right).

The energy cost can be seen in Figure 5 above. Company A has a fixed fee for electricity but not for LPG. Company B has a fixed fee for district heating but not for the other energy sources. Electricity is the highest energy cost for company A while LPG is the highest cost for company B.

The specific energy usage indicators have been chosen based on a national project within Swedish industry named ENIG (EN in Groups), see Table 1. One main difference between the two companies is that Company A uses half as much energy per year but has twice as much

production time. This is because Company A combines other varnishing techniques and offers packing and masking. Company B only uses powder coating technology which is more energy demanding. Since the turnover is similar the second indicator depends mostly on the energy use. The mass flow of parts is more than twice as high for Company B compared to Company A, which affects the third indicator (specific energy usage per ton of product).

Table 1. Specific energy usage indicators.

Company	Energy use per		
	Production time [kWh/h]	Turnover [kWh/kSEK]	Parts [kWh/Ton]
Company A	230	47	185
Company B	973	107	135

The reduction of CO_2-emissions for the suggested measures are based on values of 234 kg CO_2/MWh of LPG, 770 kg CO_2/MWh of electricity and 0 kg CO_2/MWh for district heating. Electricity has a high value due to that it is assumed to be electricity on the margin and district heating has zero emissions due to production from biomass. The energy prices can be seen in Table 2. The prices for 2010 is stated on the companies invoices and the increase until 2020 is expected to be 60% for LPG, 50% for electricity and 30% for biomass [4].

Table 2. Energy prices for 2010 and 2020.

Company	Energy price [SEK/MWh]					
	El. 2010	El. 2020	LPG 2010	LPG 2020	DH 2010	DH 2020
Company A	735	1103	953	1525		
Company B	755	1133	707	1131	391	508

Energy housekeeping measures do not include heat exchanging and are primarily targeted at identifying better operational practices. The potential energy usage reduction, based on such measures was estimated at 8 – 19%, e.g. Table 3.

Table 3. Energy housekeeping measures (compared with the total energy use for each company).

Measure	Reduction potential		
Company A	Energy [MWh/year]	Running cost [SEK/year]	CO_2-emission [Ton/year]
Lighting	22	17 000	17
Standby	65	49 000	50
Production planning	100	74 000	77
Drying oven	8	6 000	2
Total	195 (19%)	147 000 (15%)	146 (23%)
Company B			
Lighting	18	14 000	14
Dehumidifier	31	24 000	24
Powder box’s ventilation	13	10 000	10
Production planning	44	33 000	34
Fans	16	12 000	13
New powder box	44	33 000	34
Total	166 (8%)	176 000 (9%)	129 (26%)

Lighting measures include switching to low energy lighting, removing it in areas where it is not necessary as well as turning off when not in use. Both companies have several

applications on standby during nights and weekends, for example compressor and dehumidifier. Complete shut-off of such equipment can lead to substantial energy savings. Company B can turn off the powder box ventilation during breaks. Production planning could reduce the energy usage by having one start per day and process unit. Using a lower temperature in the drying oven for Company A could decrease energy usage but it also generates a risk of lower coating quality. The fans to the drying oven and cure oven are oversized for Company B and changing them could reduce the plant's power load. If Best Available Technology (BAT) is adopted for the powder box, electricity use for the ventilation within the box could be reduced by 30% and the compressed air usage by 45%.

Pinch analysis was used to identify opportunities for heat recovery by heat exchanging. Two possible heat recovery cases were investigated, e.g. Table 4. Case 1 involves heat exchanging incoming and outgoing airflows in the cure oven and drying oven, e.g. Fig. 6.

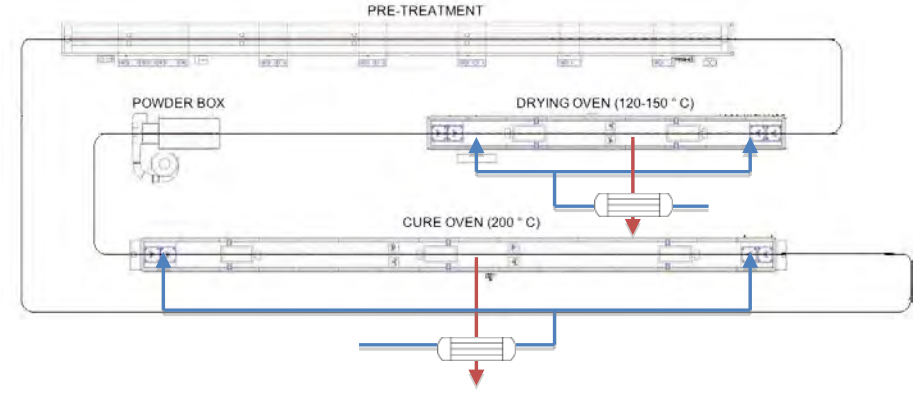

Fig. 6. Case 1 Proposed heat exchanging measures for powder coating process.

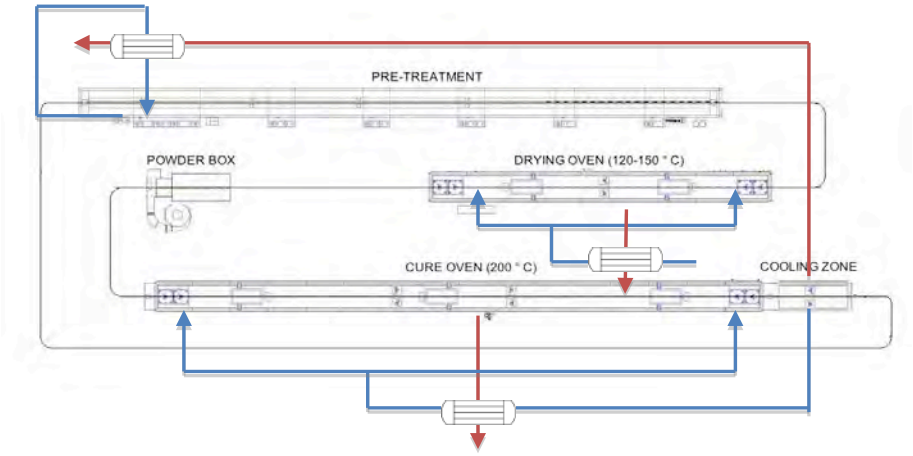

Fig. 7. Case 2 Proposed heat exchanging measures for powder coating process.

Table 4. Saving potentials for heat recovery cases.

Measure	Reduction potential		
	Energy [MWh/year]	Running cost [SEK/year]	CO_2-emission [Ton/year]
Case 1 Company A	121	90 000	76
Case 2 Company A	128	85 000	73
Case 1 Company B	140	100 000	33
Case 2 Company B	251	146 000	28

Case 2 includes a cooling zone after the cure oven. The large airflow from the cooling zone can be divided and used as preheated ingoing air to the cure oven as well as for heat exchanging to heat the pre-treatment bath. For the drying oven the heat exchange is the same as in Case 1, e.g. Fig. 7.

The economic assessment, e.g. Table 5, shows that the two cases for heat recovery are profitable for both companies. However, Case 1 has a much higher NPV and NPVR than Case 2. The total savings are presented in Table 6, showing that Company A has a higher potential for reduction of energy use due to more variations in the production as well as larger hot streams out from the ovens.

Table 5. Economic assessment with expected increased energy prices until 2020 for Company A (interest rate 10%) and Company B (interest rate 15%).

Measure				
Period 10 years	Investment cost [SEK]	Pay off period [year]	NPV [SEK]	NPVR
Case 1 Company A	135 000	0,9	795 000	5,90
Case 2 Company A	450 000	3,1	440 000	1,00
Case 1 Company B	150 000	1,2	460 000	3,08
Case 2 Company B	495 000	2,8	400 000	0,80

Table 6. Total savings for energy housekeeping measures plus thermal heat recovery cases (compared with the total energy use).

Measure	Reduction potential		
	Energy [MWh/year]	Running cost [SEK/year]	CO_2-emission [Ton/year]
EHK+Case 1 Company A	316 (32%)	237 000 (26%)	220 (35%)
EHK+Case 2 Company A	323 (33%)	232 000 (25%)	219 (34%)
EHK+Case 1 Company B	306 (16%)	276 000 (20%)	162 (26%)
EHK+Case 2 Company B	417 (21%)	322 000 (23%)	157 (25%)

4. Concluding discussion

The energy audit shows that the production processes use a substantial amount of energy 77 – 86% whereas the support processes use 14 – 23%. For the two companies investigated the energy usage can be reduced by 8 – 19% with energy housekeeping measures. Thermal heat exchange can reduce the energy use by an additional 8 – 13%. In total this gives energy savings of around 30% for company A and 20% for company B.

Improved production planning will make a large impact on energy usage. For company A this could lead to a reduction of the second electricity use peak, e.g. Fig. 1a. For company B turning on the primer part only once a day could save energy. Another measure for company A is to completely turn off equipment that is not used. For company B the powder box can be turned off during breaks. These are measures that can be implemented by changing the routines etc. within the companies. In this study, energy housekeeping measures have been shown to achieve the same or higher energy savings compared to thermal heat recovery.

Benchmarking shows that the most efficient way of heat exchanging is within the same part in the process. This will reduce the investment costs as well as contribute to a flexible process. Installing a cooling zone after the cure oven will be profitable but there are other investments

that are even more profitable. The fact that the cooling zone will give a better working environment should be taken into account. The benchmarking also shows that the airlocks from the ovens usually have too small heat content to be efficiently heat exchanged against ingoing air to the ovens. The contaminations that follow the airlocks also prevent using this air as ingoing air. Another reason is that there is a risk that to much air is pushed into the ovens if airlocks are used. However, there might be a possibility to use them for heat exchanging against facility ventilation air to reduce demand for space heating. To be able to implement thermal heat exchange further study is necessary in order to investigate the impact of contaminants released from the powders when cured in the cure oven. There is a possibility that these contaminants will stick in the heat exchangers and tests must be conducted to see if filters are required upstream from the heat exchangers. It should be noted that companies in Finland have successfully used the airlocks for space heating [5].

The economic results are based on an interest rate of 10% and 15% respectively. A lower interest rate would increase the net present value and the net present value ratio. The results in these projects show that Case 1 is the best investments from an economical perspective for both companies. However, Case 2 has other positive effects that are not accounted for in the calculations. For example a cooling zone would substantially improve the working environment by reducing the heat that is emitted to the facility. Results indicate, based on benchmarking between these two projects, that the powder coating industry may have an energy efficiency potential of 20% which corresponds to total energy savings of at least 105 GWh/year for the sector.

Abstract: This work represents a true case study and analysis of the technical and energy managerial aspects of recommended designs of the production lines of a steel factory in Jordan. A modern structure of a control system based on SCADA (Supervisory Control And Data Acquisition) technology is proposed. Furthermore, the mechanical and electrical maintenance sections in the factory were reviewed due to their major effects on the production cost and energy consumption of the factory. This study was performed in two main phases: The first phase contains the collected data and process assessment that were undertaken by traditional direct observation and activity categorization, while the second phase gave details on the proposed control methodology in terms of design and architecture.
Moreover, a proposal on maintenance planning and procedure program was also included in this study in order to reduce the time and accordingly the cost of maintenance. The steel factory studied produces various steel products such as: Concrete Reinforcement Steel Bars (Rebars), Flat & Square Bars Section which includes standard flat bars, standard square bars, and plane round bars, in addition to Wire mesh in different sizes and steel billets. In steel production industries, two automation levels can, in general, be identified. The first level involves the electromechanical actuation of the devices in the production plant; this level of automation is currently available in every plant. The second level involves the supervision of the production process; this level of automation is less frequent and is generally only partial. In fact, steel production involves a variety of complex physical phenomena, described by sophisticated mathematical models which are rarely usable to derive real-time advice for process supervision and control. Most operators' support systems for steel production are represented by simple technologies such as microprocessor-based systems.
Based on the outcomes of this study, the factory purchased a new melting furnace of (60) tons capacity instead of the (30) tons capacity melting furnace used in the factory before the study. The factory is considering also the purchase of a scrap press in its new budget in order to improve scrap quality before melting it; in order to reduce the rate of consuming the furnace electrodes. Also, the maintenance section will be restructured by merging electrical and mechanical maintenance sections into one section headed by the deputy of the factory manager.

1. Introduction

To maintain an efficiently operating unit and avoid failure of critical equipment, especially modern steel industry equipment, the focus has clearly shifted over the years, from Breakdown Maintenance, i.e. repairing the equipment after its malfunctions, to Preventive Maintenance, i.e. fixing the equipment according to planned maintenance schedule. The next trend was Computerized Maintenance Management Systems (CMMS), and the latest trend encompasses asset management and maintenance, supported by various methods of Condition Based Maintenance Systems (CBMS) and in-service inspection processes. CBMS or Predictive Maintenance methods are an extension of preventive maintenance and have been proved to minimize the cost of maintenance, improve operational safety and reduce the frequency and severity of in-service machine failures. The basic theory of condition monitoring is to know the deteriorating condition of a machine component, well in advance of a breakdown, for proactive maintenance. A conventional integrated steel plant has a vast array of equipment. The plant is a conglomeration of smaller units, each in itself complete and self-contained. These constitute Coke Ovens, Coal Chemicals, Sinter Plants, Furnace, Steel Melting Shops, Continuous Casting Machine, Tonnage Oxygen Plants, Plate Mill, Hot Strip Mill, Cold Rolling Mill, other secondary mills, Captive Power Plants and a host of other

departments. Every piece of equipment needs special care and attention, characteristic to it. The Coal Chemicals unit has Gas Boosters and Exhausters that handle coke oven gas, a highly inflammable commodity, whereas Sinter Plant Blowers and Waste Gas fans handle air containing highly abrasive sinter dust. The Turbo Alternators of Captive Power Plant require round the clock vigilance involving a variety of parameters. Seemingly innocuous Forced Draft & Induced Draft fans of the Reheating Furnaces also assume significance because of their criticality in application. Failure of these fans may lead to cut down of Hot Strip Mill/ Plate Mill production by 33 - 50 percent. Under the current business environment, cost competitiveness of steelmakers has assumed a priority role. As a global phenomenon, effective maintenance management has been accepted as the key to corporate strategy for reduced costs. This has led to integration of maintenance management function with production and business problems, not just equipment problems. With this realization that maintenance management can cost 35 - 40 percent of revenues and, in most cases up to 15 percent of unit production cost, steel companies are increasingly opting for new maintenance technologies which can be effectively and relatively easily implemented for reduced costs and increased profitability. According to industry estimates, a 10 percent reduction in maintenance costs translates to a 30 percent increase in profitability.

From the previous discussion, the need for introducing new technologies to the steel production is definite. This study provided the factory with some state-of-the-art technologies which can be adopted into the steel production processes in order to improve the product quality, minimize the need for electrical energy and human resources, reduce maintenance time and cost, and increase reliability and real-time data accuracy. The Jordanian factory is located in Zarqa area, and employs (324) technicians, engineers and administration employees. The main function of the factory is to melt Scrap (collected used steel pieces) in an electric furnace of (30) tons capacity, then cast molten iron in moulds to obtain steel billets. The steel billets are then manufactured in a sister company factory to produce concrete reinforcement steel bars (Rebar) in different sizes using rolling and extrusion, flat and square bars, and wire mesh. This factory, which was manufactured by a Turkish company, is a new one that started production in 2008. The current production capacity is around 10,000 tons of steel billets per month.

Employing SCADA system into the melting and casting processes has a good impact on the product quality, minimizing the need for human resources, reducing maintenance time and cost; increasing reliability, and real-time data accuracy. This technology should provide the following:

- Continuous (momentarily) monitoring of the state of the process and of the plant;
- Displaying warnings and alarms, at a sufficiently high level of abstraction;
- Giving advice as needed to the metallurgical management of the process.
- Generating historical reports.

Nowadays, there are two main industrial processes to produce steel: The first one, which is known as integrated steel plant, produces steel by refining iron ore. This ore-based process uses a blast furnace. The other one, which is steel-making from scrap metals, involves melting scrap metal, removing impurities and casting it into the desired shapes. Although, originally the steel production in the electric arc furnaces (EAFs) was applied mainly to the special steel grades, the situation has changed with tap's size increase, and the high productivity that has been reached progressively. This has allowed significant cost reduction, diminishing consumption of energy, electrodes and refractory. At present, electric furnace combined with chemical additives, allows to make a very important part of the worldwide steel production on

the basis of the massive recycling of the iron scrap. Under the current business environment, cost competitiveness of steelmakers has assumed a priority role. As a global phenomenon, effective maintenance management has been accepted as the key to corporate strategy for reduced costs. This has led to integration of maintenance management function with production and business problems, not just equipment problems. With this realization that maintenance management can cost 35 - 40 percent of revenues and, in most cases up to 15 percent of unit production cost, steel companies are increasingly opting for new maintenance technologies which can be effectively and relatively easily implemented for reduced costs and increased profitability. According to industry estimates, a 10 percent reduction in maintenance costs translates to a 30 percent increase in profitability [1-3].

2. Methodology

This study reviewed the structure of the maintenance section in the factory in order to improve and develop the existing maintenance processes and reduce running production costs of consumed electrodes and electricity. The current bill of electricity consumption per month by the factory is around $0.5m, which is relatively high for a factory in a developing country. As mentioned above, the automatic control system and measures used to control the process of melting iron and steel scrap, was analyzed and reviewed in order to evaluate its effect on the mechanical and electrical maintenance of the factory. Many machinery parameters can be measured, trended and analyzed to detect imminent failure or onset of problems. Common among them are: Machinery vibration, Lube oil analysis including wear debris analysis, Infrared thermograph, Ultrasonic testing, Motor current analysis, Shock pulse measurement, …,etc. Additionally, operational characteristics such as flow rates, heat, pressure, tension, speed and so on can also be monitored to detect problems. In case of machine tools, product quality in terms of surface finish or dimensional tolerances is often an indication of problems. As all these techniques have value and merit, the application of any particular technique depends on the suitability and ease of implementation [1-4].

The control systems of the Electrical Arc Furnace (EAF) used in the factory need the following improvement and development in order to reduce the final product cost. In order to achieve this aim, analytical methods were followed to improve steel production process in the EAF. In order to do so, the study was divided into two phases that are sequential yet synergistic. The first phase used traditional methods of work measurement drawn from industrial engineering practice, such as process definition, development of flow charts, and data collection via time-and-motion studies, to obtain a complete, quantitative understanding of current system operational procedures, workflow patterns, and location of productivity constraints. The second phase was built upon the understanding gained during the first phase. In the second phase, opportunities to improve throughput was identified, with particular attention to those opportunities requiring relatively low capital investment. The principal analytical tools to be used for this phase were the operations research techniques of project management, to identify both critical paths within work flow and utilization imbalances among system resources.

2.1. Improving Maintenance Management

A working definition for various types of maintenance actions is as follows:

- Failure Maintenance: This relates to the policy of repair or replacement of a part or subsystem only upon failure of the named part or assembly.
- Block Maintenance: This relates to the policy of repair or replacement of all parts on subsystems (block) at a predetermined interval of time.

- Preventive Maintenance: This relates to the policy of repair or replacement of a subset of parts or subsystems, when another part of subsystem fails or is repaired/replaced after a certain length of service [5, 6].

Proper maintenance is essential to keep production equipment and capital assets at a state conducive to its output role in maintaining a level of production at a predetermined quality and quantity. Maintenance costs typically average from 5% to 7% of the value of fixed capital assets, hence the economic implications of reducing maintenance costs are very vast. Data can be collected on costs of repair, downtime and availability percent statistics, usage of spares inventory, etc. This information can be used to set budgets, make historic comparisons and in general be used as control information. A sensible combination of failure maintenance and preventive maintenance will ensure that these objectives are met. The equipment failure characteristics often determine the worthwhileness of preventive maintenance activities. Equipment that fail randomly due to unexpected and inexplicable overstress, generally do not lend itself to preventive maintenance. Equipment that fails due to wear and tear may lend itself to preventive maintenance. Thus the 1st step in maintenance planning consists of analysis of failure characteristics of the subsystems comprising the total system. Forecasting of equipment failures in a stochastic system (probabilistic) is based on studying the past performance of the equipment and its subsystems, and assuming that these characteristics will hold in the future. Past data of equipment failures like time to fail are analyzed with a view to find a statistical distribution which closely resembles with a confidence limit of 90% or more the actual failure distribution of the subsystem. Once this is determined, methods of statistical sampling can be used to predict times to failure in any analysis. Among the most common failure distribution applicable to electromechanical systems are the Exponential distribution, Normal distribution, Log Normal distribution, Gamma distribution and Weibull distribution.

Maintenance Procedure Program (MPP) system is a series of dynamically linked programs, each of which plays an important role in the effectiveness of the maintenance program. The system applies to both electrical and/or mechanical maintenance in the steel production line and provides the process of equipment inspection as well. The MPP is a manner of applying several maintenance concepts into a complete program. This program fully utilizes each concept while combining the efforts of all. Each program element can stand alone in its own right, yet together their strength is multiplied. The need of such a program came about after many attempts of installing only one concept of preventive maintenance. It became apparent that no one method would cover all the bases at any one time. Thus, building a structure which would take into account each facet of maintenance and combine the efforts of each into a master program became a reasonable task. In Maintenance Job Order System, information is fed into this system from the crew inspectors, the department inspectors, the nondestructive testing group, the operations department, and the electrical/mechanical maintenance group. This information is in the form of necessary work to be done as a result of inspections from the various sources. The equipment history files are also important inputs into the job order system. This history helps coordinate the jobs to be completed during planned outages. The next step is to open the job order. The job order can be opened or directed to the maintenance foreman or the departmental planner. If the order is directed to the foreman, the work is assigned to a crew for completion. Normally, work assigned to the foreman would be of a nature which could be completed with the line running or which would be done during an unscheduled interruption in the operation. If the job order is opened to the departmental planner, he will coordinate the job order with the central shops crafts department using a shops job priority system, the maintenance foreman, and the maintenance spares man. These people act as a team in organizing the manpower, spares, and other factors necessary to

complete the required job during the planned outage. After the completion of the job, the job order is closed.

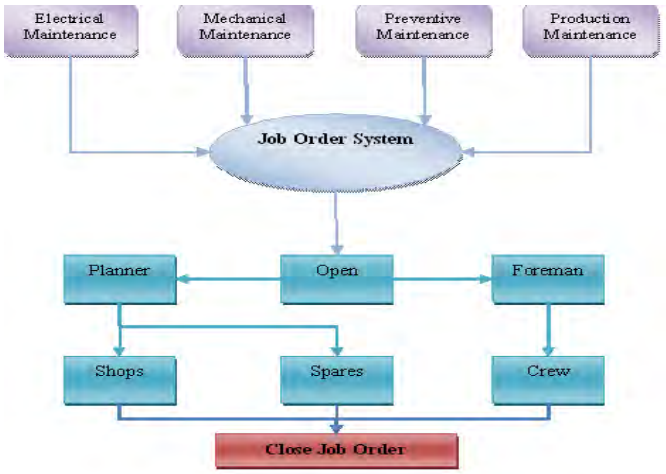

Fig 1: Maintenance Job Order System [5].

2.2. System Modelling

Fig.'s 2 and 3 show physical and electrical models of the existing EAF. In these models, three electrodes are moved vertically up and down with hydraulic actuators. Each of these electrodes weighs 0.4 tons and is 1.5m long. The ore is melted with a huge power surge from the electrodes. The actual product is denser than the scrap and thus falls to the bottom of the furnace creating the matte. Above the matte lies the slag where the electrode tips are dipped. The tremendous heat created by these electrodes causes the ore to liquefy and separate. Thereupon, more raw materials are placed in the furnace and the process repeats itself.

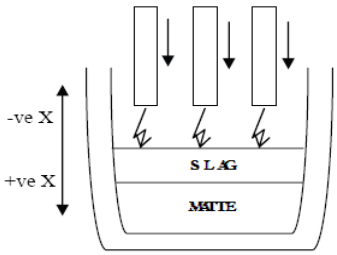

Fig. 2: Physical Model of the EAF [2].

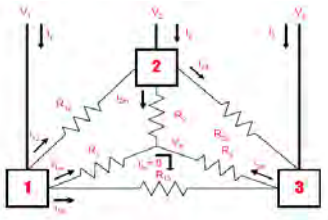

Fig. 3: Electrical Model of the EAF [2].

3. Results

The EAF operates on the principle of direct arc heating. Three graphite electrodes carry the three phase current into the furnace. An electric arc is generated between the electrodes and the metal charge which gives out heat. The charge gets melted by the direct impingement of the arc and also by the radiation from the roof and walls. A proper length of arc is to be maintained throughout the melting cycle. The furnace consists of a cylindrical steel shell

mounted on supporting rockets. There is a tapping spout for drawing molten metal and a slag door at the back for slag removal. A removable roof covers the shell. The three electrodes enter the shell through the holes on the roof and are carried by electrode holders on the electrode arm. The position of the electrodes is controlled by moving the mobile carriage over the electrode post which- is done by electrode hydraulic cylinders. The electrodes are water cooled at the point of entry into the furnace. A separate water storage tank with a centrifugal pump is provided for circulating cooling water for the shel1, electrode holder, roof and the slagging door. A control panel is provided for controlling power input to the furnace, for forward and backward tilting, to indicate the currents and voltages and for accurate lifting and lowering of the electrodes. The hydraulic cylinder used for electrode movement is controlled by PLC (S7 400) to maintain the arc impedance a constant for a given voltage, the charging of furnace is done by opening the roof by swinging it to one side. One of the main objectives of the three-electrode control study is to have the electrodes maintain constant power consumption. This is achieved by moving the electrodes to a given depth, obtaining the desired resistances (or conductance), which leads to a constant power consumption. To attain this goal, the open-loop system must be closed in order to create an error signal. The control principle is accomplished by minimizing this error signal with specific controllers. PID controller can be designed and optimized for best performance. For this system, controlling the current will lead to power control; since the power magnitudes are scalar multiples of the electrode currents. Employing SCADA system into the melting and casting processes has a good impact on t he product quality, minimizing the need for human resources, reduction maintenance time and cost, increasing reliability, and real-time data accuracy. This technology should provide the following:

- Continuous (momentarily) monitoring of the state of the process and of the plant;
- Displaying warnings and alarms, at a sufficiently high level of abstraction;
- Giving advice as needed to the metallurgical management of the process.
- Generating historical reports.

4. Discussion and Conclusions

Unfortunately, we found that the SCADA system in the factory is only used for continuous (momentarily) monitoring of the state of the process and of the plant. Therefore; it is highly recommended to activate the other three facilities of the plant. Moreover, the SCADA systems which are employed for the EAF, Ladle Furnace, and the Continuous Casting Machine (CCM) are not networked, which is causing an extra burden and difficulty in the management process [2].

Based on above analysis, great deal of improvements is suggested in order to implement an active control and analysis in order to reduce the cost of production and maintenance in this factory, including scrap management; since economic and competitive pressures force industrial and process engineers to seek continuous improvement in industrial production processes [1]. In a complex industrial system, as in an EAF, the ways to improve this process are diverse, such as selection and treatment of materials, the redesign of the facilities and new kinds of energetic contributions to the process. The evolution of electric furnaces is reflected mainly in the progressive reduction of specific consumption of energy, tap-to-tap times and improvement of the metallic yield [2]. A deep study, comparing energy consumed currently in the production of steel with theoretically needed energy, was made by the Carnegie Mellon University (Pittsburg, USA) for the US Department of Energy [3-8]. The principal analytical tools used for second phase were the operations research techniques of project management and heuristic scheduling [6]. Though the direct comparison of different EAFs is difficult due to the operational differences, the disparity between the theoretical energy and the consumed

energy contributes to the idea of potential improvement of these facilities which could be about 25% of the energy consumption. One of the pathways proposed to reach this yield improvement in EAF operation is the optimization of process sequencing by means of Programmable Logic Controllers (PLCs). Important effort has been directed towards further productivity improvements under EAF process. Much of this has focused on developing alternative energy sources to reduce the high cost of electrical energy, which means about 10-15% of EAF operation costs. Another two different types of costs that have impact on the total cost of EAF operation can be identified: the cost of the feed materials and the cost implication of not reaching control objectives. Feed materials are very conditioned by the final quality of steel to obtain (scrap substitutes are mainly used in the production of higher quality products) and the steel cost due to materials is mainly determined by the price of scrap in the world-wide market. Processing control optimization is another very important way for the reduction of the energy consumption. Because of knowledge lack of a suitable plant model, the operations in the furnace are only based on empirical knowledge. There are a large number of traditionally manually controlled variables. The furnace operator, in accordance with his own experience and in his particular way of working, has been taking the decisions. For example, he was deciding if it was necessary to inject more or less oxygen, coal or HBI (hot briquetted iron), or even stopping the process and measuring the steel temperature. The automation of these variables ensures better operation in EAFs [7-13].

Steel scrap is the most important raw material for electric steelmaking, contributing between 60% and 80% of total production costs. In addition, the degree of which the EAF process may be controlled and optimized is limited by fluctuations in scrap quality. Therefore quick estimations of properties of different steel scrap grades are very important for improving the control and optimization of the EAF process. Most countries have national classification systems for steel scrap, but there is also a European classification system that the EU-countries use for international scrap trade [13]. Steel scrap is usually graded in terms of size distribution, chemistry, density, and origin, and processing method. Some melt shops have internal classification systems that further divide the standard scrap grades into subtypes, and also a number of internal scrap grades (scrap produced within the steel plant). However, the scrap grading systems are designed for commercial purposes and the variation in scrap properties within each scrap grade is high. In general, scrap properties may be divided into two main categories, physicochemical properties and process related properties. Physicochemical properties (chemical composition, density, specific surface area, size distribution and melting temperature, specific heat capacity, metallic/ organic/oxidic content) are only dependent on the particular scrap grade and are best determined by controlled experiments in laboratories. Process related properties (yield coefficients, specific energy consumption, contribution to chemistry of steel and slag, contribution to basket and furnace filling degree, contribution to dust generation and off gas composition) depend on both the process conditions and the other materials in the scrap mix. Therefore, the process related properties for the same scrap grade may vary considerably between different melt shops. Chemical analysis, conductivity, metal content and size distribution may be measured or estimated for individual pieces of scrap and/or random samples but the fluctuation in scrap quality is often too large for these measurements to be representative for the whole population of a scrap lot on the scrap yard. Experimental design methods have been proposed to set up a series of experimental heating processes that can then be used to estimate the scrap thermophysical properties. However, because of the variation in process conditions and fluctuations in scrap quality each experiment would have to be repeated several times. The number of experiments needed to get estimations for all scrap grades can therefore be very high, depending on the number of scrap grades that are used, rendering this approach

unsuitable. An alternative to designed experiments is to firstly extract large quantities of data from process databases [3]. Advanced statistical methods can then be used to analyze the combined effect of scrap mix and process conditions on the end conditions, chemical analysis of the liquid steel, energy consumption and metal yield [2- 3, 13].

Abstract: This paper presents the results of an investigation of power production from low temperature excess process heat from a chemical cluster using Organic Rankine Cycle (ORC) technology. Process simulations and process integration methods including Pinch Technology and Total Site Analysis (TSA) are used to estimate the potential for electricity production from excess heat from the cluster. Results of a previous TSA study indicate that ca. 192 MW_{heat} of waste heat are available at 84 °C to 55 °C, a suitable temperature range for ORC applications. Process streams especially suitable for ORC power production are identified. Simulation results indicate that 14 MW_{heat} of waste heat are available from a PE-reactor, which can be used to generate ca. 1 MW_{el}. Costs of electricity production calculated range from 70 to 147 €/MWh depending on the cost for ORC integration. Economic risk evaluation indicates that pay-back periods lower than 4.5 years should not be expected at the electricity price and RES-E support (a European support system for renewable electricity) levels considered in this study. CO_2 emission reductions of up to 5900 tonnes/year were estimated for the analysed case.

Keywords: *Organic Rankine Cycle, Process integration, Total site analysis, Waste heat recovery.*

1. Introduction

1.1. Background

Growing awareness about the greenhouse effect combined with limited fossil fuel resources provide clear incentives for implementing energy savings measures and achieving CO_2 emission reductions in industry. One example to increase energy efficiency is the conversion of low temperature excess process heat into electricity using Organic Rankine Cycle (ORC) technology. The objective of this paper is to assess the potential for electric power generation from low temperature excess process heat at the chemical cluster in Stenungsund, Sweden. Results from a previously performed total site analysis [1] are used to determine the overall amount and the temperature levels of net excess heat from the cluster. Net excess heat is defined as heat that is available after all opportunities for process integration have been exploited and for which no other alternative use is available. Simulation of a selected ORC power cycle was conducted so as to quantify the power output and the overall performance of the system. A preliminary economic evaluation of a selected configuration is presented based on the simulations, supplier/literature data for ORC technology, engineering assumptions for ORC integration and scenarios for assessing profitability and carbon balances of energy investments [2]. The work aims at providing a basis for future projects to optimize energy usage and consequently lower costs and CO_2 emissions from the cluster.

1.2. ORC Technology

ORC is a technology to generate electricity from low temperature heat sources. Unlike in a conventional steam Rankine cycle, a low boiling point organic fluid is used as working fluid. In low temperature applications this technology offers advantages over conventional Rankine Cycles, and a higher heat recovery (efficiency) can be achieved [3]. ORC systems are mainly used in geothermal, solar and industrial waste heat recovery applications. Figure 1 illustrates the working principle of an ORC. The working fluid is pumped from a lower pressure level

(state 1) to a higher (state 2). Between states 2 and 3 the fluid exchanges heat with a waste heat stream in a heat exchanger and is evaporated. Contrary to Rankine cycle technology, the working fluid is usually not superheated after the evaporator. The vapour is then expanded in a turbine (state 4), which is connected to a generator to produce electricity. The expanded vapour is condensed by transferring heat to a cooling medium in the condenser (state 1). The cooling can be achieved by air coolers, cooling water or other heat sinks.

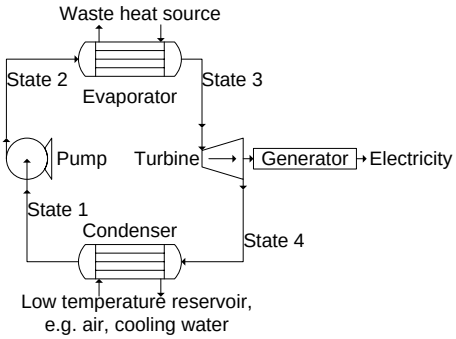

Fig. 1. Working principle of a simple ORC

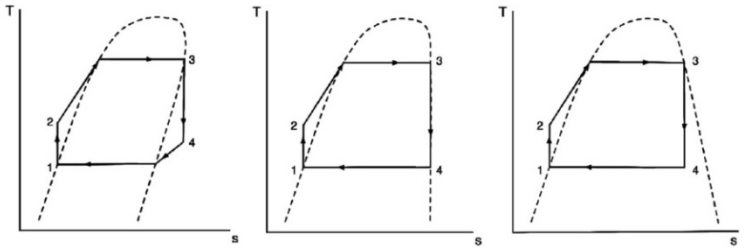

Fig. 2. Characteristic T-S process ORC diagrams for "dry", "isentropic" and "wet"-fluids [4]

The choice of the working fluid strongly influences the efficiency and economy of an ORC system. Working fluids can be divided into three different groups according to their behaviour in the thermodynamic cycle. Figure 2 shows the characteristic T-S diagrams for the three different types of working fluids. "Wet" fluids have a negative slope in the saturation vapour curve. Expansion in the turbine occurs entirely in the two-phase state, and the liquid fraction of "wet" fluids increases. The liquid droplets that form can cause blade erosion damage to the turbine. Condensation is easiest avoided by superheating of "wet" fluids. "Dry"-fluids have a positive slope (left), which means they do not condense during expansion since the degree of superheat increases as the expansion proceeds. Examples of such working fluids include organic substances such as benzene and refrigerants. The third group is "isentropic" fluids with quasi-vertical saturated vapour curves. Since the purpose of an ORC is to recover low temperature heat for electricity production, superheating is not appropriate. Therefore the working fluids used are either "dry" or "isentropic" [5]. Moreover, water has the disadvantage of having a higher specific volume compared to organic working fluids. This increases the size of the turbine, the height of the turbine's last stage blades and pipe diameters [3]. The working fluid should be selected with care so as to achieve a good match with the heat source characteristics and also the available cooling facilities. The following properties should also be considered: high thermal stability at the given operating conditions, low specific volume, low cost, low toxicity, low Ozone Depletion Potential (ODP) and low Global Warming Potential (GWP). The choice has to be based on careful analysis of the given conditions [6].

1.3. Results from total site analysis (TSA)

In a previous work the cluster was analyzed using TSA methodology [1]. The method is based on pinch technology and aims for integration of the heating and cooling demands of the different individual processes at a given site with a common utility system. In this way the amounts of hot utility generated and used by the combined individual processes, the amount of heat recovered in a common hot utility system, and the cogeneration potential can be determined [1]. The previous study [1] showed that the combined heating demand of process plants within the cluster is 442 MW of which 320 MW can be covered by heat recovery within the cluster, assuming that no changes are made to existing process utility levels. The

other 122 M W must be covered by hot utility, mostly in the form of boiler steam. Furthermore, the previous TSA study also showed that by making improvements to the overall utility system which enable increased energy collaboration between the companies it is possible to increase the amount of heat recovery at the site from 320 MW to 449 MW. As a result, boiler utility steam is no longer necessary. In addition a net surplus of 7 MW steam is achieved. The cooling demand of the cluster is then 506 MW at temperatures up to 84 °C.

These results are used in the present study to determine the maximum potential for power generation from low temperature excess heat within the cluster, using ORC technology. Because of the relatively low efficiency of low temperature heat-to-electricity conversion it is appropriate to only utilise net excess heat that cannot be utilised in another way [7]. The maximum potential for heat available for power production is estimated using TSA. Within the cluster available heat is estimated at Q_{ORC}=192 MW_{heat} at temperatures between 84°C and 55°C.

2. Methodology

2.1. Heat source selection

From the inventory of the excess process heat available, a selection is made to focus on streams with loads and temperature levels interesting for power generation and for which there is no alternative use. This temperature range was determined in a previous TSA study. The maximum heat source temperature for excess heat from the cluster is 84°C. The minimum allowable heat source temperature was selected as 55°C in order to achieve acceptable Carnot conversion efficiency values. Supplier information also confirmed this value of lower temperature limit [8].

2.2. ORC simulation

Literature data about ORC cycles only provided information about approximate efficiency values. Furthermore, it was necessary to evaluate different working fluids depending on the process conditions in order to achieve maximum efficiency. Therefore a simple ORC cycle was simulated in HYSYS. The cycle includes a pump, an evaporator, a turbine and a condenser. The tested working fluids are R134a, Propane, 1-Butene, Butane and Pentane as they are typical fluids for ORC applications at low temperature levels. The results are used as input for the economic evaluation.

2.3. Cost estimations

To determine the basic investment costs of the unit, the turbine capacity (in kW) is taken as the indicative size of the new unit. The equipment costs of a reference ORC-unit are estimated based on published data for a reference geothermal power plant located in Altheim, Austria with a capacity of 1 MW_{el} [9]. The equipment cost of this reference ORC-unit is 1.58 M€ (in 2000). This cost was updated using the Chemical Engineering Plant Cost Index (CEPCI) for 2010 and 2000, i.e. an update factor of 1.376 [10]. Furthermore, a scaling factor of 0.7 (widely used for electricity production) was used for estimating the investment costs of differently sized units [11]. The installed cost of the ORC unit can thereafter be calculated based on published cost data for an ORC plant in Lienz, Austria with an installation cost factor of 1.32 [12], which covers planning, installation and grid connection costs. Not included are the costs of integration in the considered process plant.

The costs for integrating the ORC into the process plant vary depending on the situation on-site, the process fluid, the location of the ORC-unit and other factors. Three examples of

projects presented by the ORC manufacturer Turboden [13] indicate integration cost factors ranging from 1.7 to 2.6. All projects include a thermal oil cycle which collects the heat from the waste heat source and delivers it to the ORC unit. For this reason those systems are more complicated and expensive than systems where the process stream is used directly, which might be the case for integration with a chemical cluster. Therefore integration cost factors from 1.1 to 2.6 were considered in this work. The annuity method is used for determining the annualized investment costs ($I_{\text{total annualized capital cost}}$) which are used to estimate the net Cost of Electricity (CoE) generation for the ORC plant. The assumed internal interest rate is 11 % (i_r). The economic lifetime (t_e) is assumed to be 15 years, as this is typical for CHP plants based on ORC technology [12]. The corresponding annuity factor is 0.14. Cost data for annual operating costs are assumed to be 3 % of the installed costs of the ORC plus the personnel costs (400 h/yr á 30 €/h) [12]. The CoE are calculated by Eq. (1)

$$\text{CoE} = \frac{I_{\text{total annualized capital cost}} + \text{Annual operating costs}}{\text{Annual electricity production}} \qquad (1)$$

CoE can then be compared with scenario values for electricity purchased from the grid. The economic value of the electricity produced is based on avoided costs of purchasing electricity. Five different grid electricity price scenarios are analysed, see Table 1.

In order to discuss the economic risk of investment in an ORC unit, the payback period for a new ORC investment is also calculated. The total annual savings take into account the avoidance of electricity purchased (equal to net power output of ORC) and the electricity saved by less cooling water pumping (2.5 % of net power output of ORC). When producing electricity from waste heat, which otherwise is cooled by cooling water, part of the cooling is saved. The main part of the cooling costs is the pump work in the cooling water system. In this study it is assumed that for each avoided MW of cooling, 0.025 MW_{el} are saved. These cost savings are calculated with the assumed electricity price and included in the annual cash flow to calculate the payback period (see below). An annual running time of 8000 h per year is assumed. The pay-back period for the ORC investment can then be calculated according to Eq. (2).

$$\text{Pay - back period} = \frac{I_{\text{total ORC}}}{(\text{Annual savings - Annual operating costs})} \qquad (2)$$

The scenarios were generated using the ENPAC tool, developed with the purpose of evaluating the performance of future or long-term energy investments at industrial sites using consistent scenarios. Scenarios chosen in this study include the current electricity price and two scenarios (high/low) for the years 2020 and 2030. RES-E support is currently not granted in Sweden for electricity production from waste heat with fossil origin. In this study both case (with and without support) will be shown in order to show its influence on the overall economic performance of ORC investments. By using a number of different scenarios that outline possible cornerstones of the future energy market, robust investments can be identified and the climate benefit can be evaluated. To obtain reliable results, it is important that the energy market parameters within a scenario are consistent. Consistent scenarios can be achieved by using a tool in which the energy-market parameters (e.g. energy prices and energy conversion technologies) are related to each other [14]. Table 1 shows the electricity prices, support levels for "green" electricity generation and CO_2 emissions from electricity production from the assumed long term marginal electricity production.

Table 1. Electricity prices, support for green electricity, CO_2 emissions from electricity production and marginal long term electricity production for the five scenarios [2]

Scenario		1	2	3	4	5
Year		2010	2020	2020	2030	2030
Fossil fuel price		2010	Low	High	Low	High
CO_2 charge	[€/ton]	20	15	58	15	58
Electricity price SPOT	[€/MWh_{el}]	51	46	74	45	81
RES-E support[1]	[€/MWh_{el}]	20	20	20	20	20

2.4. CO_2 emissions reduction

CO_2 emissions reduction by electricity produced with an ORC unit is calculated from CO_2 emissions data for future long term marginal electricity production in Table 1. It is assumed that electricity from the ORC unit replaces marginal electricity and that the waste heat used for electricity production has no alternative use (in this case the possibility to deliver waste heat to the district heating system close to the cluster is fully exploited).

3. Results

3.1. Heat source selection

One heat source is chosen as an example to carry out further investigations, including simulation of the ORC unit using HYSYS and economic assessment and calculation of CO_2 emissions reduction. The stream chosen is a loop reactor jacket cooling water stream with T_{start} and T_{target} of 78 °C and 68 °C, respectively. This results in a Carnot efficiency of 17 %. The heat load of the stream is 13970 kW.

3.2. ORC simulation

Simulations were carried out with different "dry" fluids appropriate for use in ORC systems. The main results are presented in Table 2. The turbine inlet and outlet pressure is chosen so that the boiling point of the working fluid is matched with the temperature profile of the heat source and the heat sink (cooling water at 20 to 25 °C) respectively. Among the five working fluids investigated, butane shows the best net electrical output and electrical efficiency. R134a and Propane are interesting cases, but the cycle needs to operate at higher pressure than the cycle with butane. Lower operating pressure should be preferred as increased pressure implies higher investment costs. Pentane is not suitable as the minimum pressure in the cycle is set to 0 bar(g), to avoid extra costs for vacuum operation. Pentane is more suitable for higher temperature heat sources. Butane has a slightly higher power output and efficiency compared to 1-Butene. The simulation with a mixture of pentane and butane does not show better results than with a single fluid, even though the temperature profiles of heat source and working media match better, which results in less exergy losses during evaporation. High performance is not reached with the mixture as the pressure difference for expansion in the turbine is not sufficient. Pentane limits the maximum and butane the minimum possible pressure in the given case (ΔT_{min} of 5 K in the evaporator and condenser). Butane was retained as working

fluid for the ORC unit. This cycle has a net electricity output of 958 kW_{el} (7.7 GWh/yr for 8000 hours/yr of operation), with 6.85 % electrical efficiency.

Table 2 Results from the simulation in HYSYS for an ORC unit using loop reactor cooling water heat source

	R 134a	Propane	1-Butene	**Butane**	Pentane	Butane +Pentane
$p_{turb,in}$ [bar(g)]	18.5	23	7.6	**6.2**	1.45	3.5
$p_{turb,out}$ [bar(g)]	6.7	9.8	2.5	**1.8**	0	0.6
$Q_{el,out}$ (net) [kW]	923	900	948	**958**	798	950
η_{el} [%]	6.6	6.4	6.8	**6.85**	5.7	6.8

3.3. Cost estimation

The results for the selected heat source stream are presented below. Costs calculations have been performed according to the procedure defined in Section 2.3. Table 3 shows simulation and economic results for the selected waste heat source assuming butane as working fluid

Table 3 Turbine capacity, basic equipment investment costs, installed costs and operating costs

Turbine output [kW]	Net power output [kW]	Equipment investment costs for ORC unit [€]	Investment costs ORC including installation [€]	Operating costs [€/yr]
993	958	2 163 489	2 855 806	97 674

The calculated CoE range from 70 to 147 €/MWh, depending on the integration cost factor, see Figure 3 and Figure 4. The electricity price scenarios in Figure 3 do not include RES-E support. It can be seen that at the current electricity price (Scenario 1: ca. 51 €/MWh) and without RES-E support, investing in an ORC is not profitable.

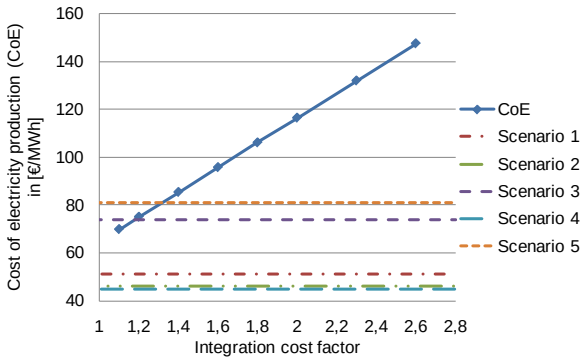

Fig. 3. CoE depending on the integration cost factor (with electricity price scenarios without RES-E support)

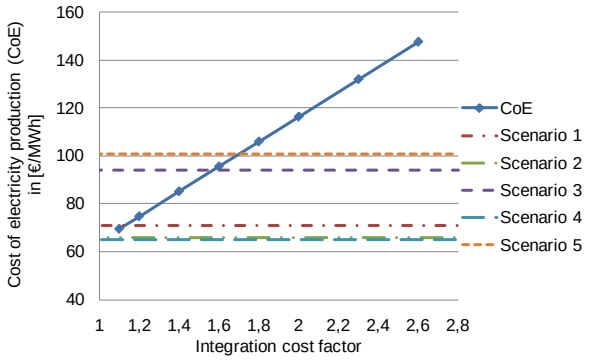

Fig. 4. CoE depending on the integration cost factor (with scenarios including RES-E support)

Without RES-E support, ORC electricity generation is only profitable for the two highest price scenarios (Scenario 3 and 5) considered in this study and at low costs of integration. If RES-E support is granted also more complicated integration is feasible at high electricity prices. At low integration costs even the current electricity price shows a feasible investment. Calculations on the pay-back period of an ORC investment show that without support for electricity production the pay-back period for the lowest costs of integration estimated (10 % of ORC installed costs) ranges from 5.8 to 12.3 years depending on the electricity price scenario. With RES-E support the pay-back period is decreased for the low integration factor

case to between 4.5 to 7.7 years. Even if RES-E support is considered, pay-back periods lower than 4.5 years should not be expected for ORC technologies at the electricity price and RES-E support levels considered in this study. On-site electricity production bears lower risks than other investments, as the produced electricity can be used on-site. This might justify longer pay-back periods. The scenarios used in this study include costs for CO_2 emissions from fossil-fuel fired power plants. It can also be seen that in the scenarios with low CO_2 emission charge (scenario 2 and 4) the costs of electricity production and pay-back period are highest, while high CO_2 emissions charge (scenario 3 and 5) shows lower values. Therefore CO_2 emissions charge is seen as an important parameter which has a large influence on the profitability of ORC investments.

3.4. CO_2 emissions reduction

Figure 5 shows the CO_2 emissions reduction in the different scenarios when electricity is produced with an ORC unit. It can be seen that the reduction is high if marginal electricity from coal power plants is replaced by electricity from the ORC unit, 5204-5902 tonnes-CO_2/year. The least reduction is achieved if marginal electricity is produced in coal power plants with carbon capture and storage (CCS) technology (989 tonnes-CO_2/year). This is the case because the electricity produced with an ORC replaces marginal electricity, which in the CCS case already has relatively low CO_2 emissions.

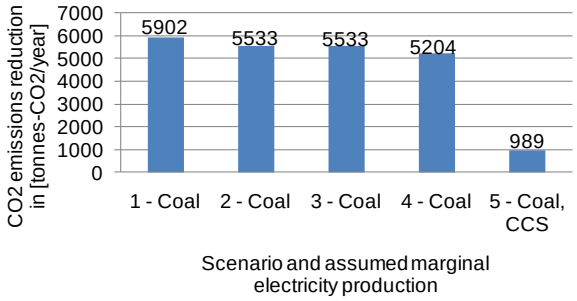

Figure 5 CO_2 emissions reduction associated with electricity production from excess process heat using ORC unit

4. Conclusions and Discussion

In this paper TSA methodology was used to identify the amount of net excess heat from a chemical cluster including the corresponding temperature levels suitable for low temperature heat-to-electricity production by ORC technology. For a more detailed analysis a suitable process stream was selected as heat source. Process simulation was used to determine the best working fluid for the suggested ORC unit, to calculate the net electricity output and the electrical efficiency of the unit. The simulation results were used for preliminary economic assessment and calculation of CO_2 emissions reduction potential based on different future energy market scenarios. From the TSA study it was found that there is 192 MW_{heat} at a temperature range between 84 °C and 55 °C available that can potentially be used for ORC applications. It was shown by process simulation that the selected ORC reaches an electrical efficiency of 6.85 % when converting ca. 14 MW_{heat} into 953 kW_{el}, using butane as working fluid. Economic assessment of the system shows a strong dependence of profitability to the costs for integration of the ORC unit in the process. Production costs were determined in a range between 70 and 147 €/MWh, indicating that at the current prices and without support an ORC project is not feasible and also only two out of seven scenarios showed feasibility without support. Depending on the scenario, pay-back periods between 5.8 to 12.3 years

assuming low costs of integration. RES-E support and CO_2 emissions charge were found to have a strong influence on profitability. Pay-back periods lower than 4.5 years should not be expected at the electricity price and RES-E support levels considered in this study, even if in the future support is granted for this kind of electricity production. Standardisation and technology improvements are expected to have a p ositive effect on the costs of ORC technology, leading to lower electricity production costs and pay-back periods in the future.

Abstract: This study has considered hybrid system SOFC/GT with the new approach. This cycle, as a power plant is designed to reduce losses and improve comprehensive cycle performance. In the first part cycle, fluidized bed system with biomass (wood chips) fuel using gas cleaning mechanism, produce combustible gases which are required fuel combustion chambers of steam reformer and the GT. Second part cycle, required hydrogen for SOFC system is supplied through external SR. In the third part, the treated bio syn-gas from the cleaning unit outlet, in conjunction with recycled exhaust gases of the cell's anode will feed SR and GT combustors. In the fourth part cycle, flue gas would pass through heat recovery steam generator. Thus, high pressure and low pressure steams with values 3.39&0.45 ton/hr, respectively are generated. In this study, SOFC and GT with a capacity of 1000 & 750.81 kW respectively are designed. Overall efficiency of power production 74.4% is obtained. In comparison with similar study done in 2008 at the University of Delft, that overall 47% efficiency, increasing the efficiency of such systems has been viewed.

1. Introduction

Recent studies have indicated that in integrated SOFC/GT cycles which employ natural gas, the overall efficiency of the system is estimated to be 50% to 60%. Burning and gasifying the biomass and combining the result with SOFC/GT system, enables the hybrid system to contribute to an efficient power plant [1], [2]. Generally, in order to generate power in a cost effective way and develop generating systems, distributed power generation has recommended an effective measure [3], [4]. The general prospect of the present study has been the integration of industries which normally generate combustible wastes and plants that consume such wastes. This study mainly focuses on de signing an integerated SOFC/GT power plant based on burning biomass in combustion chambers and reforming the natural gas in a steam reformer. The a-grade wood has been considered as the biomass in the planning and 1.75 MW of the electrical energy is expected to be generated. According to the field available technologies and the studies which have already been conducted in this field, our proposed cycle can be considered as a new approach in designing similar power plants in the future. A thorough analysis of energy in the system will determine and visualize the losses and realize the thermodynamically efficiency.

2. System Approach

2.1. Improving the efficiency

1- Trying to improve energy generation efficiency and enhancing energy transfer and distribution efficiency (utilizing CHP systems and cogeneration to maximize absorption and recovery).
2- Determining the essential fuel and each of the aforementioned units' efficiency.

2.2. Employing renewable form of energy

1- Calculation related to considerable amount of electrical energy by using renewable forms of energy (SOFC/GT).
2- Estimating a portion of required fuel by renewable forms of energy (Biomass gasification system).

2.3. Managing the industrial process products

1- Putting to use the by-products of industrial process (such as pulp and paper industry) to supply the fuel required for SR and GT systems [9].

2- Making use of hot flue gases and generated heat, for consuming in the comprehensive cycle and auxiliary units.

3. System Configuration

As it is illustrated in the figure 1, this system is comprised of different sections which have been pinpointed by the sections' names. These sections are as the following:

Fluidized bed system and gas cleaning, External Reforming SOFC system, GT system, HRSG[1] system, heat exchangers for pre heating fuel and air generating steam required for the reformer. Burning and gasification of the fuel biomass (wood) is usually preformed in the FB system. The gasifier operates at $500^{\circ C}$ and 4 bar. Heat is transferred by circulating the materials. Impurities within the components of the bed are separated from the gases by a C, SiO_2 separator [6], [7]. The gas which is exhausted from FB unit cannot be directly used within SR combustion chamber and GT. This is mainly due to the fact that the gas turbine. Therefore components such as H_2S, SO_2, COS and NH_3 are effectively removed from the exhaust gas [8]. Form chemical prospect, performing gas treatment, within the higher temperature ranges, seem to be able to be really demanding and imposes restriction treatment process. It is generally believed that the hot gas needs to be appropriately cooled down before being treated. Hot gas temperature is diminished to $500^{\circ C}$ in the heat exchanger [9], [10]. The cooled exhaust gas from cooling and treatment units is then mixed with hot exhaust gas from SOFC which mainly contain non-reacted steam and hydrogen. The mixture will then be transferred to GT and SR combustion chambers. The SR units have been employed to supply the fuel required for SOFC. This unit makes use of natural gas reformation to produce the fuel. The operating temperature and pressure of SR are considered to be $800^{\circ C}$ and 1 bar respectively [11]. The treated syn-gas from the cleaning unit outlet, in conjunction with recycled flue/exhaust gases of the cell's anode (off-gas), which contains some combustible remnants; will feed SR and GT combustors. The pressurized air is directed towards the cathode. Fuel cell with an external reformer (SOFC) is able to directly turn hydrogen, which is the product of already reformed natural gas method, in to electricity. The hot exhaust gas from the cathode (off-gas) is recycled to supply the gas turbine. The expanded flue gas has been used to recuperate the incoming air, after it had been pressurized. An air compressor attached to the turbine supplies the essential air for the integrated SOFC/GT system. Connecting the turbine to the generator, the second electrical current in the cycle is generated. HRSG system has been designed based on a dual pressure-mode in which both high and low steam pressures are generated, in order to improve the system performance and enhance steam generation rate. The results of the previous studies took the HRSG planning process into consideration. There is a feed water boiler in the methodology where the water supply after leaving LP (Low Pressure) economizer is split into two parts. One portion is directed

2- Heat Recovery Steam Generator

towards LP evaporator and another one to HP (High Pressure) economizer. Figure 2 illustrates the schematic performance mechanism of HRSG in the cycle [12].

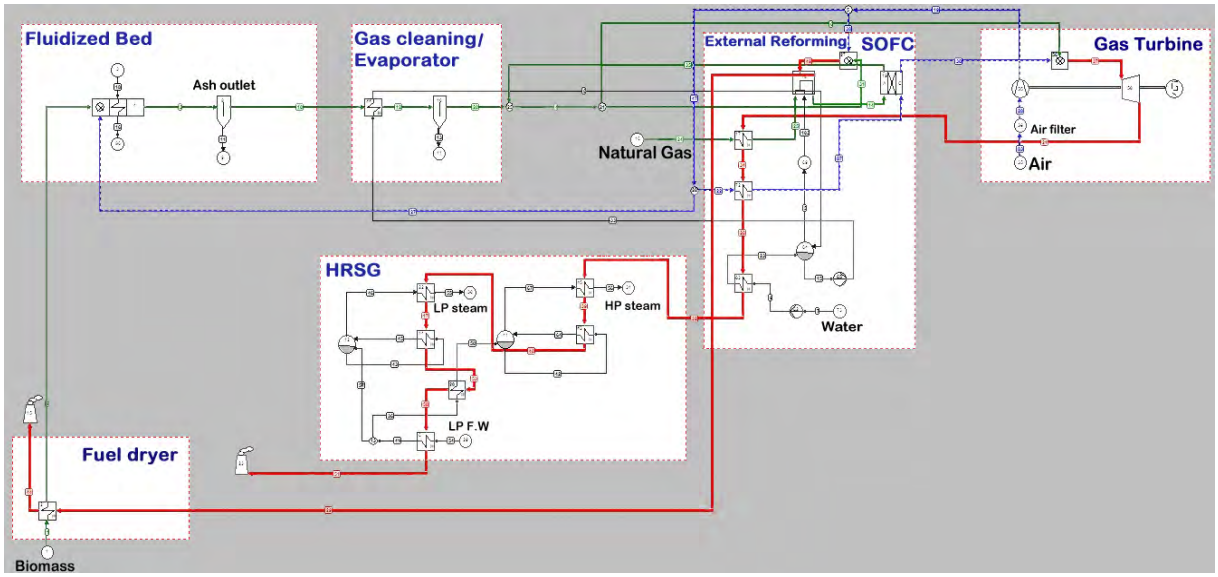

Fig. 1. Schematic of hybrid system

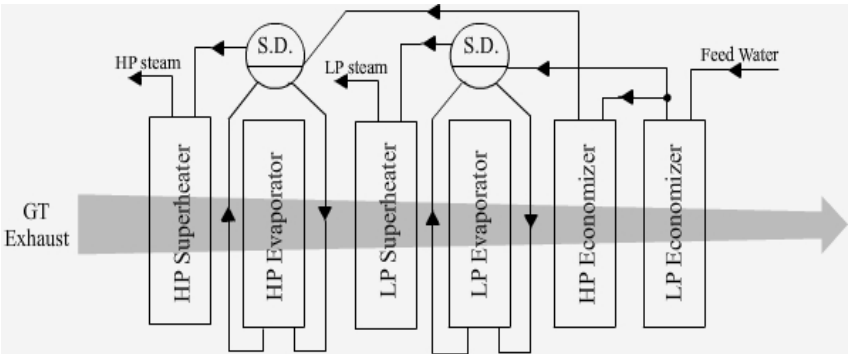

Fig. 2. Schematic of HRSG mechanism

4. System modeling

4.1. Model assumptions

In order to evaluate the system and obtain a balance between mass and energy of the cycle, Cycle-tempo software was employed. The main purpose of using such software was to create a model in the study state. Therefore a model consisting of subsystems has been created. Achieving a consensus on subsystem calculations is the prime objective in creating this model. There are some general assumptions which have been made in creating this model [13], [14].

- The whole system operates at steady state.
- In SR steam generating section, isentropic efficiency of the pump after the steam drum equals 75% and prior to the economizer is 85%.
- Isotopic efficiency of the compressor and gas turbine are 87% and 86% respectively.
- The mechanical efficiency for compressor and gas turbine is set to 99%.
- The generator efficiency is set to 98%.
- The pressure drop within the heat exchanger has been assumed to be zero. Pressure and temperature prior to the system have been listed in table 1.

Table 1. Pressure and temperature of fuels, air and water inlet to the system

Sink name	Pressure(bar)	Temperature(^{oC})
Biomass	4	15
Natural gas	1.18	15
Air	1.013	15
Water*	1.2	20

* Inlet water in SR system

The operational temperature of the fuel cell is 950^{oC} and the pressure is 3.45 bar. The fuel cell area is supposed to be 700 m^2 and the fuel cell resistance 0.75 $\Omega.cm^2$. The efficiency of the DC/AC converter is 96%.

Figure 1 illustrates the SOFC and GT integrated cycle power system schematically. Based on temperature and pressure, two different types of system are generated in HRSG unit. High pressure steam (50 bar) which is as hot as 470$^{°C}$ and low presser steam of 15 bar and 270$^{°C}$.

4.2. Preliminary discussion

With a view to reach a higher efficiency in SOFC/GT hybrid system, the following points should be considered in planning the cycle.

- The combustible gases which have been produced in FB can be directly used in SR and GT combustors.
- Making use of the released heat while cooling the gas leaving FB and prior to cleaning which can be used to supply the necessary steam for SR unit.
- Employing a portion of the gas turbine flue gas heat in pre heating the fuel (natural gas) and the air entering the SOFC system.
- Using the pressurized air by the gas turbine compressor in the cathode.
- Using a great deal of gas turbine flue gas heat to generate steam in HRSG.
- Making use of the exhaust heat from SR in drying biomass entering the system.

After considering the application of a SOFC system with a constant power of 1MW for reaching such power in GT, the present study adjusted reaction pressure and outlet pressure of the FB unit to 4 bar. The outlet pressure of the compressor was sent to 3.46. Minimizing fuel consumption was one of our other objectives.
Comparing this hybrid system with 1.75MW gas turbine system within similar temperature & pressure states, implies a considerable reduction in fuel consumption. Table 2 shows the comparison of these two systems.

Table 2. Comparison of fuel consumption in hybrid and GT systems with similar capacity

System type	Natural gas consumption (kg/hr)	Biomass consumption (kg/hr)
Hybrid system	159.41	129.6
Gas Turbine system	1396.8	-

In order to substitute the integrated system of heat and power generation, a pulp manufacturing plant which is also capable to be developed to produce pulp and paper (the 22Bahman particle board manufacturing company located in northern city of Behshahr in Iran) was considered. This plant is traditionally supplied by the regional electrical transmission network in tandem with burning fossil fuel, to run its manufacturing process. The main characteristics of this study are presented in table 3. The annual production of the

plant has been estimated to be 41438880 kg. The capacity which has been selected for the hybrid system is in congruity with electrical power consumption of the plant.

Table 3. Energy consumption comparison between the Traditional and integrated power generation

	Description	Energy unit
Traditional system	Electric power consumption	52753716 MJ
	Heat consumption	60802100 MJ
	Specific energy consumption (SEC)	5.28 MJ/kg
Hybrid system	Electric power generation capacity	1.75 MW
	Heat consumption	97136501 MJ
	Specific energy consumption (SEC)	2.34 MJ/kg

Based on the results from the study, the specific energy consumption shows a decrease of 2.94 MJ/kg. The first reason for such decrease is electrical power generation in the new system. The second reason to be mentioned is daily generation of 690.65 kg waste product which constitutes the 22% biomass fuel essential for hybrid system.

5. Results and conclusion

5.1. Quantitative approach

In the present model, according to the power generation capacity of the integrated SOFC/GT system which is 1.75 MW the mass flow rate entering biomass is set to be 129.6 kg/hr. The already generated gas leaved FB with 4 bar and 1543.04$^{\circ C}$. The main ingredients and their mole fractions have been shown in table 4.

Table 4. Mole fractions of FB exhaust gases

Component	Mole fraction (%)
H_2	7.07
N_2	49.72
CH_4	4.34
H_2O	18.45
CO_2	18.42
CO	1.37
AR	0.59

Here, 31.9 kg/hr ash leaves the system as mentioned earlier; the mixture contains some harmful gases which will affect the SR and GT system unless they are controlled. The gas which has undergone cleaning process is mixed with the gas leaving the fuel cell anode under a pressure around 3.45 bar. The hot flue gases (1200$^{\circ C}$) from the combustor enter SR. SR requires steam with a flow rate of 460.26 kg/hr. In view of the reactions occurred in SR, the convenient fuel with a mass flow rate of 619.67 kg/hr, are generated in SOFC. The fuel cell operating at 950$^{\circ C}$ produces 1000 kW of electrical energy. Not all fuel is converted in the SOFC stack; the fuel utilization is 85%. The SOFC characteristics for current & power densities are rendered 1963.04 A/m^2 & 1488.1 W/m^2 respectively. The TIT[1] is 1100$^{\circ C}$. Expansion of the mixture of gases entering the turbine 1276 kJ/kg generates power. Having

1- Turbine Inlet Temperature

preheated the fuel and air in the SOFC system, and also exchanged heat in SR steam generating economizer, the flue gas from the gas turbine enters HRSG; meanwhile its energy content and temperature are 3908.7 kW and 782.94$^{\circ C}$ respectively. Economizer outlet is split into two 183$^{\circ C}$ currents, which enter the LP and HP evaporators. The outlet pressures of HP and LP evaporators reach 15 bar and 50 bar respectively. The flow rate of steam leaving HP and LP super heater outlets are 0.45 ton/hr and 3.39 ton/hr respectively. Energetic HRSG efficiency equal to 92% was obtained. In table 5 the energy inputs and consumptions of the system for the conversion of biomass into electricity are presented.

Table 5. Energy input and consumption of the biomass gasifier and SOFC-GT hybrid system

	Biomass	Natural Gas	Fuel Cell	Gas Turbine
Absorbed power(kW)	670.32	1682.81	–	–
Delivered gross power(kW)	–	–	1000	750.81

5.2. Qualitative approach and recommendations

In the Figure 3, the nature of heat recovery and constant output is reasonable. Increase in bio fuel consumption is mainly due to FB system performance as a bottleneck. We have to cross out (as a decrease) in some of the objective to increase Bio. In reality if there is a necessity for increasing the bio fuel, right after that increase ash production rate is maximized to a great extent and puts a restriction on power generation and heat recovery.

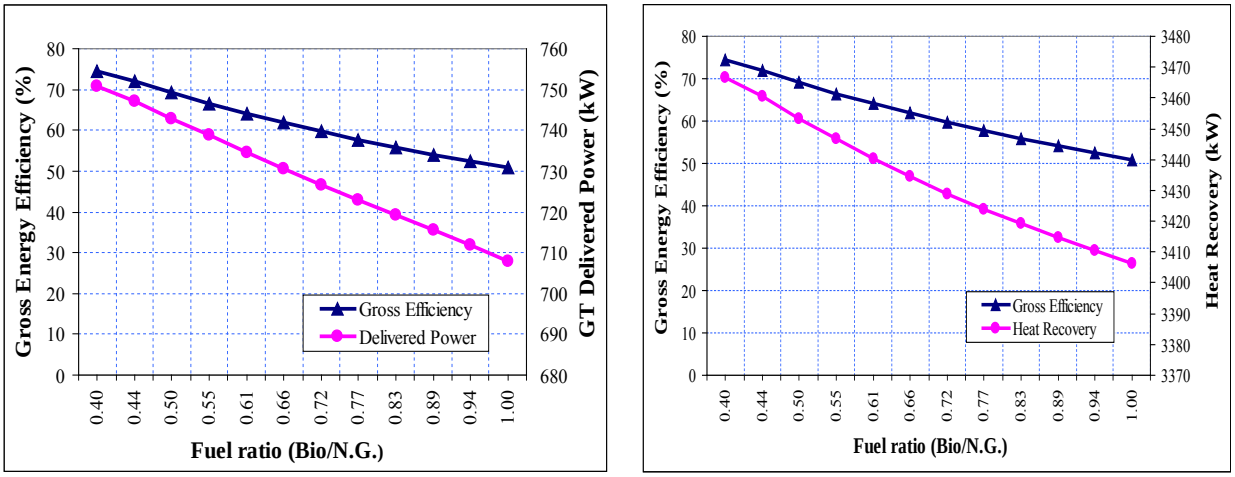

Fig. 3. Fuel ratio variations against hybrid system energy profiles

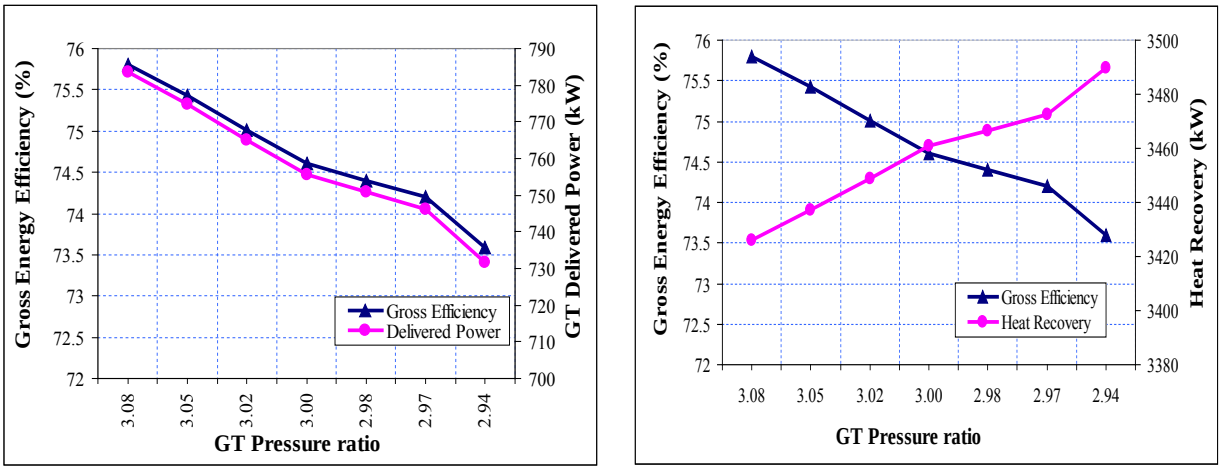
The point that is worth mentioning is that geometry of the bed and incoming fuel level can be increased but the thermal value and residence time, which is considered to be a more important factor, are limited. In Figure 4(a), the real difference in curves' tails is strongly depends on irreversibilities that taking place by more rated pressure in GT. (As GT's property, sacrificing efficiency against more power production is technically predicted).



(a) *(b)*

Fig. 4. GT pressure ratio variations against hybrid system energy profiles

But in Figure 4(b), the pressure ratio in GT is working as a balancing element, which is correlated directly with GT delivered power and inversed with Heat recovery. These explanations are clearly demonstrated in mentioned graphs. In this stage a trade-off point is found at 3 for pressure ratio, which covers all two targets named GT delivered power and heat recovery. This point can be applied as a nominative reference for our designed system called best practice point in our modeling approach. In the comparison of graphs Nos. 4(a), 4(b) it can be observed that mentioned increased irreversibilities based on pr essure decreasing, would be transferred to stack as an increased source for heat recovery. The best proportion for electricity generation in an integrated SOFC/GT system is 60 to 40 [15]. Therefore the power which is expected to be generated by the system is planned in such a way that 1000 kW is generated by SOFC. Likewise according to the assumptions and calculations conducted, the power generated by GT equals 750.81 kW. As it c an be implied from table 5, the gross efficiency of the cycle is 74.4%. This can be compared with the gross efficiency of the similar study which had been conducted in university of Delft [3]. It is thus evident that an increase in gross efficiency has been fulfilled. Such increase can be attributed to the following reasons.

1. Direct burning of FB combustible gases output at GT combustion chambers and SR
2. Using natural gas (with a higher percentage of hydrogen) as fuel input SR system and its sense of more appropriate quality in fuel Sign for SOFC
3. Changes in the recovery position of SOFC gas combustible system, comes from SOFC process recycling by adding them to the purified gas cleaning unit (obviously, internal reforming itself is a part of the energy consumption indeed)

In order to obtain a h igher efficiency and higher steam mass flow rate generated by the system, some changes in heat exchangers' locations were applied. The pinch point which is located between the evaporator's outlet and inlet has been adjusted to be 10 ^{o}C. LP and HP steam produced in the cycle can be used for steam units placed side-consumer. Also adding a steam cycle power generation, steam production can be used to generate electricity. Thus, the overall efficiency of power production systems will increase.

Abstract: Industrial energy systems are complicated networks where changes in one process influence its neighboring processes. The network complexity increases if production/use of bio fuel is introduced in an existing system. Process integration can be a useful tool to study such systems and thus avoid sub optimization.

However, changes in an industrial complex do not only influence the technical values of energy and material efficiency. The social impact is also important and sometimes is comparable to that of technical factors.
A process integration project has recently been carried out for a paper mill in northern Sweden with a side view on future expansion with a bio refinery. An activity to study the social impacts were included through a Conjoint analysis, a stated preference method that combines statistics and interviewing technique.

The results indicate that the participants are divided in four groups, the largest group focusing on a change in the process towards a bio refinery, the second largest focusing on the local environment. The third and fourth group both look at the local forestry, one group wanting to increase local forest production, and one rejecting an increase.

Keywords: *process integration, bio refinery, conjoint analysis, social values.*

1. Introduction

1.1. Pulp and paper – development of energy efficiency and biofuel production

The Swedish wood industry is an important part of the Swedish economy and is responsible for 12 % of the Swedish export. Totally, it is the world's second largest exporter of total paper, pulp and sawn timber. The forest industry is Sweden's largest user of bio-energy and also the largest producer of bio energy. Presently this energy is used mainly internally [1]. A lot of effort is put on work to improve energy efficiency and sustainability. Also several large projects have been started on conversion of by-product into bio fuel e.g. green motor fuel [2].
A partly conversion of a paper producer into a bio refinery involves a lot of changes which will influence the rest of the mill, the employees, the surrounding society and the interaction with the actors involved in supply of wood raw material. It is important, in order to get a successful practical implementation, to consider also non-technical factors, like ete attitudes and reactions of these actors.

It was decided to test these ideas in a process integration project that was carried 2009-2010 in an existing pulp and paper mill. The project studied changes to improve energy efficiency as well as a hypothetical transformation to also include a bio refinery [3]. The project included several different methods and models. A process integration model of the paper mill was developed using the mathematical programming tool reMIND [4]. The results from this model was compared to a Pinch-analysis. The work also included a study on the effect on the wood suppliers and market prices of raw material, using the tool ReCOM, a regional economic market model. A study using the conjoint method [5] was included to study the effect of a plant conversion on attitudes and popular acceptance. Only plant employees were included as test group to limit the size of the first study.

1.2. What is conjoint

The choices people make are based on many things as previous experiences, training, attitude, habits, ethics etc. A person will choose the product or alternative that is most useful for this person (utility theory). The decision is formed by simultaneously considering multiple factors, a unique quality of the human brain. On a daily basis a person makes hundreds or possibly thousands of choices in this way, and this is what the method of conjoint analysis takes advantage of.

Conjoint analysis is a stated preference method, which can be used to assess people's preferences for a specific product, service or situation. It is used to evaluate the attributes of the product/service/situation and thereby makes it possible to determine which attribute is the most important in the evaluated situation. Individual or group level preferences can be estimated by decomposing the responses into part-worth's, thus the results come in quantitative measures which means that they can potentially be incorporated into other models such as process integration models and/or economic models. Studies have previously been made in which conjoint analysis results has been integrated in a Life Cycle Assessment (LCA) as weights in the environmental valuation phase [6]. There has been some attempts to integrate process integration with economic modeling [7] but to the best of out knowledge studies of social values has never been integrated in a process integration project. Further information on conjoint analysis can be found in [8-11].

The purpose of the study was to study the preferences of the employees when asked to compare local environment, global environment, increased local forest outtake and change of process from paper/pulp to paper/pulp and bio refinery. Another aim of the study was to find methods to integrate the result with the process integration result.

1.3. Scope of paper

The paper describes the conjoint method as such, the possibility to integrate the result with process integration models and economic models, as well as the possible use of the results as a basis for decision-making in the paper mill as well as for community decisions.

2. Methodology

The study was carried out through a web-based questionnaire where employees at a paper mill were asked to rank eight different alternatives where local and global environmental impact, local forestry and change in the process were altered in different ways. From the responses, individual as well ass average preferences have been estimated.

2.1. Conjoint analysis

In a conjoint study, the respondent is asked to evaluate a set of alternatives where the factors are varied in a fractional factorial design (reduced design), with two or three levels of each factor (attribute). The factors must be carefully chosen, and can be identified through group discussions, in depth interviews or expert elicitation. Each factor must be provided with two or more levels (high/low). The number of factors must be limited since respondents will not be able to maintain the same level of concentration if the number of evaluations is too large. Four to six attributes are often considered functional [11].

The alternatives that the respondents are asked to evaluate are created through an experimental plan. In order to keep the workload manageable for the respondents the number of alternatives to evaluate needs to be kept at a reasonable level.

The factors were chosen through discussions with Billerud Karlsborg AB in order to make the study relevant for the paper/pulp mill. Relatively early in the process it was decided that the study should be held internally at Karlsborg in order to avoid rumours and speculations in the surrounding society since a bio refinery is not planned in Karlsborg as of today. In the final design of the study, a fractional factorial design with four factors in two levels (2^4) were used, see table 1. The resolution of the design was IV, and only main effects were studied.

Table 1, The design of the study.

Alternative	Local forestry	Process	Emission of carbon dioxide	Local environmental impact
A	Same as now	Pulp/paper + bio refinery	Same as now	20% increase
B	Same as now	Pulp/paper	Same as now	Same as now
C	Same as now	Pulp/paper + bio refinery	Decrease	Same as now
D	Increased outtake	Pulp/paper + bio refinery	Decrease	20% increase
E	Increased outtake	Pulp/paper	Same as now	20% increase
F	Increased outtake	Pulp/paper + bio refinery	Same as now	Same as now
G	Same as now	Pulp/paper	Decrease	20% increase
H	Increased outtake	Pulp/paper	Decrease	Same as now

The study was distributed as a web questionnaire. A message was posted on the intranet to encourage employees to participate. The questionnaire consisted of three parts, first an introductory letter with information on the study and the factors, then the conjoint analysis where the respondents were asked to rank the alternatives in Table 1 from 1-8, and finally the participants were asked questions on residency, age, gender, educational level, work situation and any training in energy efficiency, environment, work environment and forestry.

All employees hand the opportunity to fill out the questionnaire, it was open for two weeks in order to cover all shifts. In all 61 persons answered the questionnaire and from these six responses had to be removed due to inconsistent answers, leaving 55 responses. There are 425 employees at the mill leaving us with a response rate of 13%.

2.2. Analysis of data

In this study two ways of analysing the data are used, first by calculating the main effects from the experimental plan, and then using partial least squares regression, PLSR.

Partial Least Squares Regression (PLSR) is a bilinear multivariate regression method that can simultaneously handle several response variables. PLSR is based on a linear transformation of the original variables to a limited set of latent variables (orthogonal factors), PLSR also attempts to maximize the covariance between the independent and dependent variables. The main advantage of PLSR is that the results can be presented graphically with all individual responses visible. Further information on this method can be found in [12]. The Unscrambler software was used to perform the PLS regressions in this survey [13].

Cluster analysis has proven useful to find segments among respondents in conjoint analysis studies [14-15]. The cluster analysis forms clusters of the respondents by putting respondents (samples) that are similar to each other into groups, at the same time as respondents that differ in response are kept apart. In this project, a hierarchical cluster analysis was applied to the individual main effects from the experimental plan (cluster method: between-groups linkage and interval measure: squared euclidean distance). The analysis was performed with the classification unit from the SPSS v. 17.0 software package [16].

3. Results

3.1. Respondents

Age and gender of the respondents can be seen in table 2. 22 respondents (40%) worked with operation of the mill, 12 respondents (22%) worked with maintenance, 9 respondents (16%) worked with process- and product development and 11 respondents (20%) worked with administration. 41 of the respondents (75%) worked daytime while 14 (25%) worked shifts.

Table 2, age and gender of the respondents in numbers.

Born	80's	70's	60's	50's	40's	No information	Sum
Men	3	6	9	18	6	2	44
Women	3	3	2	3	0	0	11

37 respondents (67%) lived 6-30 km from Karlsborg, 10 respondents (18%) lived in the vicinity, i.e. closer than 5 km and 8 respondents (15%) had more than 31 km to Karlsborg from their homes. 29 of the respondents (53%) were forest owners (or had someone in their closest family that owned forest), 25 respondents (45%) were not and 1 respondent (2 %) did not give any information on this question. 5 of the respondents (9%) had finished primary school, 27 respondents (49%) had finished secondary school and 23 respondents (42%) had a university degree.

3.2. Preferences

The average results are presented in Figure 1. It must be remembered that the number of respondents is small, only 55 complete responses, which means that the result could probably look different with more respondents.

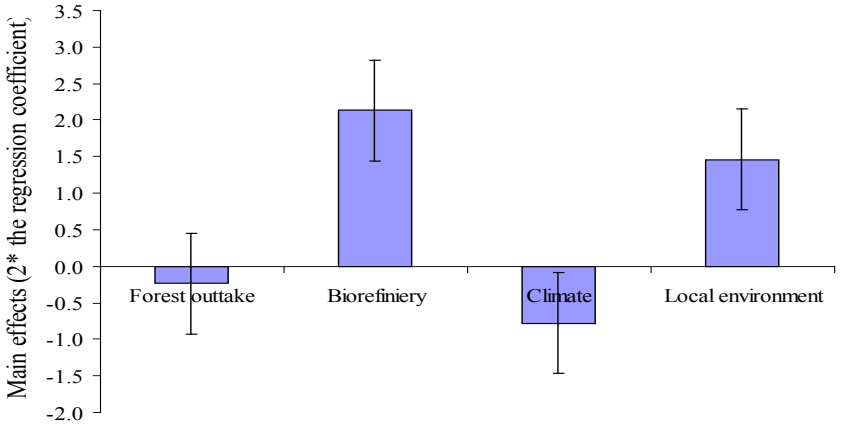

Figure 1. Averaged main effects with standard error for all respondents.

By using a PLSR-plot, individual results can be illustrated, see Figure 2. In the plot, the numbered marks represent individual respondents while the factors are marked with text. The PLSR plot is multi-dimensional, but here, only the first two latent variables are shown,

making the graph two-dimensional. The plot can be interpreted like a map, the closer a respondent lies to a factor, the more important the respondent regard the factor. The plot also reveals negative correlations when a respondent lies on the other end of the latent variable (axis) from a factor, she or he has a negative preference for the specific factor.

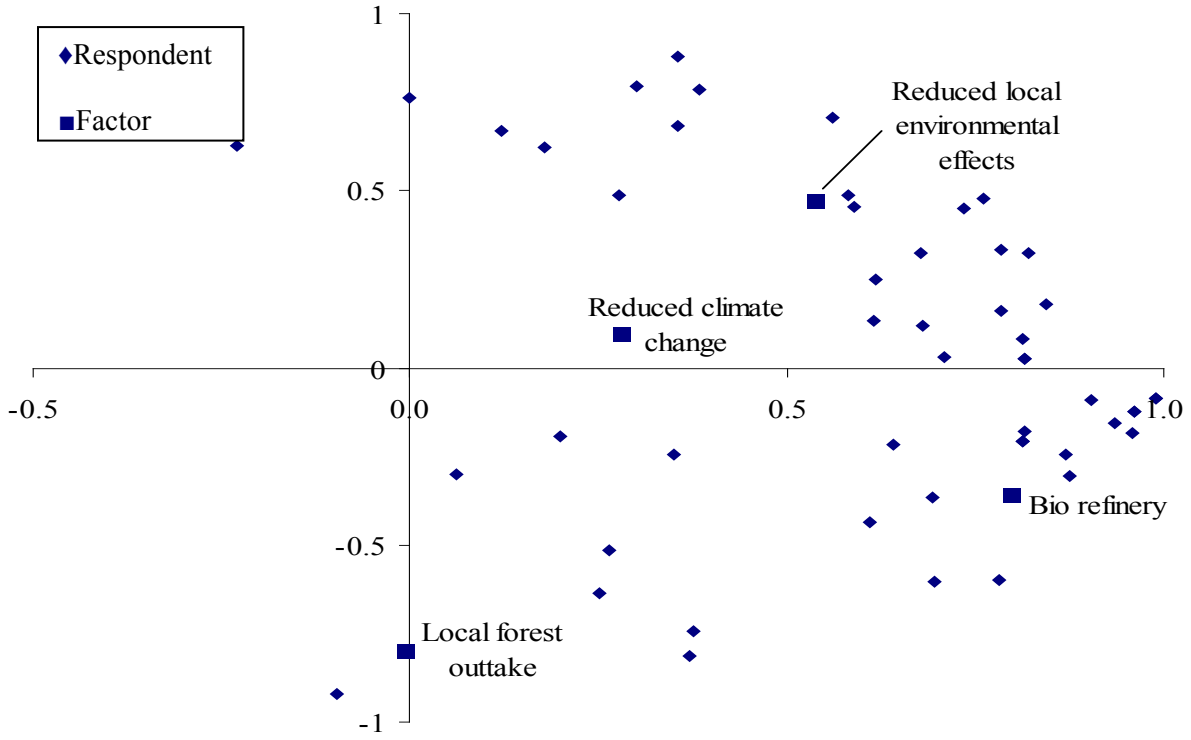

Fig 2. PLSR2. The first two latent variables explaining 65% of the total variance.

If the preferences are compared to the known facts on the respondents, from the information they left in the questionnaire, women are generally more concerned for the local environment than men (p=0.009). Age influence the view on local forestry (p=0.011). Preferences for the local environment are influenced by educational level (p=0.016) and whether or not the respondent or anyone in her/his close family own forest (p=0.010).

If respondents working with maintenance are compared to respondents working with process and product development, there is a significant difference in how they prioritize an increase in forest outtake (p=0.033), see Figure 3.

3.2.1. Training

Respondents with a university degree prioritise increased forest outtake more than respondents with primary and secondary school degrees (p=0.046). 10 respondents had taken part in three or four of the training subjects (forestry, energy, environment or work environment) and for these respondents preferences for forestry differed significantly from the others (p=0.010). The training subjects individually had no influence on the preferences at all. One more thing is interesting to notice, all educations correlate to each other, i.e. if a person has attended one education, she or he is more likely to attend educations in other areas as well.

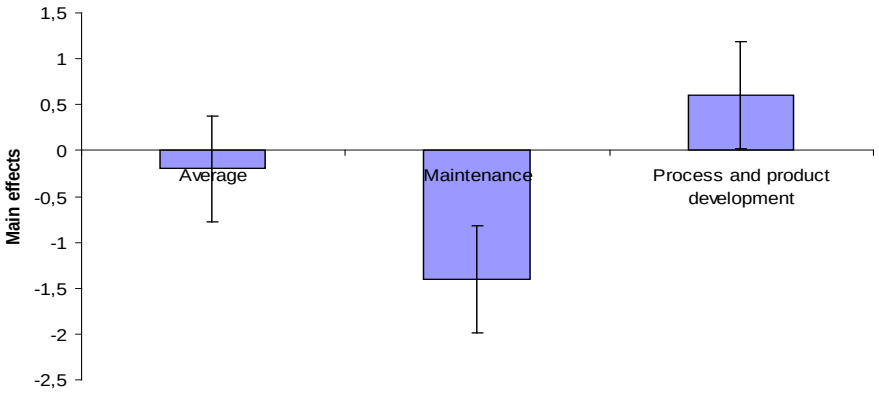

Fig 3. Averaged main effects for respondents working with maintenance (n=12) and process and product development (n=10).

3.2.2. Clusters

Through cluster analysis four clusters (groups) of respondents were formed, see Figure 5.

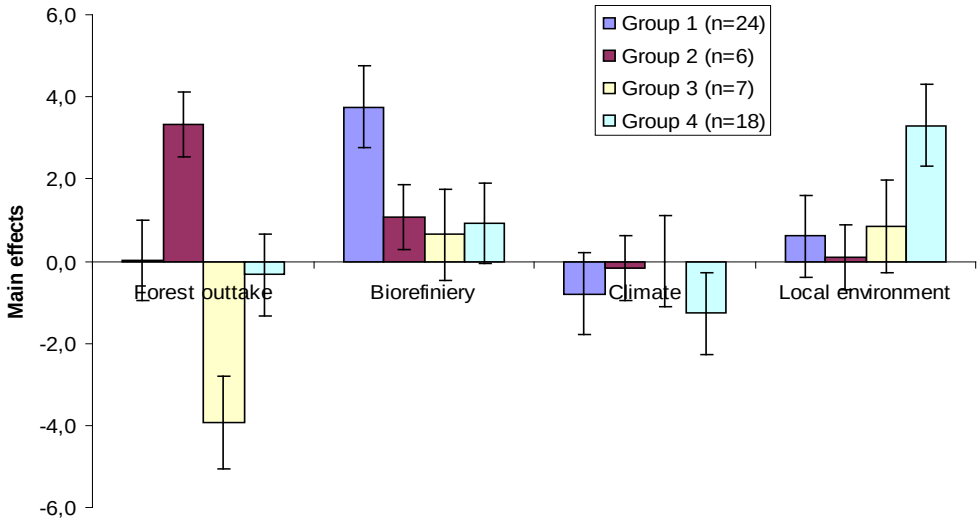

Fig 5. Groups created through cluster analysis.

The number of respondents in this study are to few to draw any further conclusions from the clusters, but in a large-scale study, the clusters could be analyzed for common characteristics such as educational level, occupation, gender etc.

4. Discussion and Conclusions

4.1. Discussion

The number of respondents were fewer than most favorable, probably due to many different reasons. The questionnaire was made available on the Billerud intranet for two weeks, in order to cover all shifts, but it would probably have needed further marketing for more employees to fill out the questionnaire. It would have been preferable to have at least 100 correct responses to the questionnaire.

The results from a conjoint analysis are quantitative. They can be averaged for the whole group or presented individually for each respondent. New groups can also be found through

cluster analysis (see Figure 5). Since the number of respondents are so small, it is not possible to draw any further conclusions on common features among the people in the same group (cluster), but with a larger set of samples (respondents) this would be possible. For the industry this means that it could be possible to pinpoint groups of employees that can be especially helpful in implementing new energy efficient processes, or groups that need extra information to be able to carry out new procedures in a correct way.

Conjoint analysis has been used to illustrate and discuss if the results from a conjoint analysis can be used together with a process integration tool such as a remind model and/or an economic model such as the ReCOM model.

The quantitative results can be used in process integration in several ways, see Figure 6.

A It can be used together with en economic model such as ReCOM as a means of choosing scenarios in the model. The factors in the conjoint analysis can be tailored to indicate how the market would respond in a hypothetical situation.

B Conjoint analysis can also be combined with economic theory and used to derive Willingness To Pay (WTP). This implicit pricing can also be used in economic models such as the ReCOM model. The economic model can be used to derive relevant levels to the factors of the conjoint analysis.

C Conjoint analysis can be used to weight different factors in the process integration model. The weighting can possibly also be used in the economic model. The factors will need to bee rather specific, for example emission of NOx from process XX.

D A process integration model can be used to derive relevant levels to the factors of the conjoint analysis.

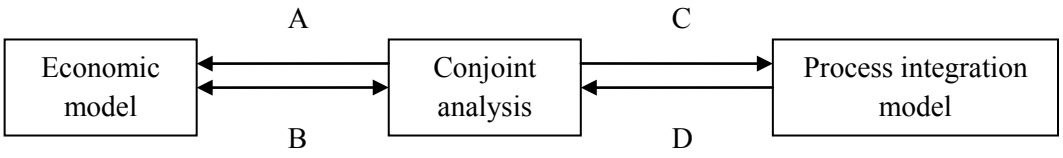

Figure 6. Possible exchanges between conjoint analysis, a process integration model such as a remind model and an economic model such as the ReMIND model.

4.2. Conclusions

Preference studies using Conjoint can be an important tool in studies and actions to improve energy efficiency and sustainability. It can be related in different ways to process integration models and economic models associated with them.

It is also interesting to notice that it is possible to find groups of respondents that were unknown previous to the study, as with the example with two groups of employees working with maintenance and process and product development. If an organisation wants to implement a change in the process conjoint analysis can be used to identify groups of participants with similar preferences and then tailor information to suit these specific groups.

The results of this study leave no clear information on the effect of training. If behaviour and attitudes of the employees are crucial for the full scale implementation of a process integration model, more research needs to be done on the effect of training. In this study, there were no significant connections at all between training and preferences.

Acknowledgements

The authors would like to thank the Swedish energy agency and the Billerud Karlsborg paper mill for financing the work. Also the people at Billerud Karlsborg are thanked for their cooperation in the work

Low-Energy Architecture

Earthen buildings for a low-cost high-energy performance social housing

Stefania Liuzzi[1,*], Pietro Stefanizzi[2]

Abstract: A social housing project was carried out in a developing country (Benin, West Central Africa). A complex of twenty two-storey houses was designed in the city of Cotonou, in order to achieve the best architectural solution with the lowest cost. The project was carried out taking into account the bioclimatic and passive architectural devices in a h ot-humid climate site. By using the software ECOTECT V 5.50 the hygrothermal behavior of the buildings was assessed. Every building was supposed with a reinforced concrete structure, and unfired brick walls. The raw earth was also used as a filler layer in the floor and roof slabs. None HVAC was assumed. The simulation has led the best results in terms of thermal performances and indoor comfort conditions. A partial do-it-yourself building was also supposed in the project, allowing to bring down, with use of the earthen materials, the cost of the whole project of almost 30%.
Further investigations on the earthen materials were started at the Laboratory of Thermophysics of Materials (LTM), University of Politecnico di Bari. The aim of the study is to obtain a low-cost high-energy performance building material suitable to achieve a better hygrothermal comfort in sustainable buildings.

Keywords: *Earth, Hygrothermal behavior, Social housing*

1. Introduction

One of the most important issue in the developing countries is the very poor quality of the houses. Several people build by themselves their houses by using local available materials; producing in the most cases a very high level of indoor discomfort, moreover increasing the environmental pollution.

In terms of architectural design, a global policy attempts to invert this trend by increasing the energy efficiency of the building themselves [1].

Several authors [2,3] pointed out the importance to design a building in regards to the bioclimatic and passive architecture devices, taking into account the climate of the site besides the availability of the local resources. In the tropical climates, heat as well as moisture poses an important consideration that must be factored into design of suitable and affordable housing in such an environment [4].

It can be remarked that the temperature and the relative humidity of the indoor building environment are mainly related to the construction materials [5].

Many studies highlighted the importance of the earth, as an ancient eco-friendly building material, able to keep constant indoor temperature and relative humidity values [6,7,8,9]. Different earthen building techniques and several codes are used also in the hot-humid climate countries [10].

The main aim of the present work was to design in a developing country, Benin, an architectural complex of social affordable houses with the highest energy efficiency and the lowest economic cost. The project, started from the social and economic site analysis, has carried out following the bioclimatic and passive architecture devices and was analyzed by the software ECOTECT V 5.50.

2. Methodology

2.1. Site analysis

The work was carried out in the city of Cotonou, which belongs to the country of Benin, in Central West Africa. Before starting the project several social-economic and climatic aspects were taken into account in order to obtain a sustainable project. As refers by the lists of the UNDP [11] Benin is one of the poorest countries in the world; a study extracted by the Government of Benin [12] has demonstrated that 79,1% of the houses were built with metal sheet roofs in 2002.

According to Koppen's climate classification the city of Cotonou was characterized by a tropical wet climate. The main features of this climate are a very small annual temperature range, heavy rainfalls and wet-warm winds. During the year the average daily temperature is included between 27°C and 32°C; the relative humidity of the air is very high with frequent peaks of about 80%.

Several aspects of the prevailing winds were also taken into account: during the driest season (from November to April) the wind, named Harmattan, with direction North-East, is warm and dry. The wetter season (from April to July), instead, is characterized by the Monsoni winds; their speed can achieve 72 km/h.

2.2. Design of the residences

The project area was a popular zone of the city of Cotonou. The main objective to accomplish was to create an integrated design building form and material as a total system able to achieve the optimum indoor comfort with the best energy saving and the lowest economic cost. Twenty two-storey houses were designed. There were considered two types of residences: type A was supposed as a duplex house for two different low-income households of 4/5 people; type B was assumed as a simplex house for one medium-income household for 6 people.

Fig. 1. The project of the residences (From left to right: Urban layout; type A building; type B building)

None HVAC system was assumed in the buildings. Different passive cooling strategies were taken into account: prevailing winds and solar irradiation analysis, shape of the buildings in regard to the site climate, study of the shape of the single building respect to the whole architectural complex, set up of the internal spaces with the different functions and use of building materials suitable to keep constant indoor temperature and relative humidity values.
According to the bioclimatic architecture devices for the hot-humid climate [2] the buildings were designed along the East-West axis with a surface/volume ratio of 0,64.
All the residences were placed along North-South direction, at the sides of the area. Some "cooling corridors" were also created by using the vegetation and thus different sun path diagrams during the day were analyzed in order to study the daily percentages of shadow.

The layout of each house was built up by a starting modular grid of 6 m by 3,5 m; then some modules were staggered with the aim to produce some external cohorts which can allow to reduce the wind speed and work as sunscreens avoiding the overheating of the internal rooms. Furthermore in each building was created a central natural ventilation chimney [13] by using the stairwell; the sizes and the position of the windows were also taken into account to optimize the indoor comfort by studying the direction of the airflows.

Since the relative humidity rate was very high during the whole year, it was assumed that all the non load-bearing walls and some layers of the floor slabs and the roofs were made respectively of unfired bricks and unbaked earth layer. Several studies pointed out the good moisture buffering capacity of the loam as a building material [6,7,8,9].

3. Results

3.1. Analysis of the thermal performances

According to the EN ISO 13786 [14] the thermal transmittance ($W \cdot m^2/K$), the time lag (h) and the decrement factor of the walls and the floor slabs were evaluated (tab.1-2). Every building was assumed with a reinforced concrete structure. The non-load bearing walls were supposed with an air cavity of 7 cm, two internal and external layers of earthen bricks of 15 cm covered with common plaster layers of 1,5 cm. About the floor slabs the thermo-acoustic layer were supposed of a mixture of wood shavings and raw earth. Minke pointed out the excellent thermal capacity of the unbaked earth [15].

The results showed in the tables 1 suggest that by using the unbaked earth it can be achieved a good thermal inertia; thus it was possible to keep constant values in terms of indoor temperature during all the day even if high variation of external temperature values occur.
According to the EN ISO 13788 [16] the internal moisture of the walls was also verified by using the MC4 software. It can be seen by the figure 2 that during the whole year the saturation vapor pressure (red line) was higher than the vapor pressure (blue line) in each layer of the wall. This means that none internal moisture condensation is possible.

The performance of a passive cooling system through an underground duct was estimated. According to the EN ISO 13370 [17] the average annual ground temperature was assessed at a deepness of about 1 m. It was calculated that this allows to reduce the indoor temperature in a range between 1,5°C and 7,5°C during the summer.

Table 1.Thermophysical properties.

	Surface Mass (kg/m^2)	Thermal Resistance (m^2K/W)	Thermal Transmittance (m^2K/W)	Thermal lag (h)	Decrement factor (-)
External walls	306,1	2,246	0,445	14,69	0,136
Roof slab – type B	453,3	1,991	0,502	12,94	0,102

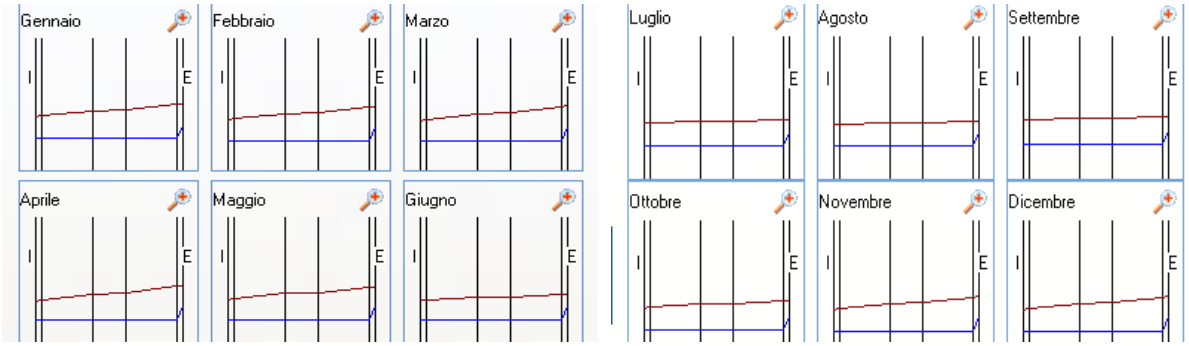

Fig. 2. Water Vapor Pressure profile in the external wall (in red the saturation vapor pressure, in blue the vapor pressure)

3.2. *Analysis of the energy performances with ECOTECT*

Both the two residences (type A and B) were assessed by the software ECOTECT V 5.50.
Each type of building was supposed as a block of different "thermal zones", each of one set with specific hygrothermal and physical properties as shown in the table 2. The database, previously calculated according to the EN ISO norms, was used to carry on the simulation.

Table 2. Hygrothermal and physical properties of the zones.

	Clo value	Air relative humidity (%)	Air speed (m/s)	Illumination level (lux)	Comfort Band (°C)	Latent - sensibile heat gain (W/m^2)
Living area	0.40	60	0.5	300	18-26	2.14-0.86
Night area	0.40	60	0.5	200	18-26	2.14-0.86
Bathroom	0.20	65	0.5	200	18-26	5-2
Kitchen	0.40	65	0.5	300	18-26	5-2
Corridor	0.40	60	0.5	150	18-26	5-2

3.2.1. Indoor temperature analysis

The graph 3 shows the annual temperature distribution of the main internal zones. The comfort band (in yellow) was considered included in the range between 18°C and 26°C.
The temperature of the living area (in red) is in the comfort band for 70% of the hours.
Moreover in the sleeping area (in green) the temperature is in the comfort area for 79% and 89% of the hours. This condition changes in regard to the floor in which the area is.
Conversely the warmest zones of the building are the corridors, the bathrooms and the kitchen.

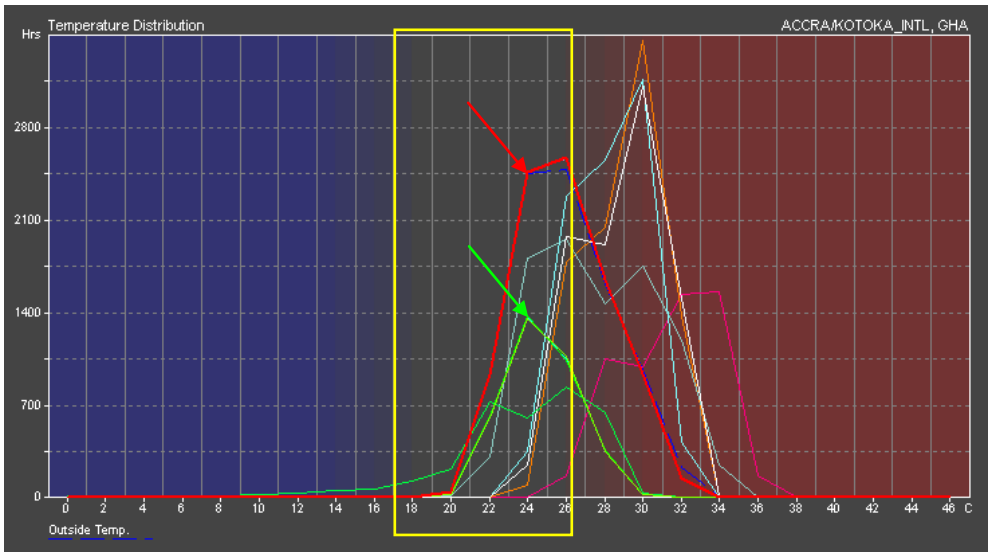

Fig. 3. Annual temperature distribution (in red the living area; in green the sleeping area, in yellow the comfort band)

3.2.2. Internal gain analysis

It was carried out, also, the annual and daily thermal gain and loss analysis due to the temperature gradient in the building.

Due to the solar radiation intensity the main daily gain, of about 1.760 Watts, was achieved during the first afternoon hours in the first and the last months, i.e the driest season of the year. In the night hours there were found the best indoor comfort conditions.

This is owing to the good thermal transmittance, the time lag and the decrement factor described above (table 1) of unfired brick walls.

3.2.3. Wind and solar radiation analysis

The passive ventilation is one of the most effective strategies to use in a hot-humid climate. This is the reason why the buildings were designed in regard to the direction and the type of the winds. The buildings were set with the direction North–South, using the opposite direction of the winds that allowed to dump the discomfort effect produced by the external relative humidity and temperature. On the other hand the design of the external cohorts could also reduce the speed of the air fluxes, when the wind speed is too high.

The design of the buildings was carried on taking into account the solar exposure. Fig. 4 shows the average daily absorbed solar radiation. It can be noticed that the roof is the part of the building mainly involved, with a value between 480 and 600 Wh/m^2. This is the reason why it was created a system of ventilate roof by an air cavity of 4 cm (type A) and a second upturned cover above the roof slab (type B).

The annual sun path diagrams were also studied in order to design the best solution in terms of passive sunscreens. The sun path diagram (Fig. 4) shows that each building is in the shady area for the most time during the whole year.

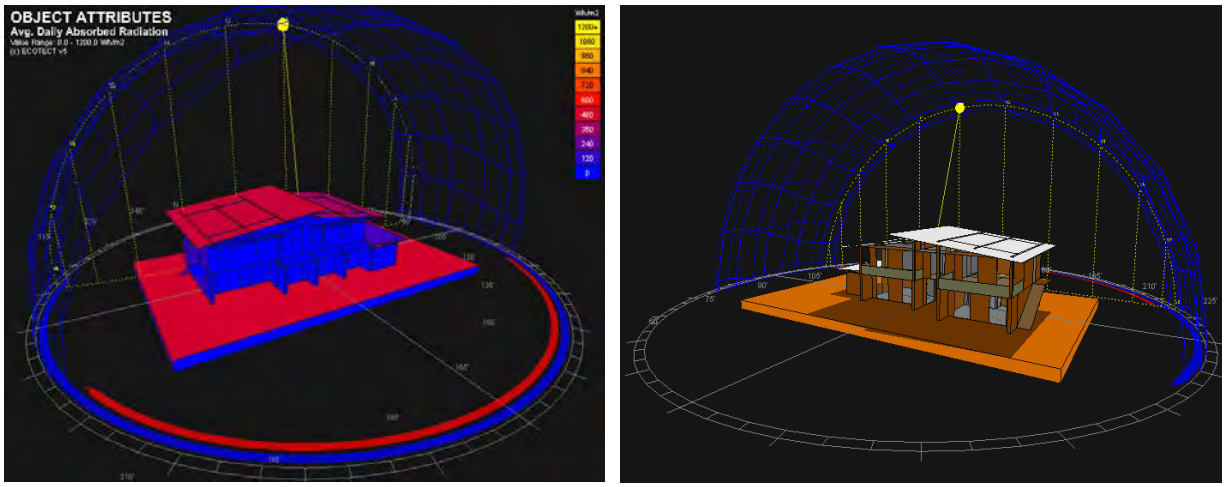

Fig. 4. Solar radiation analysis (Left: Absorbed Radiation; Right: Sun path diagram)

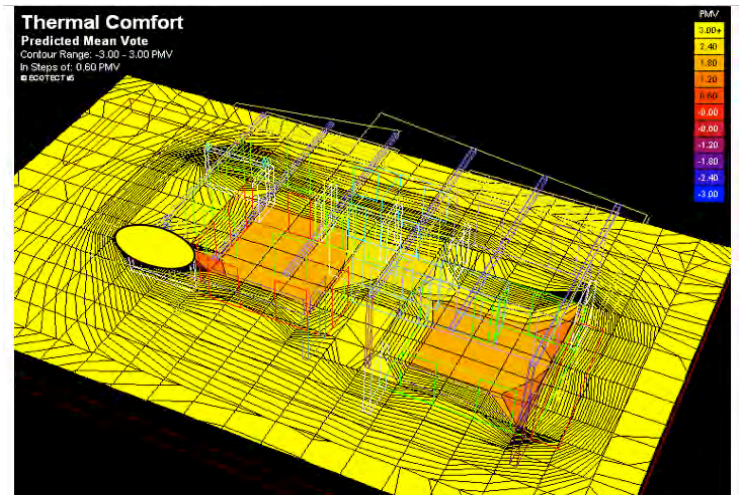
3.2.4. Indoor comfort analysis

According to the EN ISO 7730 [18] the PMV value (Predicted Mean Vote) was computed. The analysis was carried on considering the hottest and coldest days of the year. The graph in figure 5 refers to the warmest day of the year (April 21th) at midday. The main areas of the house, i.e the living and the night areas, show an average PMV value of 1.20. According to the software settings this value means a feeling of lightly warm.



Vote	PMV	Feeling
+3	3.00+	Very warm
Up to 2	2.40 1.80 1.20	Lightly warm
Up to1	0.60 -0.00	Lightly warm
0	-0.60	impartial
Up to -1	-1.20	Lightly cold
Up to -2	-1.80 -2.40	cold
-3	-3.00	Very cold

Fig. 5. Thermal comfort – Predicted Mean Vote

3.3. Cost accounting and sustainability of the project

Several economic saving factors were taken into account in order to accomplish to low cost housing objective. The whole design of the architectural complex and the tree-shaped disposal of the buildings (fig. 1) can allow to suppose an expansion of the houses themselves in the future, solving one of the most pressing problem of a developing country: the uncontrolled population grow.

The structure of the buildings was supposed simple with a modular grid of 3,5 by 6 m. This allows to realize the housing typologies partially with do-it-yourself building, employing the future users.

In order to support the local economy, the use of many local building materials was assumed in the project. Thus it was used unbaked earth both as unfired bricks for non-load-bearing walls and as filler layer of the slabs.

A comparison between the use of fired bricks and unfired bricks was carried out; by the cost analysis it could be noticed that the unbaked earth as a building material allows to bring down the full economic cost of the project of almost 30%. As common strategy in a developing country, assuming the structure cost is at expense of the government, it was calculated that the total cost of a duplex house is about 16.900 euro and the total cost of a simplex house is about 8.500 euro at expense of the future users.

Moreover it was also calculated that with the do-it-yourself building it can be achieved a further lowering cost of about 30%; in this latter case for example the simplex house cost could be 6.000 euro at expense of the user.

4. Conclusion

The main objective of the work was to project an architectural complex of low cost houses in a developing country, characterized by a hot-humid climate. Several architectural devices and socio-economic aspects were taken into account.

The results obtained by the software analysis demonstrated that by using the unbaked earth as a building material it can be achieved a good thermal performance of the whole building envelope, in terms of thermal inertia.

Furthermore the use of many passive cooling strategies, starting from the shape of the buildings themselves up to the whole architectural configuration, have led to obtain excellent results in terms of indoor comfort.

In order to achieve a low-cost high-energy performance housing many economic strategies were also considered. Among these, the use of a local and sustainable material as unbaked earth, on the one hand, and the hypothesis of partial do-it-yourself building, on the other hand, have allowed to bring down the total housing cost of about 60% if compared with a common house built with fired bricks and traditional labor.

Several experimental investigations were started in the Laboratory of Thermophysics of Materials (LTM) (Politecnico di Bari) in order to study the hygrothermal behavior of the unbaked earth building materials.

Two different research lines are carrying on: the lightweight earth by using different additives, like straw and sawdust, and stabilized earth by the addition of the lime. The main objective of the ongoing research is to study how to optimize and obtain a sustainable building material suitable to reduce the energy consumption of the buildings with the lowest economic cost.

Abstract: This study was conducted to determine a significant relationship between energy performance of residential buildings and their architectural configuration. It is known that there are high amount of energy expenses of residential buildings while they are in use. Utilizing knowledge to decrease costs in housing construction and energy consumption during their lifetime, it has been worth to study this subject here. Case study examples were selected from residential buildings in İzmir, Turkey, which were 5-11 storey-blocks with various construction dates. Utilizing architectural and mechanical production drawings, certain area-based ratios and building dimensions were determined as architectural configuration indicators. Energy performance of case buildings were determined by using a calculation method according to the Thermal insulation Requirements for Buildings-TS825. The significant relationship between architectural configuration aspects and energy performance of buildings were analyzed through statistical analysis and scatter charts. Findings were discussed on the basis of TS825. Thus, instead of renovation of existing buildings' energy performance by limited solutions (to add insulation material etc.), taking simple and inexpensive precautions in design process and their application might provide a wide energy saving potential.

Keywords: *Energy performance, Design efficiency, Architectural, Residential buildings.*

1. Introduction

Energy efficiency has been a critical issue to design residential buildings of good quality, all over the world, and in Turkey as well. It is a high indicator of thermal and visual comfort, and also a significant and powerful impact on energy costs. Due to sheltering needs of increasing population and providing a qualified habitat, the field of housing design is rife with proposals that lay claim in improving efficiency [1-3]. As the residential heating is the main source for energy and resource consumption in Turkey, residential design has gained utmost concern nowadays to reduce energy and resource consumption. Utilizing dwellings offering comfortable interior spaces, it would also be possible to reduce harmful gases released into the environment [4-6].

It is clear in literature that architectural configuration of buildings and design norms have direct impact on energy performance of buildings. Several studies have been conducted about thermo-physical characteristics of the exterior walls, building orientation and geometry, building location together with energy efficiency of buildings [7-10]. In a study, for example, optimum window dimensions and heat insulation with an optimum thickness together resulted in a high energy performance among case buildings [11]. In another study, the impact of glass types and overhangs on the heat conductance of wall and roofs were analyzed [12].

Studies on energy rating offered a variety of methods and software (design tools) to design and analyze energy efficient indoor environments [13-18]. Especially the attempt of construction sector consuming high energy in developed countries was to take measures and programs to

rationalize energy consumption in residential buildings. The main objective was to reduce energy consumption for heating [1-3]. To achieve this goal, the design and evaluation process should be in accordance with the proposed method [19]. Considering the lack of comprehensive studies on the relations of energy performance and architectural parameters of buildings in Turkey, a detailed research has been conducting in Izmir and the initial findings will be discussed here.

From the beginning of the 1990s, the Member States in Europe dealt with the legal regulations about energy consumption in order to reduce carbon dioxide emissions, according to Kyoto Protocol. Turkey is now responsible to provide regulations to comply for the latest European Energy Performance of Buildings Directive 2010/31/EC. [20]. In particular, the Thermal insulation requirements for buildings-TS825 and Heat Insulation Regulation (2000) were legally adopted in 2000: the latter is the complementary regulation of the former which offers the calculation method for the energy demand for heating in buildings [21]. Heat Insulation Regulation sets rules for all buildings to reduce heat loss, to provide energy saving and to determine application guideline [22]. Turkey complied with the rules by Directive 2010/31/EC, through Energy Efficiency Law (2007) and Building Energy Performance Regulation (2008). As regards these regulations, following actions were proposed: the evaluation for the energy consumption of buildings, the classification of buildings, determination of minimum energy performance requirements of existing buildings for their renovation [23,24]. "Standard Assessment Method for Energy Performance of Buildings" has been developed by The Ministry of Public Works and is expected to be published in January 2011. It will be legally adopted and will draft energy certificate and compare the energy performance of a building with ascertained energy limits. This method will include heating, cooling, domestic hot water production, lighting energy consumptions and CO_2 emissions. This study, however, included the calculation method which is currently in use.

Design efficiency in architecture is a concept to design and construct buildings and spaces inside more efficiently. It is derived from architectural configuration factors. By this way, it provides construction and maintenance costs at an optimum level. Energy performance is an indicator for the energy cost of the building and for the visual and thermal comfort conditions of users, as well. Again, Turkey, preparing legislations for energy performance, is responsible to ensure compliance of 2010/31/EC and these legislations offer to conduct several studies for new and existing buildings in a 10-year-period. In view of these resent research and ongoing knowledge, this study was constructed for residential buildings in İzmir, which is the third most populated city of Turkey to analyze their energy performance and architectural configuration. The objective is to determine relations between energy performance of residential buildings and their design efficiency. Energy performance of case buildings were determined by using a calculation method defined by TS825. The significant relationship between architectural configuration aspects and energy performance of buildings were determined through statistical analysis and scatter charts. To rank buildings according to their energy performance, the ratio of calculated energy demand to maximum allowed energy demand defined in TS825 were used.

2. Methodology

2.1. Residential buildings in İzmir

Case study examples were selected from İzmir which is situated in the western part of Turkey (latitude 38°25'N, longitude 27°08'E), along the Gulf of İzmir, by the Aegean Sea. İzmir has a

typical Mediterranean climate which is characterized by long, hot and dry summers; and mild to cool, rainy winters. The average minimum temperatures during winter months vary between 6 and 8°C. Average daytime temperatures, however, during summer months (May to October) are almost 25°C or higher.

To determine case buildings, Building Construction Statistics by Turkish Statistical Institute were analyzed. According to these, the number of multi-story residential buildings is 40% of the whole residential buildings constructed from 1960s to 2008, in İzmir. This rate tends to increase because of increasing population and lack of construction area. Thus, subject buildings in this study were defined to be 5-11 storey residential buildings. A total of 30 buildings were selected from three municipalities due to variation in zoning status and high construction rate. Among these, ten out of 30 were in Konak (designated as K1,K2, …), the other ten were in Karabağlar (designated as Ka1,Ka2…), and the rest in Balçova (designated as Ba1,Ba2…). Architectural and mechanical production drawings were obtained from archives of related municipalities. Buildings were classified with reference to zoning status, orientation, floor number, designer and construction year. The data obtained from drawings included address, construction year, number of flats, floor number, zoning status, designer's professional status, width and height of the building, total floor area, total floor area of common spaces, total volume, total area of façade. The principal aim of this study was to analyze existing residential buildings in İzmir with respect to their architectural configuration as a representative tool for their energy performance. It was also thought that results of this analysis would provide much-needed feedback for designers and professionals in İzmir and in other cities.

2.2. Architectural configuration indicators

Relevant attributes of the architectural configuration are basically building form, orientation, zoning status together with several building envelope factors and climate [7-11]. In addition to data cited in previous section, relevant areas of architectural configuration calculated from drawings in this study were the following: n*et-usable floor area (*inclusive of all internal areas left out from footprint area of all structural elements); e*xternal surface area(*calculated from external perimeter and the floor to ceiling height of residential building); n*et-usable common floor area (*the exclusive of all residential flats from net-usable floor area); w*indow area (*area where high amount of heat would be gained/lost); *external wall area* and e*xternal dimension*(width and length). Architectural configuration indicators, as shown in Table 1, were, then, offered to conduct the assessment for the occurrence of significant relations between energy performances and architectural configuration of buildings. These ratios derived from above areas are described below;

Ratio of external surface area to net usable floor area: This is an indicator that reflects form of building by its volume in zoning status. So it is highly related in exterior surface design and in cost efficiency of energy consumption by concerning surfaces. *Ratio of window area to external surface area:* This was viewed as the indicator for the equilibrium of solid-void, describing effects of void surfaces to hold minimum heat load. *Ratio of width to length:* This is an indicator of plan configuration. The objective here was to determine maximum utility spaces and building surfaces in suggested zoning plan. *Ratio of external wall area to net-usable area:* This ratio was used to define design efficiency indicator related flexibility, utility and cost efficiency of designed spaces. It is the one of the general design principle, creating minimum wall area and

minimum fragment plan scheme. *Ratio of net-usable common floor area to net-usable floor area:* Minimum common spaces have great potential on useful spaces to make them usable and generative. It is related in management cost of first and after construction.

Table 1 Architectural configuration indicators(Balçova:Ba, Konak:K, Karabağlar:Ka)

2.3. Thermal Insulation Requirements for Buildings -TS 825

TS 825 [21] "Thermal Insulation Requirements for Buildings" is an official obligatory standard of Turkey derived from DIN V 18599. TS 825 has been in use since 2000 which is revised in

2008 by lowering maximum allowable total heat transfer coefficient. Main purpose of TS 825 is to limit building's energy demand according to exposed area to volume (A/V) ratio. TS 825 uses solar radiation and outdoor air temperature values which are tabulated according to climatic regions specifically determined for Turkey using degree-day method. Heat demand is calculated monthly including specific heat loss, efficiency factor, internal and solar gains. Thermal bridging effect is taken into account with length of the element (I) and longitudinal heat loss coefficient (U_L) according to TS EN ISO 14683 (2004). In TS 825, internal gains are simplified as 5 W/m^2 for net floor area. Gain utilization factor (η) is used to correct the total of internal and solar gains to calculate average monthly useful gains in a statistical way. Calculation of yearly heat demand is followed by comparison of limiting values given in TS 825 according to A/V ratio. If the yearly heat demand is within the limits, the procedure is completed; otherwise properties of the building elements should be re-evaluated and re-calculated.

2.4 Statistical Analysis

The relations between variables, namely, ratio of external surface area to net usable floor area, ratio of window area to external surface area, ratio of width to length, ratio of external wall area to net-usable area, ratio of net-usable common floor area to net-usable floor area and energy performance ratio were tested by single-factor ANOVA at a 5% level of significance (α=0.05). Scatter plots were derived from paired values of variables, namely, heating energy demand, ratio of building surface area to net usable floor area, ratio of window area to external surface area, ratio of width to length, net-usable common floor area to net-usable floor area. These were constructed to understand the relation between architectural configuration indicators and heating energy demand.

3. Results and Discussion

3.1 Findings obtained from TS825.

The results of calculation method-TS825 were tabulated according to construction year, orientation and zoning status. Here, external surface area per volume, heat loss, solar gain, calculated energy demand, max. energy demand, energy performance ratio, and annual fuel demand were tabulated according to construction year as shown in Table 2. In the analysis, heat loss through ventilation and heat gain from internal environment were also calculated. Energy performance ratio of 9 buildings range from 0,94 to 1,00, while 11 of them were from 1,03 to 1,92. Rest of the buildings' energy performance ratio varies between 2,14 and 2,88. Most of the buildings with high energy performance were situated in Balçova. They were the recently constructed buildings according to construction year. However, buildings constructed mostly in 1970s in Karabağlar were having low energy performance.

3.2 Findings obtained from statistical analysis.

The null hypothesis was H_0:τ_i=0; there is no relation among energy performance according to ratio of window area to external surface area. Accordingly, H_0 was accepted at 5% level of significance. It was concluded that ratio of window area to external surface area did not varied significantly according to energy performance. All findings showed that there was no relation between architectural configuration indicators mentioned above and energy performance ratio. Scatter charts also supported this result.

4. Conclusions and Recommendations

The analyses of variance and scatter charts were applied to determine relation between architectural configuration indicators and energy performance of residential buildings. Energy demand calculations were constructed by TS 825. A number of results about architectural configuration indicators and their relationship with energy performance ratio were considered as noteworthy on their own merit. One was that the energy performance ratio was independent of

architectural configuration indicators, despite literature [7-14], showing distinct impact of architectural aspects on building energy performance. Another noteworthy observation was the independence of zoning status and orientation on the energy performance ratio. Several conditions may indicate such an anomaly. One is that the study included a limited number of sample buildings. The other one is that the calculation method is independent from orientation, building form. TS 825, as a static method, is well established to control overall heat transfer coefficient and limit heating energy demand of a building. However, using monthly average climatic values, single zone assumption, ignoring thermal mass, assuming continuous heating regime, lack of internal gain details and control of HVAC systems leads inaccurate results compared with measurements. Results of the static methods give an estimate of monthly heating load and idea about applicable measures to reduce the heat loss of the building. On the other hand, dynamic methods calculate gains and losses from different elements in a building, giving details about different zones and their interactions with the building. Therefore, once the dynamic method which has been developed for building energy performance for Turkey is released, this study will be repeated accordingly. The authors hoped that the new method will exhibit the relationship with building energy performance and architectural parameters. It is necessary to conduct further investigations with inclusion of high number of sample buildings in Turkey. Then, all findings which will be resulted by objective evaluations about existing buildings will be presented to all correspondings' knowledge and use.

Existing buildings – users, renovations and policy

Kirsten Gram-Hanssen

**Corresponding author: Tel: (+45) 23605653, E-mail:kgh@sbi.dk*

Abstract: This paper deals with the energy consumption of existing owner-occupied detached houses and the question of how they can be energy renovated. Data on the age of the Danish housing stock, and its energy consumption is presented. Research on the potential for energy reductions in the Danish housing sector is presented, and it is shown that there is a huge potential for reductions. It is a well-known problem that even if there are relevant technical means, and even if it is economically feasible, the majority of house owners do not energy renovate their homes. This paper intends to address what can be done with this problem. The paper draws on different sources of why, when, how, and why not people renovate their home. These results are then compared and discussed together with a presentation and discussion of the Danish policy measures that are put forward in order to encourage people to energy renovate their home. These policy measures include building regulations, energy tax and different types of incentives and information dissemination. The conclusion calls for new innovative policy measures to cope with the realities of energy renovations of owner-occupied houses.

Keywords: *Detached houses, Energy renovations, User practices, Energy policy.*

1. Introduction

In low-energy architecture focus is often on new buildings and their potential for reducing or eliminating energy consumption for heating purposes as is seen in zero-emission buildings and passive houses. Figure 1 shows the construction age of the Danish building stock in 2004. In the figure is seen that buildings typically have a lifetime of more than 50 years and if we envision the same level of construction activities for the next 20 years as seen for the last 10-20 years, for a very long time the majority of the Danish building stock will continue to be built before the era of low energy housing. This corresponds to British data suggesting that 70% of all homes that will exist in 2050 have already been built [1].

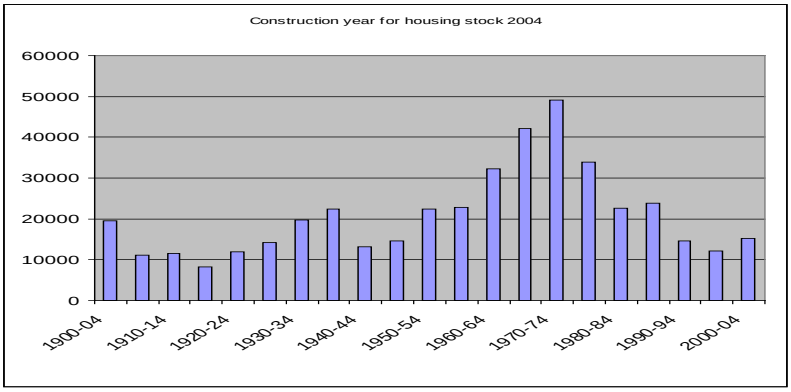

Fig. 1. The construction year of the Danish housing stock in 2004, source Statistics Denmark.

Questions have been raised whether it is better, from an environmental perspective, to demolish buildings and build new ones rather than to renovate, and a few case studies based on LCA analysis have been conducted; however, there does not seem to be agreement on the results [1], [2]. Furthermore there might be other arguments than energy and environment calling for renovating rather than demolishing, including the arguments of cultural heritage and people's personal relation to their homes.

Thus attention has to be paid to how energy reductions in existing buildings can be achieved. In 2009 the final energy consumption in households was 192,145 TJ, representing 30.4% of the total Danish energy consumption, and out of this approx. 83% was related to heating purposes in households [3]. Studies have documented the potential for energy savings if the existing building stock were proper energy renovated [4]. Here the Danish building stock is divided into five groups, including farm houses, detached houses, terraced houses, multi-storey buildings and commercial buildings. In a scenario where only energy renovations that have a payback time of less than 15-25 years are considered, the total amount of energy savings are calculated to 37 PJ, which corresponds to 23% of the annual energy used for the heating of buildings. The building type with the highest potential for energy savings is the detached house, which stands for 41% of the possible energy savings relating to energy renovation in all of the building stock. The reason for the high potential for energy savings in detached housing is a combination of the volume of this type of buildings - the majority of the Danish population lives in detached housing (the Danish housing stock consists of approx. 40% apartments, 46% single-family houses and 14% terraced houses) and these homes are typically considerably bigger compared with e.g. apartments in multi-storey buildings - and the fact that many of these houses were built in the 1960s and 1970s, or earlier, and thus before stricter energy requirements in the Danish Building Regulations came into force.

On the whole there are good arguments for having a closer look at how energy renovations of the existing housing stock, especially the detached owner-occupied housing, can be promoted. In the following, empirical investigations on why people renovate their home will be presented and compared with the policy measures that are put forward in Denmark to encourage energy renovation.

2. Methodology

Results presented in this paper have been conducted in two previously reported studies. The first study is from 2000 and focused on to what extent environment and architecture were considered when people renovated their homes [5]. This study deals with two middle class neighbourhoods from the 1960-70s and from the 1940-50s respectively and it contains a questionnaire survey and qualitative interviews with four house owners. Another study from 2005 included people who had bought a house within the last three years, and focused on what renovations they had so far carried out or planned to do, and to what extent the energy label on their home had influenced their buying of the home or the renovations they had done [6], [7]. This study included 10 qualitative interviews. All 14 interviews have been recorded, transcribed and analysed according to qualitative social science standards [8]. The survey questionnaire was mailed to approx. 350 households, approx. 50% of which responded, i.e. 170 house owners, and the answers have been analysed by the use of SPSS. The new approach in this paper is that these empirical findings are combined and analysed together with a review of Danish energy policy directed at house owners. Furthermore the majority of the empirical results have not been published in English before. As some of these data are more than 10 years old, they will be compared with more resent data on renovation, though, as will be shown, these types of data are rather scarce.

3. Results

The following will first present extracts from studies on house owners' renovation of their homes followed by a review of existing policy measures in Danish energy policy to induce energy renovations of detached single family housing.

3.1 Why, what and how households renovate their homes

According to the survey the renovations made by most of the house owners are kitchen and bathrooms, which 52% and 40% respectively of the house owners have done, whereas for example new windows or roof are only done by 32% and 22% respectively of house owners. Connection to district heating is also made by many of the house owners; however, this should be seen in light of Danish law where authorities can impose this connection. Furthermore Table 1 shows that more than one third of the households have insulated their house. Thus it is seen that renovations including the indoor aesthetics and functions are higher on the agenda than renovations which might save energy for heat consumption. Interviews with house owners supplement and support this: A new kitchen is something to dream about, make plans for and show to others. Renovation of the roof on the contrary is typically made because of necessity more than because of dreams and passion. In Figure 2 this tension is illustrated by an axis called Lifestyle vs. Wear and tear.

Table 1. Results from survey on what type of renovations the present house owners had made to their house. Results are divided between answers from the neighbourhood with houses built in 1960-70s, and in 1940-50s and show the overall percentages as well.

	1960-70s	1940-50s	Overall
Kitchen	44%	57%	52%
Bathroom	38%	41%	40%
Windows	21%	40%	32%
Extensions	30%	16%	22%
Roof	15%	27%	22%
Façade	15%	14%	14%
Patio	17%	8%	12%
Connection to district heating	48%	35%	40%
Radiators and pipes	22%	32%	28%
Insulation	34%	37%	36%
Electric installations	6%	21%	15%
Number of answering households	71	99	170

Table 2. Results from survey on the relation between how long people have resided in their house and whether they have made any renovations

How long have they lived in the house	Have not renovated	Have renovated
0-5 years	65%	35%
5-10 years	42%	58%
10-20 years	31%	69%
More than 20 years	19%	81%
Answers (numbers)	58	104

When looking at who is doing the renovations, the survey shows that in most cases the house owners do some or the majority of the renovations themselves and only in a minority of the houses are renovations made solely by craftsmen. Craftsmen might be involved in the DIY (Do-It-Yourself) renovations as well, because the house owners, or their friends or family helping them, are craftsmen as we heard in several interviews. Furthermore the survey shows that the longer people have lived in their house, the higher the possibility that they have done any renovations (see Table 2). This breaks with a myth indicating that when people buy a house, they renovate it before they move in. On the contrary, renovations are typically something that is done continuously during all the years people live in the house. Also from interviews we know that house owners often have a sort of imaginary list of renovations they

could do or would like to do, but as there is not always time, money or other resources, and as it is not always funny to live in a house that is being renovated, some renovations are postponed and others are carried out. From the interviews, however, we also know that for some families the renovations are not only a dull duty, it might be a creative task, which people appreciate. For several house owners it might even be part of the reason why they have bought a house that they wanted a house to work on and build and that renovating the house is an integrated part of living in it. This tension on the one hand between seeing renovations as something that is interesting in itself because of the process and on the other hand wanting to renovate the house primarily, because one is interested in the result of the renovation is shown in Figure 2, as the axis Process vs. Project.

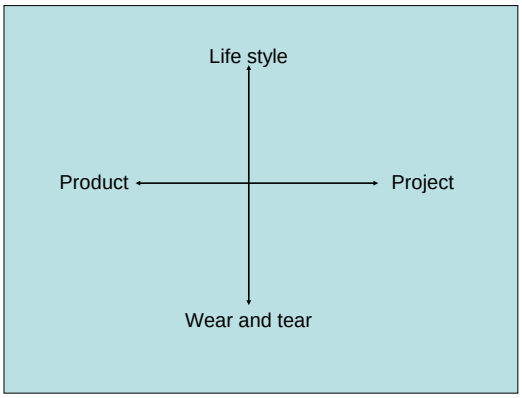

Fig. 2. Reasons for renovating. The figure distinguishes between whether house owners are primarily interested in doing the actual renovating (project) or in the result of (product) the renovation, or whether the renovation is primarily done because of necessity due to wear and tear or because house owners like to have something new (lifestyle). Different house owners, as well as different types of renovations, will be placed differently in the figure.

Different types of renovations thus might have to be interpreted in different terms. Some renovations are done because of aesthetics and dreams of having what friends or family have or what can be seen in catalogues. These renovations might best be understood within understandings of lifestyle, status and consumer choice [9]. This is often the case with kitchens and bathrooms that are renovated without it actually being necessary from a more functional perspective. Outdoor renovations like roofs and windows are more often done as maintenance resulting from wear and tear, though in some of the interviews there are also examples of this being done primarily because of aesthetics. In some families, an important aspect of why people renovate their house is that they actually like to work physically on their house, they enjoy the project and the process. This may include light maintenance like painting walls or it might include completely new construction work like building extensions etc. During these DIY projects people often feel that by working on their own house they get more attached to their home and feel that the house becomes more of a home, as compared with just buying a new and maintenance-free house. In other families, maintenance and renovation are, however, primarily seen as a dull duty that they would rather be without. When understanding this, it is important to see renovation as a part of the specific everyday life of every different family. For example, in some families and at some times living in a house being renovated is a big problem and at other times and families it is easily part of the everyday life. As an example, one of the interviewed families had just had quadruplets, and could thus envision not having any time at all for renovating for the next many years to come. Under other circumstances this family might have liked to renovate their house themselves, however, they had decided to have new windows installed by craftsmen before they moved in.

There might be different types of energy-related issues connected with the renovations. Renewing the windows or the roof most often also include improving the energy efficiency of the house, and renovating the kitchen might include buying new and more efficient technologies. However, in most of these cases energy concern is not part of the main reason for doing the renovation, even though the renovation includes improved energy efficiency. It is just something following from other wishes and dreams. On the other hand some renovations might also include higher levels of comfort, e.g. more heated square meters, a higher indoor temperature or bathrooms with spa, and thus involve increasing energy consumption.

As some of this empirical material is up to 10 years old, it is relevant to compare it with more recent results and with international results. A study comparing the residential building stock in eight European countries (AT, FI, FR, DE, NL, SE, CH, UK) observes that there is not any statistics on the renovation of the building stock in any of the countries [10]. Instead this study uses interviews with key stakeholders to estimate size and type of renovations, and they conclude that modernisation of kitchen and bathrooms is the most common renovation activity in all the studied countries, and furthermore that most of these modernisation activities take place before the end of the components' service life is reached. A recent German study based on a survey of 1000 households [11] and 44 qualitative interviews [12] gives a more solid base for comparison. In the qualitative studies as well as in the survey, it is found that the everyday life situation of the house owners is important for the decision to renovate, and that the reasons for renovating are diverse and include other arguments than a response to an urgent need and that the economy of energy renovation is not a main argument.

3.2 Danish energy policy directed at house owners

The following will present a review of the different elements of Danish energy policy which seeks to promote energy renovation of owner-occupied detached housing [13].

3.2.1 Danish Buildings Regulations

In 1979 for the first time, the Danish Building Regulations included minimum requirements for energy consumption for new buildings. Since then, the Building Regulations have been tightened several times and since 2006 they have also included provisions on the renovation of existing buildings. Here the Building Regulations distinguishes between whether activities include more or less than 25% of the building's physical surface or economic value. If it includes more than 25%, all renovation measures stated in the energy label that are economically profitable have to be implemented. Furthermore the U-values, as required in the Building Regulations for different types of building components, have to be kept, as well as do standards for heating supply etc. If the rebuilding includes less than 25% of the existing building, only the U-values and the standards for heating supply have to be kept.

3.2.2 Energy label and energy inspection schemes

The energy label system in Denmark dates back to the 1980s and since 2006 the labelling system follows the implementation of the EU Directive 2002/91 on the Energy Performance of Buildings (EPBD), which partly builds on the ideas and early experiences in Denmark with energy labels for buildings. The label has to be issued for houses sold as well as for new buildings, and the label includes grades from A1 to G, based on the calculated energy consumption, together with the grade that could be achieved if the house was renovated according to the recommendations. Recommendations are given in an energy plan where the proposals are divided into profitable improvements and "other improvements" respectively

and include estimates of necessary investments, annual savings from improvements (in DKK and energy units) and the payback period of investments.

3.2.3 Utilities' saving obligations

Utilities have been advising their customers on energy since the beginning of the 1990s, and the legal obligation for the utilities to promote energy savings has been part of the law since 1996. According to the energy agreement from 2009, the utilities are responsible for their costumers realizing 6.1 PJ in saved energy. Utilities are free to choose their methods which typically include different types of advice, communication and economic incentives. As regards heating consumption in detached housing, it is primarily the district heating companies that have had the responsibility to promote savings; however, as will be described later, they have primarily focused on change of type of heat supply, to more efficient technologies and to gas and district heating rather than electric heating. The energy authorities require documentation from the utilities that they actually reach these targets on energy savings.

3.2.3 Economic means

There have been energy taxes in Denmark since 1977, and today they represent a considerable amount of what households pay for their energy. Compared with other European countries, Denmark is among those with the highest energy taxes in per cent of GDP [14]. The Danish authorities estimate that over the last 30 years energy taxes have resulted in a 16% reduction in energy [14]. It must be assumed that this has been realized partly through energy efficient renovation.

Economic incentives to households have to a lesser degree been part of Danish energy policy towards households. Examples include a governmental "Growth Fond" with 1.5 billion DKK (200 million euros) to get the Danish construction sector going in 2009. The fond provided subsidy for renovation and building projects in private housing including energy renovations.

3.2.4 Information dissemination

Informative initiatives have been part of the utilities' saving obligations and obviously the energy label on buildings is also an example of an informative mean. However, there are also other initiatives in Denmark that use information as a means of promoting energy savings. Besides different types of campaigns aimed at households, throughout the years the most relevant to mention is a Knowledge Centre for energy savings in buildings. The purpose of the Knowledge Centre is to collect knowledge on how to reduce energy consumption in buildings and communicate it to the professional actors in the building sector, including craftsmen. In the years 2008-2011, 10 million DKK are allocated to the centre.

4. Discussion and Conclusions

As described in paragraph 3.1, energy renovations seen from the perspective of the house owner is an integrated part of living in and continuously renovating the house. Energy renovations are typically done as an integrated part of other renovations, and considering the tear and wear of e.g. roofs or windows, however, the renovation rate has so far been too slow, as the majority of the houses still lack sufficient insulation. This is partly because these types of renovations are prioritised lower than other renovations and according to available time, money and mental surplus. Most often indoor renovations of kitchen and bathroom are higher on the priority list, than renovations related to reducing energy consumption for heating. So a

relevant question is how to make people do more renovations on their home and how to make them prioritise those related to energy savings higher.

As described in paragraph 3.2, there have been political efforts over the last thirty years to make house owners energy renovate their homes. Apart from the mandatory elements of the Danish Building Regulations, all these efforts have focused on information on rational choices related to energy and economy and on economic incentives making it more economically attractive to choose the most energy efficient when renovating. Policy measures thus indirectly assume that economic and rational decision making is decisive when house owners decide what and how to renovate. As shown in paragraph 3.1 this is, however, not necessarily the case. Economy can be decisive in the sense that the amount of money that the house owner is able to, or interested in, spending on renovations is limited, though this does not imply that house owners also make an economic calculation on payback time. Kitchens and bathrooms do not pay back in any economic meaning of the word, and they are still at the top of the priority list. If the family has decided to change windows or renew the roof, then rational economic calculations on saved energy might be decisive for the decision on the amount of insulation material or the energy quality of the windows, however, when deciding to renovate or not, or what renovation to implement, economic payback time is very seldom included as grounds for decisions.

This can be elaborated by including Figure 2, summarising the different reasons that people have for doing renovations. Thus the majority of policy efforts so far can be said to have focused on the right bottom part of the figure: renovations done because of necessity owing to *wear and tear*, and because of an interest in the result (*product)* of the renovation, and on how it can be more economically attractive to include energy in this type of renovation. However, as the text in 3.1 describes and Figure 2 illustrates, there are other, and maybe stronger, reasons why people renovate their homes. They include that the house owner wants something new and more fashionable (*lifestyle*) and that they enjoy working on the house, and in this way appropriate it and make it their home (*project*). Based on the results presented in this paper, it is relevant to raise the question of how to make policy or in other ways to promote that energy renovation is also seen as something that is done because of fashion and lifestyle or because the project in itself is interesting.

I will conclude by giving two examples of what this might include. The first example comes from a Belgian project, which includes interviews with house owners having had an energy assessment [7]. Some of the interviewees indicated that they had thought about installing PVs, and they were rather disappointed because the energy adviser advised against it based on economy. These house owners found PVs interesting more from a lifestyle perspective than from an energy-economic perspective. PVs are visible from outside, you can show them to your neighbours and you can feel good about them – like a new kitchen. Insulation in comparison has none of these qualities. However, having an energy adviser arguing against installing PVs, made the house owners change their mind. This point to the need of energy advisers to be educated in other approaches than the simple economic rational approach as well as the informative materiel also appreciating lifestyle arguments for doing energy renovations. The other example calls for more user-oriented products in energy renovation. What would happen if insulation companies put more emphasis on developing new products with an explicit emphasis on making it interesting, fun and easy to insulate your building, and at the same time give people a possibility of putting a personal stamp on their home, through these products?

An energy-autonomous home in Melbourne – myth or reality?

R.J. Fuller* and S.J. Loersch

School of Architecture and Building, Deakin University, Geelong 3217, Victoria, Australia
** Corresponding author. Tel: +61 352278300, Fax: +61 352278303, E-mail: rjfull@deakin.edu.au*

Abstract: Energy-autonomous buildings are possible. Completely energy self-sufficient houses can be found, for example, in Europe. If it is possible to cover the entire energy demand of a household from only renewable energy generated on site in a central European climate, what is required in a temperate climate, typical of southern Australia? This paper describes an investigation to broadly assess the technical, practical and financial feasibility of energy-autonomy for a hypothetical suburban house in Melbourne, Victoria. The findings firstly demonstrate the importance of reducing energy demand by using passive solar building strategies and energy efficient appliances to reduce demand to a reasonable level. The paper then discusses four scenarios and combinations of technologies to meet this reduced demand. The three scenarios which give energy autonomy increase the capital cost of a typical house by between 15% and 33%, and there would be insufficient roof area to accommodate the solar technologies required in two of the scenarios investigated. It is therefore concluded that while the goal of energy autonomy is technically feasible, it is not likely to be financially or practically acceptable. A fourth scenario of an energy-exporting house was also investigated and is shown to be a much more attractive option.

Keywords: *Energy autonomy, Housing, Melbourne, Conservation, Solar Technologies*

1. Introduction

Globally there is a long tradition in energy-autonomous housing. Examples include the Vale home built in 1974 [1] and more recently, the Solar House at Freiburg built in 1992 [2]. If energy-autonomous buildings can be realized in Europe, what does it take for residential housing in the temperate climate of southern Australia to be energy-autonomous? This paper explores the potential for an energy-autonomous home in the suburbs of Melbourne. The purpose is to broadly assess the available renewable energy (RE) technologies in terms of their likely cost and physical requirements in order to determine whether energy-autonomy is feasible and worthwhile. The current energy consumption of a hypothetical household has been analysed. The assumptions made to reduce this demand using accepted conservation strategies are then described. Various approaches to meet the remaining energy demand from renewable sources have then been assessed.

2. Residential energy consumption in Victoria

Residential energy consumption can be divided into five end-use groups (Fig. 1). Space heating accounts for 44.3 GJ per household per year or 58% of the total energy demand. Electrical appliances and water heaters are the next two major energy consumers, accounting for 20% and 18% of usage respectively. Energy used for cooking and space cooling is only 3% and 1% respectively, despite the large increase in the penetration of air conditioning since 1990 [3].

3. Energy conservation

Reducing the demand for energy for heating and cooling through energy conservation measures is crucial for an energy-autonomous building. Melbourne has a mild, temperate climate with cool winters and mean minimum temperatures of approximately 7° C. The summers are mild-to-hot with mean maximum temperatures of approximately 24°C from December until February. Peak temperatures, however, can exceed 40°C on occasions. The

average daily horizontal solar radiation levels in winter and summer are 2.0 and 6.4 kWh m^{-2} respectively. Proper passive design is essential to moderate internal temperatures within a dwelling to minimise the need for conditioning. In this study, it has been assumed that accepted passive design practices in terms of: house orientation and aspect ratio; magnitude of north-facing glazing; thermal mass and insulation; living room and bedroom location; provision for cross ventilation; summer shading; and reduced infiltration have all been followed. Minimum energy performance requirements for new homes in Victoria currently require an energy rating of 5-stars. This rating equates to using 165 $MJ.m^{-2}$ annually for heating and cooling the home. However, sections of the building industry are already demonstrating that much more efficient homes can be constructed. One commercial builder of mass housing has unveiled a 9-star home, which has a predicted energy consumption of 21.9 $MJ.m^{-2}$. This practice should mean that the heating and cooling demand can be reduced substantially. In this study, it has been assumed that heating demand can be reduced by almost 90% and that cooling can be achieved without air conditioning. For a 220 m^2 home, the energy consumption will therefore be 4818 MJ per annum (1338 kWh).

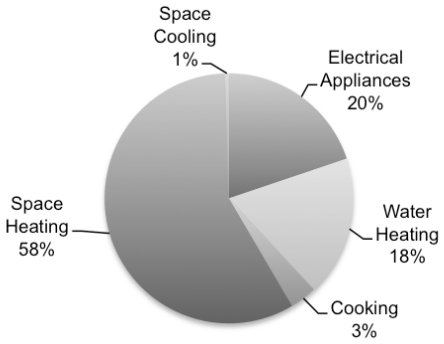

Fig. 1. Residential energy consumption by end use in Victoria (source: adapted from [3])

The average electricity demand of Victorian households in 2008 was 5,824 kWh per year or 16 kWh per day [3]. The electricity consumption of several families (three or four persons), who have made a conscious decision to reduce their energy use, shows that a daily use of 5 kWh is easily achievable without abandoning a modern and comfortable lifestyle [4][5]. Typical strategies to achieve this reduction include: choosing energy efficient appliances; reducing the size of the appliances e.g. the refrigerator to be appropriate to the demand; eliminating standby energy consumption (alone equal to about 10% of the total electricity use); and installing more efficient lighting. According to [6], most homes could reduce their energy use for lighting by 50 per cent or more by using more efficient technologies. In this study, it has been assumed that most or all of these strategies have been used to reduce annual electricity requirements to 1825 kWh i.e. 5 kWh per day.

In Victoria, 74% of household uses a gas cook top and 60% use an electric oven [3]. In an energy-autonomous home powered by RE, gas would not be used. The production of gas from biomass is an unrealistic proposition for a normal suburban household and therefore it has been assumed that electricity will be used for cooking using a combination of electric and microwave ovens, and an induction cook top. An induction cook top is about twice as efficient as a gas cook top [7]. In this study, a modest 5% reduction in energy required for cooking has been assumed because of the uncertainty of the usage patterns of the three cooking technologies to be employed.

The daily hot water usage of an average Australian household is about 193 litres i.e. 76 litres per person [8]; 57% of the hot water is used for showering, 11% for clothes washing and 32% for washing dishes and general household cleaning. High efficiency shower heads can reduce water usage in the shower to 7 litres per minute. Cold water clothes washing can reduce this hot water requirement by at least half. Although improvements in hot water system efficiency could produce further savings in the hot water energy use, this study has assumed that energy consumption for hot water will be achieved by a reduction in hot water usage alone and this will cut the demand down to 50 litres per day per person. Table 2 shows a summary of the current average and reduced annual energy demand for various tasks for a Victorian household.

Table 2: Current and reduced annual energy demand for a Victorian household [3]

	Average household consumption (kWh)	Reduced demand (kWh)
Electrical appliances	4,207	1,825
Water heating	3,851	2,460
Cooking	740	700
Space heating	12,292	1,338
Space cooling	109	0
Total	21,199	6,323

4. Renewable energy technologies

A wide range of technologies are available to harness RE sources. These technologies include solar photovoltaic and thermal systems, hydro, wave or tidal energy systems, wind turbines, biomass burners and digesters, and heat pumps. However, many of these systems are unsuitable either for a single residential dwelling or the RE sources are unavailable in an urban location. Micro-hydro, wave and tidal systems obviously cannot be employed in an urban area like Melbourne. Although wind turbine systems have been developed for rooftop installation in urban areas, wind energy technology is considered unsuitable for Melbourne [9].

Biomass burners in the form of woodstoves are currently used to heat Melbourne homes but their popularity is declining in preference to natural gas. It is predicted that residential energy supplied by wood will decline from 21% in 1990 to 8% by 2020 [3]. In Europe, high efficiency stoves burning pellets made from wood waste are used on a wide scale and encouraged. Although pellet stoves are still relatively new in Australia, pellets from plantation forests are set to become easily available in coming years in Australia. Whether pellet-burning stoves will reverse the preference for gas space heating is uncertain and therefore this technology is not considered in this study. Individual biogas digesters are also not considered because of the need for a reliable supply of feedstock, which is unrealistic for a suburban residence. Solar (electric and thermal) systems and heat pumps using geothermal energy are therefore considered to be the most suitable RE technologies for an energy-autonomous house in a Melbourne suburb and are discussed in more detail below.

4.1. Space heating

There two options for solar heating systems. One system is water-based i.e. hydronic, using radiators or coils in a concrete slab. A system capable of heating a 232 m^2 house would need eight 12-tube evacuated collectors and a 1200 litre storage tank [10]. The cost of the solar components of a hydronic system is estimated to be approximately A$19,000. However, the system would also provide domestic hot water, which would therefore reduce the cost by

about A$5,000. The other system is air-based and would consist of a solar air heater, fan and thermal storage. In the 1970s and 1980s, rockbeds or piles were the preferred thermal storage medium [11]. However, solar air heating systems have declined in popularity and few systems have been installed in recent times and were therefore not considered in this study.

A ground-source heat pump uses the year-round relatively-constant temperature of the earth at 2-3 m below the surface. In Melbourne, this is approximately 15°C. A heat pump uses the energy in the ground to heat the house in winter. In summer, the process can be reversed for cooling by transferring the heat from the building to the ground, using it as a heat sink. In the case of a well-designed house, cooling should not be required. The pipe heat exchanger system, containing water or refrigerant, can be installed either vertically or horizontally. Vertical pipes require boreholes of 30 to 120 metre in depth. A horizontal system requires more space, but it is cheaper to install the pipes at depths of 1-2 m. In addition to space conditioning, ground-source heat pumps can also be used for hot water production. Their main disadvantage is the higher first cost for the excavation work compared to conventional HVAC technologies. In this study, it is assumed that the pipe heat exchanger is installed vertically because of the space restriction of a small urban garden and that the installed price is approximately twice the price of the heat pump alone [12].

4.2. Hot water production

A 30-tube evacuated tube system with a 315 litre storage tank and electric booster has a recommended retail price of approximately A$6500 [13]. In Melbourne, a correctly-sized domestic solar water heating system is generally estimated to contribute about 60-65% of a household's hot water demand. In order to achieve a higher solar fraction and therefore greater energy autonomy, a larger area would be required.

4.3. Electricity generation and storage

Depending on the type of RE system, the electricity generation will vary depending on the daily and seasonal conditions. Compared to a grid-interactive system which uses the main electricity grid as backup, a stand-alone power supply has to provide the entire energy demand either from the generation system directly or from a storage system. This means that the system has to be larger to meet peak loads, and therefore will be oversized at other times. Stand-alone photovoltaic systems in particular require energy storage to enable the energy generated during the sunshine hours to be available for later use. The most common storage system in Australia for stand-alone systems is a large capacity battery bank.

Fuel cells, like batteries, are electro-chemical power sources but, unlike batteries which store energy, fuel cells transform energy, the primary fuel source being hydrogen. Hydrogen can be produced from water by electrolysis with low emissions, if the electricity used for the process is generated by a RE technology such as a photovoltaic array or wind turbine. Such a system could provide electricity on demand and therefore offers the potential to overcome the intermittence of RE sources. The system will require an RE electricity supply, an electrolyser, compressor, purification system, storage cylinders and a fuel cell. The feasibility of a similar system in Australia has been investigated [14] and although the load requirement was ten times greater, some of their findings are relevant to this study. The PV system was the least cost of any combination investigated, and the electrolyser represented about half of the system costs, which was over A$300,000. One manufacturer has sold its first 4 kW RE fuel cell systems and the price of these is approximately A$57,000 [15].

5. Methodology

The various RE technologies considered have been sized and their cost estimated using on-line calculators. To simplify sizing, various assumptions have been made. The energy demand for water heating, cooking and general electricity is assumed to be independent of ambient conditions. Because of the solar passive design features and energy conservation measures, space heating is required now only in the three main winter months i.e. June, July and August. Energy demand is assumed to be equally spread across these three months. Fig. 2 shows the energy demand for the proposed autonomous house throughout the year.

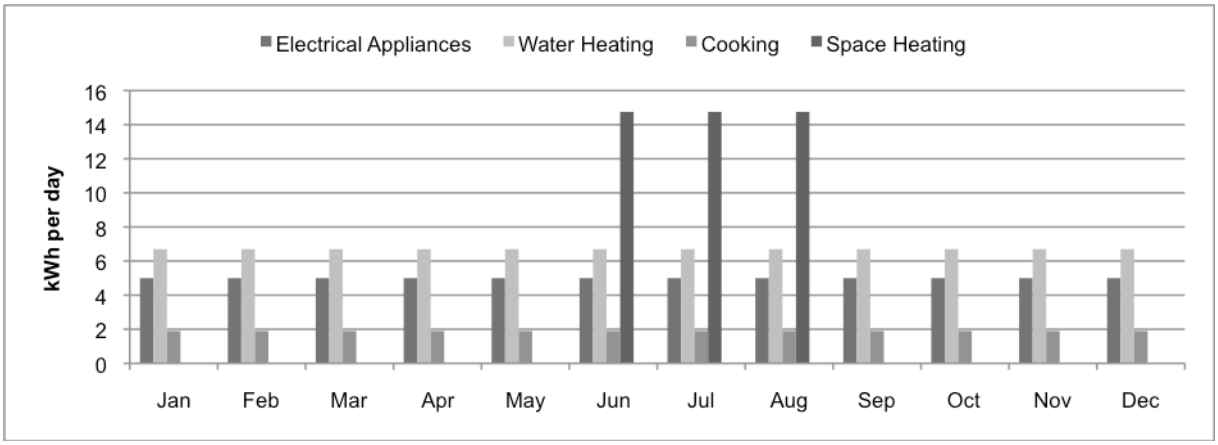

Fig. 2: Daily energy demand (kWh) throughout the year

6. Scenarios

Using different combinations of RE systems, three scenarios to provide the required energy to the autonomous house have been analysed. A fourth scenario using RE technologies in combination with conventional energy systems has also been included for comparison (Table 3). In each case, the house is a detached dwelling with a floor area of 220 m^2 and is occupied by three people. The assumed energy requirements for space heating, hot water and cooking are the 'reduced demands' shown in Table 2 and, depending on the technologies, the demand for electricity will increase above the requirements just for electrical appliances. In Scenario 1, 2525 kWh is required and spread evenly throughout the year. In Scenario 2, an additional 14.9 kWh per day are required in the winter months from the fuel cell. In Scenario 3, the heat pump will require electricity to provide hot water for both washing and space heating. Operating continuously in the winter months, it will therefore require an additional 5.3 kWh per day, assuming a COP of 4. In Scenario 4, only 1825 kWh is required because natural gas is used for cooking.

7. Results and discussion

In Scenario 1, a 17 m^2 evacuated tube array would provide both the space heating and water heating demand, although the system will be greatly oversized for the non-winter months. The photovoltaic system is sized to provide sufficient energy for the daily use in the winter months. A 6.6 kW system with a 1515 Ah battery bank to provide five days of backup is required to provide the electricity for cooking and appliance use [16].

Table 3: Scenarios of RE systems for energy-autonomous and grid-connected houses

End use	Scenario 1	Scenario 2	Scenario 3	Scenario 4
Space Heating	Solar hot water	Hydrogen fuel cell	Ground source heat pump	Solar hot water
Hot Water	Solar hot water	Solar hot water + fuel cell waste heat	Ground source heat pump	Solar hot water + gas booster
Cooking	Photovoltaics	Fuel cell - cooktop Photovoltaics - oven	Photovoltaics	Natural gas
Appliances	Photovoltaics	Photovoltaics	Photovoltaics	Photovoltaics
Energy Storage	Batteries	Hydrogen in storage cylinders	Batteries	Grid-connected

In Scenario 2 the output from the photovoltaic system can be used both directly and indirectly to meet the various energy demands. Electrical appliance use and oven cooking can be met directly. The heating system and the cook top use the PV electricity indirectly in form of electrolysis-produced hydrogen. For space heating the hydrogen is fed to a fuel cell. The cook top is powered by hydrogen gas. Assuming a combined efficiency of 0.74 for the electrolyzer and purifier [14] and a fuel cell hydrogen-electricity conversion efficiency of 0.5, Scenario 2 has an annual electricity demand of 6181 kWh. However, the PV array size required is smaller than Scenario 1. If the electricity generated from the solar panels is insufficient in the winter months, the household can draw from the excess hydrogen energy stored over the summer, thus obviating the need for battery storage and an overly-large PV array size designed to produce the daily requirements in winter. The 4.2 kW system requires an area of approximately 34 m^2 [16][17]. The solar thermal system in this scenario provides 70 per cent of the hot water demand. It consists of a collector area of 5 m^2 with evacuated tubes and a storage tank of 315 litres. When the solar hot water production is insufficient, the waste heat from the fuel cell can be used as a back-up system.

In Scenario 3, a 2.1 kW ground-source heat pump (A$12,000 installed) provides the household with domestic hot water and space heating; a total of 21.28 kWh per day during the winter months. Assuming a COP of 4, this means that 5.32 kWh per day must be generated by the PV array in addition to that required to provide energy for the appliances and cooking. An 11.4 kW system is therefore required. In Scenario 4, the space heating demand is covered by a solar thermal heating system, as in Scenario 1. The photovoltaic system is sized to cover the annual electricity demand, rather than the daily load. A 1.5 kW solar system would generate 2,132 kWh over the year providing an excess of 307 kWh [16]. Natural gas is used for cooking and also to back up the solar hot water system with a solar fraction of 0.65, thus using another 1,561 kWh in total. A 2.5 kW photovoltaic system with an annual output of 3,553 kWh would make the household a net energy-exporter.

8. Feasibility Assessment

Table 4 shows the estimated area requirements and cost for each scenario. The median price of a house in Melbourne in mid-2010 was approximately A$560,000 and a typical house of the size assumed would have a north-facing roof of approximately 50 m^2. In terms of the physical feasibility, Scenarios 1 and 3 require a larger roof area than is available and are therefore not practical unless alternative unobstructed north-facing areas are available. The

data in Table 4 also indicates that a fully energy-autonomous house would add between 15% and 33 % to the median price (Scenarios 1-3). However, a net-energy exporting house would only increase the price by 6%. It is acknowledged that the solar system costs are from one supplier only and lower prices may be available. In addition, the costs used do not include government rebates, which would also reduce the price, but only by approximately 10%. Reducing the number of days of battery storage would also reduce capital costs. The purpose of this exercise, however, is to achieve an order-of-magnitude assessment rather than detailed costing.

Table 4: Additional costs and roof area requirements for an energy-autonomous house

	Scenario 1	Scenario 2	Scenario 3	Scenario 4
Area (m^2)	SHD/HWS - 17 PV (6.6kW) - 48 Total = ~ 65	HWS - 5 PV (4.5 kW) - 34 Total = ~ 39	PV (11.4 kW) - 88 Total = ~ 88	SHD/HWS - 17 PV (2.5kW) - 19 Total ~ 36
Cost (A$k)	SHD/HWS ~ 19 PV(6.6kW) ~ 100 Total = ~119	HWS ~ 6.5 PV(4.5kW) ~ 22 H_2 ~ 57+ Total = ~86	HP ~ 12 PV(11.4kW) ~ 174 Total = ~186	SHD/HWS ~ 19 PV(2.5kW) ~ 15 Total = ~ 34

9. Conclusions

The purpose of this study was to broadly assess the technical, practical and financial feasibility of an energy-autonomous house in Melbourne. It is concluded that the energy-autonomous home in Melbourne is technically possible. With reduced demand, RE technologies are capable of providing a household's complete energy needs, but energy autonomy can only be achieved by installing over-sized systems, the output from which is not used much of the time. This means that very large and expensive systems are required, which are likely to be unacceptable to most homeowners. It is therefore concluded that the goal of energy-autonomy in a suburban Melbourne house is currently not worth pursuing. The alternative option of a low-energy house, which exports electricity produced from renewable sources to the grid offers many benefits in comparison to the autonomous version. Electricity storage systems are not necessary and the energy generating systems can be smaller and cheaper because seasonal differences can be balanced out by the grid. Furthermore, any excess energy produced in summer is not wasted but supplied to other grid users.

Abstract: Here, the capability of the SC-EAHE system to meet the required thermal needs of individuals and also the dependence of the system performance on environmental and geometrical issues, have been studied. To determine the heat transfer characteristics of the system, a mathematical model based on energy conservation equations has been developed and solved by an iterative method. The results of study for the effect of air gap size variation on the air change per hour (ACH) at various solar radiation values shows that this effect (air gap depth on the ACH) is significant up to 0.2 (m), and the ACH and room air temperature remains almost constant beyond the 0.2 (m). The results also revealed that the design of EAHE with the diameter of 0.5 (m) would lead to the best performance. It is found that, with proper insulation, SC system can provide thermal comfort condition even at the ambient temperature as low as 5 ^{o}C and the solar radiation intensity of 185 (w/m^2).

1. Introduction

Traditional energy resources such as fossil fuels which lead to the greenhouse effect, global warming, are expected to dwindle gradually. As environmental regulations are becoming strict, further investigation on alternative solutions to meet the energy needs of residential

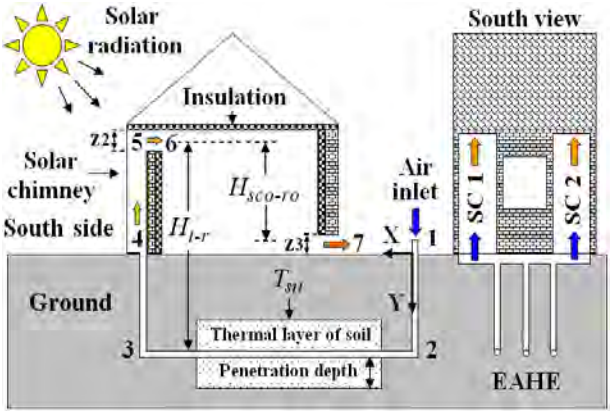

Fig. 1. Schematic diagram of integrated EAHE and SC.

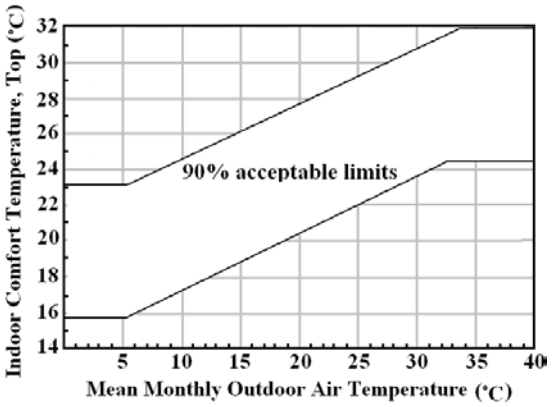

Fig. 2. Adaptive Comfort standard.

units as well as industrial ones is also on the table. The use of passive techniques is an effective tool for attenuating the growth of the energy consumption for air conditioning. Earth to air heat exchanger (EAHE) and solar chimney (SC) are passive heating systems which are commonly used for reducing energy consumption.

Many researches have been conducted on using EAHE for producing cool or warm air so far. Hollmuller [1] considered a periodic input for the air in the buried pipe, yielding a physical interpretation of the amplitude-dampening and the phase-shifting of the periodic input signal. Al-Ajmi et al. [2] developed a theoretical model of an EAHE for predicting the outlet air temperature and cooling potential of these devices. They showed that it have the potential for reducing cooling energy demand in a typical house by 30% over the peak summer season.

Solar chimneys have attracted much attention of researchers. Bansal et al. [3] analytically studied a solar chimney-assisted wind tower for natural ventilation in buildings. The estimated effect of the solar chimney was shown to be substantial in inducing natural ventilation for low wind speeds. Gan and Riffat [4] also investigated solar assisted natural ventilation with heat-pipe heat recovery in naturally ventilated buildings, using a CFD technique. Mathur et al. [5] analytically studied the effect of absorber inclination on the air flow rate in a solar induced ventilation system using roof solar chimney. The results showed that optimum absorber inclination depending upon the latitude of the location. Maerefat and Haghighi [6] introduced and investigated integrated EAHE-SC system. They showed that the solar chimney can be perfectly used to power the underground cooling system during the daytime, without any need for electricity. The review of the related literature shows that the combination of EAHE and SC as a heating system has not been fully investigated yet.

Fig.1 illustrates a schematic plan of the system. The solar chimney comprises a glass surface oriented to the south and an absorber wall which acts as a capturing surface. The EAHE consists of horizontal long pipe that is placed underground. The air is heated up in the SC by the solar energy, and by natural convection mechanism the outside air is sucked-in through the pipe. It will be shown that this system can provide good indoor condition in accordance with the Adapted Comfort Standard (ACS). The required indoor temperatures according to the adaptive comfort model are shown in Fig. 2. ACS does not recommend the ventilation rate [7]. Therefore, the minimum ventilation rate is set around 3 ACH [8].

2. Problem formulation

The modeling includes models of earth to air heat exchanger (Fig. 3) and solar chimney Fig. 4). The following assumptions are made in this analysis.

1. Only buoyancy force is considered, wind induced natural ventilation is not included.
2. The flows in the channels are hydro dynamically and thermally fully developed.

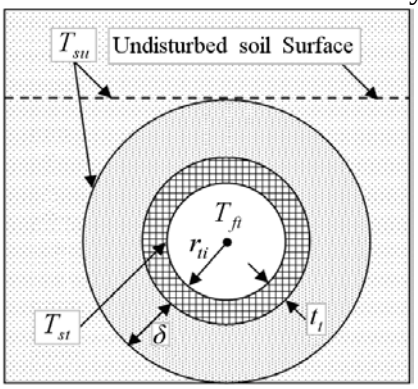

Fig. 3. Cross section of an EAHE.

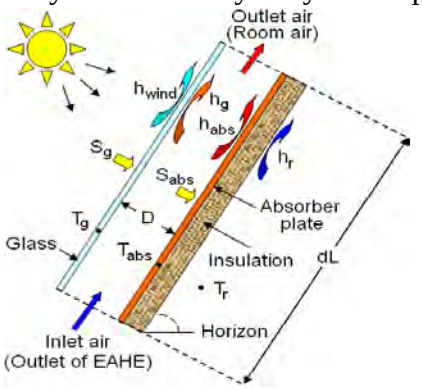

Fig. 4. Diagram of the heat transfer in the SC.

3. The glass cover is opaque for infrared radiation.
4. Thermal capacities of glass and absorber wall are negligible.
5. The air flow in the channel is radiation non-participating media.
6. The soil is homogeneous and the soil type does not change along the channel.
7. The system is at steady-state condition.

2.1. Mathematical modeling of EAHE

The cross section of EAHE used in the model is shown in Fig. 3. In order to impose the ground thermal loads as boundary conditions at the EAHE wall, the undisturbed soil temperature (T_{su}) has been used. The soil temperature is nearly constant at the penetration depth. It is defined when the surface of the soil is subjected to a periodic temperature [1].

$$\delta = \sqrt{2\lambda_s / \omega} \tag{1}$$

The air temperature through the EAHE is calculated by the following equation [6].

$$T_{ft}(x) = T_{su} + (T_a - T_{su}) exp\left(-x / \left(mC_{ft} R_{total}\right)\right) \tag{2}$$

Where R_{total} represents the overall thermal resistance and is given by [6]:

$$R_{total} = \frac{1}{2\pi L_t}\left(1/h_{ft} + \ln\left(\frac{r_{ti}+t_t}{r_{ti}}\right)/k_t + \ln\left(1+\frac{\delta}{r_{ti}+t_t}+\sqrt{\left(1+\frac{\delta}{r_{ti}+t_t}\right)^2-1}\right)/k_s\right) \tag{3}$$

2.2. Mathematical modeling of SC

An element of the model for SC is shown in Fig. 4. In principle and based on the energy conservation law, a set of differential equations are obtained along the length of SC [6].
The energy balance equation for glass cover is:

$$\alpha_g I A_g + hr_{abs-g} A_{abs}\left(T_{abs} - T_g\right) = h_g A_g\left(T_g - T_{fsc}\right) + U_{g-a} A_g\left(T_g - T_a\right) \tag{4}$$

The overall top heat loss coefficient from glass cover to ambient air U_{g-a}, can be written as:

$$U_{g-a} = h_{wind} + hr_{g-sky} + h_{g-a} \tag{5}$$

The convective heat transfer coefficient due to the wind is $h_{wind} = 2.8 + 3.0u_{wind}$ [9].

The radiative heat transfer coefficient from the outer glass surface to the sky and between absorber plate and glass cover may be obtained from [9]:

$$hr_{g-sky} = \sigma\varepsilon_g \left(T_g + T_{sky}\right)\left(T_g^2 + T_{sky}^2\right)\left(T_g - T_{sky}\right)/\left(T_g - T_a\right) \quad (6)$$

$$hr_{abs-g} = \sigma\left(T_g^2 + T_{abs}^2\right)\left(T_g + T_{abs}\right)/\left(1/\varepsilon_g + 1/\varepsilon_{abs} - 1\right) \quad (7)$$

Where, the sky temperature is $T_{sky} = 0.0552T_a^{1.5}$ [9].

The convective heat transfer coefficient is given by: [5]:

$$h = \mathrm{Nu}k_{fsc}/L \quad (8)$$

All property values are evaluated at average surface – air temperatures.

The energy balance equation for air flow in the chimney is:

$$h_{abs}A_{abs}\left(T_{abs} - T_{fsc}\right) + h_g A_g\left(T_g - T_{fsc}\right) = -mC_{fsc}\left(T_{fsc} - T_{fto}\right)/\gamma \quad (9)$$

The mean air temperature was experimentally determined to follow the non-linear form [10]:

$$T_{fsc} = \gamma T_{fsco} + (1-\gamma)T_{fscin} \quad (10)$$

Value of the constant γ is taken as 0.74 according to Ref. [10].

The energy balance equation for the absorber plate is written as:

$$\alpha_{abs}IA_{abs} = h_{abs}A_{abs}\left(T_{abs} - T_{fsc}\right) + hr_{abs-g}A_{abs}\left(T_{abs} - T_g\right) + U_{abs-r}A_{abs}\left(T_{abs} - T_r\right) \quad (11)$$

The overall heat transfer coefficient from the absorber wall to the room U_{abs-a} is given by:

$$U_{abs-r} = 1/\left(1/h_r + t_{ins}/k_{ins}\right) \quad (12)$$

In the above equation h_r has been taken as 2.8 W/m^2 K [10].

2.3. Room ventilation and temperature

The buoyancy pressure due to increasing air temperature in SC, sucks the air through the EAHE. The friction losses due to fluid flow through the channels and across the fittings, refrain from the fluid flow. If the buoyancy pressure overcomes the sum of all flow pressure losses, the natural ventilation may take place.

A mathematical model based on Bernoulli's equation has been used to estimate the system flow rate. Thus, the chimney net draft can be calculated by the following equation:

$$Draft_{sc} = \left(\rho_{fto} - \rho_{fsco}\right)gL_{sc} - \left(\sum_{j=5}^{6} c_j + \xi_{sc}\frac{L_{sc}}{(d_{hyd})_{sc}}\right)\left(\frac{\rho_{fsco}u_{sc}^2}{2}\right) \quad (13)$$

Where the c_j is the pressure loss coefficients at the locations which are indicated in Fig. 1.

The EAHE pressure loss ΔP_{EAHE} is:

$$\Delta P_{EAHE} = \left(\sum_{j=1}^{4} c_j + \xi_t\frac{L_{EAHE}}{d_{tin}}\right)\left(\frac{\rho_{ft}u_{ft}^2}{2}\right) \quad (14)$$

The chimney effects $Draft_{EAHE}$ and $Draft_{Room}$ can be expressed as:

$$Draft_{EAHE} = \left(\rho_{fa} - \rho_{ft}\right)g\left(H_{t-r} - L_{sc}\right) \quad (15)$$

$$Draft_r = \left(\rho_{fr} - \rho_{fsco}\right)gH_{sco-ro} \quad (16)$$

The required draft for heating system $Draft_{System}$ is the sum of the pipe pressure loss and the positive pressure $Draft_{EAHE}$ and $Draft_{Room}$.

$$Draft_{System} = \Delta P_{EAHE} + Draft_{EAHE} + Draft_r \quad (17)$$

Under steady-state conditions, we can write:

$$Draft_{System} = Draft_{sc} \quad (18)$$

The air mass flow rate at the chimney and EAHE are the same if there is no air infiltration:

$$m = \rho A u\Big|_{Chimney\ outlet} = \rho A u\Big|_{Chimney\ inlet} = \rho A u\Big|_{EAHE} \quad (19)$$

By expanding equation (18), the air velocity in the SC can be obtained as:

Table 1. Comparison of experimental and theoretical results for solar chimney included ACH No.

Solar radiation (W/m^2)	Absorber Length (m)	Inlet chim. Dimens (m×m)	Ambient temp. (K)	ACH			Errors of [10] (%)	Errors of present study (%)
				Exp. [10]	Theo. [10]	Theo. (present study)		
500	0.8	1.0×0.2	298-304	4.53	4.89	4.68	7.95	3.31
500	0.9	1.0×0.1	294-296	2.66	3.46	3.44	30.07	29.32
700	0.8	1.0×0.2	298-304	5.33	5.17	5.31	3.00	0.37
700	0.9	1.0×0.1	294-296	2.93	3.67	3.32	25.25	13.31

$$u_{sc} = \sqrt{Bouyancy\ Terms / Friction\ Terms} \quad (20)$$

$$Buoyancy\ Terms = 2\left\{\begin{matrix}\left(\rho_{fto} - \rho_{fsco}\right)gL_{sc} - \left(\rho_{fa} - \rho_{ft}\right)g\left(H_{t-r} - L_{sc}\right) - \\ \left(\rho_{fr} - \rho_{fsco}\right)gH_{sco-ro}\end{matrix}\right\} \quad (21)$$

$$Friction\ Terms = (c)_7\left(\frac{\rho_{fsco}A_{sco}}{\rho_{fr}A_{ro}}\right)^2\rho_{fr} + \left\{(c)_5 + (c)_6 + \xi_{sc}\frac{L_{sc}}{(d_{hyd})_{sc}}\right\}\rho_{fsco} + \left\{\left(\sum_{j=1}^{4}c_j + \xi_t\frac{L_t + 2(H_{t-r} - L_{sc})}{d_t}\right)\left(\frac{\rho_{fsco}A_{sco}}{\rho_{ft}A_t}\right)^2\right\}\rho_{ft} \quad (22)$$

The ACH is calculated under steady-state conditions by the following equation [10]:

$$ACH = 3600m/\left(\rho_{fsc}V\right) \quad (23)$$

The room air temperature which depends on room heat gain is given by:

$$T_r = T_{fscout} - Q_r/\left(mC_{fr}\right) \quad (24)$$

Where Q_r is sum of the heats that the room gains through the walls and the heat generated by internal heat sources.

The coupled governing equations (2), (4), (9), (11) and (20) are the full description of the system and have to be solved iteratively until convergence of the results.

3. Model validation

There is no experimental data to validate the results of theoretical model for the integrated system. So, the calculation has been carried out for SC and EAHE separately under same conditions of experimental studies of [10] and [11]. Table 1 shows the results of present model and the theoretical and experimental results of Mathur et al. [10]. The quantitative comparison shows a reasonable agreement between the results obtained by the present study and the published results of [10]. The results of present study are closer to the experimental results than the theoretical results of Ref. [10]. It should be noted that the calculation carried out at the same conditions of Ref. [10] in which the room volume is 27.0 (m^3). Fig. 5 shows the air temperature variation along the cooling pipe. The results of the present work are calculated at the conditions of experiments based on Ref. [11]. As the figure shows, there is good agreement between the present theoretical results and the experimental results of Ref. [11]. However, it is reasonable to conclude that the mathematical model can predict air temperature quite accurately and the calculated results are reliable.

4. Results and discussion

The following dimensions and specifications are used in the modeling. The room has size of

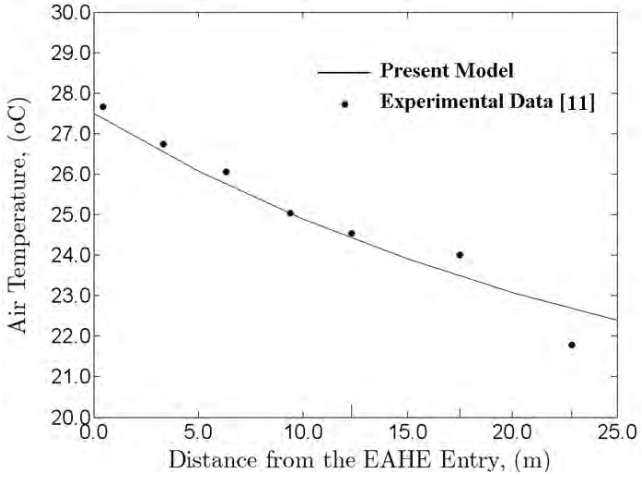

Fig. 5. Comparison present results with experimental data.

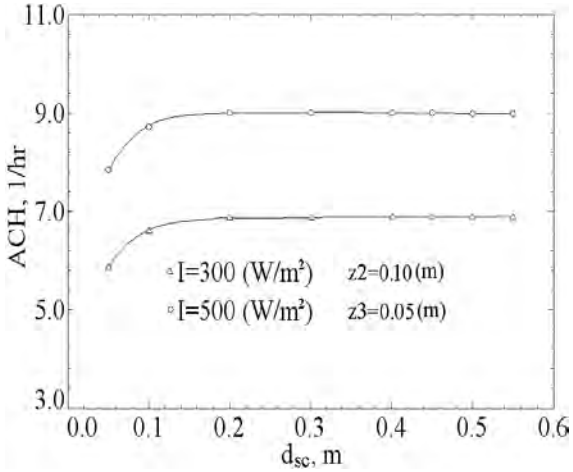

Fig. 6. ACH variation with changes of air gap depth of SC (T_a=10°C).

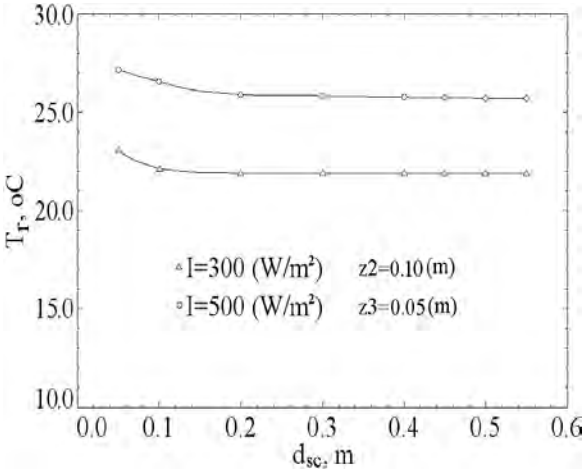

Fig. 7. Room air temperature variation with changes of air gap depth of SC (T_a=10°C).

4.0(m)×4.0(m)×3.125(m) without air infiltration. The heating demand is assumed to change within the range of 0.0-1000 (W) in the calculations. A solar chimney with the length of 3.125 (m), width of 4.0 (m) and air gap depth of 0.2 (m) is considered. The thickness and thermal conductivity of the insulation located in south wall of the room are 0.2 (m) and 0.046 ($Wm^{-1}K^{-1}$), respectively. The transmissivity of the glass wall is 0.84 and the absorber wall has an emissivity and absorptivity equal to 0.95. The outlet sizes of SC and room (Fig. 1) are 0.05(m)×4.0(m) and 0.1(m)×4.0(m) respectively. The heating pipe of EAHE is a PVC pipe with 25.0 (m) length, 0.01 (m) thickness, and inside diameter of 0.5 (m) and is buried 3.0 (m) below the soil surface. The initial soil temperature at it, is approximated to be 19°C for a dry shaded soil surface condition and it is considered to be the heat source temperature.

4.1. Effective dimensions of the system

There are many geometrical dimensions which affect the system performance: i) air gap depth of the SC, ii) heating surface area of the EAHE. Fig. 6 shows the effect of air gap size variation on the ACH. It shows that the effect of air gap depth on the ACH is significant up to 0.2 (m) and, the ACH remains almost constant beyond 0.2 (m). Fig. 7 shows that as the air

gap depth increases, the room air temperature decreases gradually. This decrease is due to the result of increasing the ACH which causes reduction in the energy gained by the absorber. A comparison between these figures shows that as the chimney air gap size increases up to almost 0.2 (m), any further increase does not have a significant effect on room air temperature and it is considered as an optimum required value of the air gap.

Table 2. Effects of diameter of EAHE on system performance.

Heating demand (W)	Solar radiation (W/m^2)	Ambient air temp. (^oC)	Length of EAHE (m)	Diameter of EAHE (m)	ACH	Room air temp. (^oC)	Number of SC and EAHE
0	300	10	25	0.3	3.82	27.2	1
0	300	10	25	0.5	6.85	21.9	1
0	300	10	25	0.7	7.72	20.7	1
500	300	10	25	0.3	Thermal comfort cannot be provided.		
500	300	10	25	0.5	5.04	20.0	1
500	300	10	25	0.7	5.74	18.5	1

Table 3. Effects of length of EAHE on system performance.

Heating demand (W)	Solar radiation (W/m^2)	Ambient air temp. (^oC)	Length of EAHE (m)	Diameter of EAHE (m)	ACH	Room air temp. (^oC)	Number of SC and EAHE
0	300	10	25	0.5	6.85	21.9	1
0	300	10	35	0.5	6.35	23.2	1
0	300	10	45	0.5	5.89	24.4	1
500	300	10	25	0.5	5.04	20.0	1
500	300	10	35	0.5	4.73	21.3	1
500	300	10	45	0.5	Thermal comfort cannot be provided.		

In order to increase the heating surface one may increase the diameter and/or the length of the pipe. Table 2 shows the effect of EAHE diameter on system performance. A comparative survey shows that that as the diameter of EAHE increases up to almost 0.5 (m), any further increase does not have a significant effect on ACH and room air temperature. Therefore this value is adopted as default value of diameter. Table 3 shows the effect of EAHE length on system performance. For the length of EAHE more than 35 (m), the comfort temperature may not be provided and smaller EAHE should be employed.

4.2. Effect of environmental conditions on the system performance

The results of Table 4 also show that when air temperature rises, thermal comfort can be achieved in lower solar radiation. It is also found that when the heating demand is high, thermal comfort can be achieved only at high solar radiation. However, with proper insulation and reduction of the heating demand, SC can provide good indoor condition in the poor solar intensity and low ambient air temperature. The results show that when the heating demand is low, SC can provide thermal comfort condition even when the ambient temperature and solar intensity are equal to 5 ^oC and 185w/m^2, respectively.

5. Conclusions

Natural ventilation and heating of a room which uses SC and an EAHE have been studied in this paper. The results show that there is an optimum size for air gap size of SC (0.2 (m)) and diameter of heating pipe (0.5 (m)). It has been found that the long EAHE with the length of

less than 35 (m) should be employed to provide the thermal comfort condition. The results also show that when the ambient temperature is low, although providing thermal comfort is difficult, proper configurations could provide good indoor condition even in the poor solar intensity.

Abstract: The potential for reducing greenhouse gas emission from buildings comes from both operational and embodied emissions. To date the focus has been on reducing the operational element, although, it is suggested that it is also important to consider early embodied carbon reductions.
This paper describes a case study on the whole life carbon cycle of a building in the UK. Specific issues addressed are the relationship between embodied carbon (Ec) and operational carbon (Oc), the proportions of Ec from the structural and non-structural elements, carbon benchmarking of the structure, the value of 'cradle to site' or 'cradle to grave' assessments and the significance of the timing of emissions during the life of the building.
The case study indicates that Ec can be an important consideration and that the structure was responsible for more than half of the Ec.
An indicative structural benchmark for the building is between 260kgCO_2/m^2 and 286kgCO_2/m^2.
Weighting of future emissions appears to be an important factor to consider. The PAS 2050 reduction factors had only a modest effect but weighting to allow for future decarbonisation of the energy supply had a large effect.

Keywords: *Embodied carbon, Carbon emission, Building, Operational carbon, CO_2.*

1. Introduction

The potential for reducing greenhouse gas emission from buildings comes from both operational emissions, produced by buildings during use, and embodied emissions, produced during manufacture of materials and components, and construction and demolition of buildings.

To date the UK government has focused attention on reducing the, apparently, larger operational element. This is reflected in the current methods of environmental assessment of buildings, which allow the highest environmental ratings to be achieved without any consideration of embodied emissions. This, together with the lack of readily available and usable data on embodied emissions, has hampered the consideration of embodied carbon during building design.

UK Building Regulations are employing a phased approach to increasing energy conservation criteria, resulting in reduced carbon emissions, in the period up to 2020. However, this only applies to operational carbon.

In terms of meeting the UK carbon reduction targets of 34% by 2020 and 80% by 2050 (measured against the 1990 baseline), it may be equally, if not more, important to consider early embodied carbon reductions, rather than just future operational reductions. Future decarbonisation of energy supply and more efficient lighting and M&E equipment installed in future refits is likely to significantly reduce operational emissions, lending further weight to this argument. Methods of emission discounting to evaluate the present value of future emissions, may allow more realistic comparisons to be made between the embodied and operational elements.

Currently, there is lack of a consistent and accepted approach to the calculation of embodied emissions, the relationship and interaction between the embodied and operational elements is not well understood, and there is considerable uncertainty and variability in the available information on emission factors for building materials and processes. Work under the European Standards Mandate M350 'Sustainability of Construction Works' [1] seeks to remedy this by developing a harmonised approach to the measurement of embodied and operational environmental impacts of construction products and whole buildings, across the entire life cycle. At this stage, it is not clear when this will become available. In the meantime, PAS 2050 [2] is available, which builds on the life cycle analysis frameworks given in the BS EN 14040 [3] suite of standards and the Greenhouse Gas (GHG) Protocol [4] developed by the World Resources Institute and the World Business Council for Sustainable Development in 2004. PAS 2050 focuses exclusively on GHGs produced during the life of a product and services. However there is huge scope for variability in the data, life cycle boundaries selected, and assumptions made [5].

This paper describes a case study on the whole life carbon cycle of a book storage building in the UK. This is part of a research project aimed at producing data on embodied carbon for different types of building, components and forms of construction to assist designers in optimising building designs and minimising carbon emissions.

The paper investigates the following specific issues:
- the relationship between embodied carbon emissions (Ec) and operational carbon emissions (Oc)
- the proportions of Ec from the structural and non-structural elements, in order to determine the relative importance of Ec from the structure and to provide data for carbon benchmarking
- how 'cradle to site' and 'cradle to grave' based assessments compare
- the significance of considering when emissions occur during the life of the building.

2. Methodology

2.1. Description of the case study building

The case study building is a book storage facility, completed in October 2010, with a total internal floor area of 11,578m^2, designed to house around eight million volumes, in carefully regulated internal temperature and humidity conditions. It has a steel framed structure on mass concrete foundations, in-situ concrete floor and precast concrete insulated sandwich cladding panels to the external walls. The 12m-high main storage chamber has insulated metal deck roof cladding and the lower 7m high section has a composite concrete and metal deck roof to support the building plant and equipment. The building is well insulated, with high thermal mass provided by the external wall panels, and is well sealed, achieving an on-site air test result of 1.6m3/h/m^2.

2.2. Assumptions and procedure

In the majority of cases, available emission factors are for CO_2, and do not include the full basket of greenhouse gases (GHGs). Therefore, this study is based on CO_2 emissions only. It is estimated [6] that, for most building materials, CO_2 represents the vast majority of GHGs (e.g., around 95%), although for plastics other GHGs are more significant. It is anticipated that as materials data evolves and becomes more comprehensive, factors including all GHGs will become available.

A building life of 60 years has been assumed for the purposes of this study.

Ec values include emissions from materials and components ('cradle to gate'), transport to site and site construction ('cradle to site'), three M&E refits at 15, 30 and 45 years, a general building refurbishment at 30 years, demolition, transport and end of life treatment for demolished materials. End of life treatment has been assumed to be based on the following hierarchy: recycled where possible (e.g., steel); downcycled to a usable but lower grade material (e.g., concrete); incinerate for energy generation (e.g., timber); landfill.

Ec values for structural elements and non-structural have been calculated separately to assess their relative importance and to provide information for structural benchmarking. These are then compared with predicted Oc. This information can be valuable when assessing where to concentrate effort most effectively to reduce emissions.

Both 'cradle to site' and 'cradle to grave' assessments are carried out. The former is more straightforward to establish at the design stage. It is, therefore, useful to investigate if the additional effort required for a 'cradle to grave' assessment produces very different overall results. In this study 'cradle to site' also included site construction.

Previous studies [7] have shown that lifetime Oc is generally larger than Ec. However, Oc occurs over the lifetime of a building (generally 60 to 100years), whereas the vast majority of Ec occurs at the start of a building's life. In terms of the timeframe in which carbon reductions need to be made, it is possible that carbon savings made at the start of a building's life could be more valuable than predicted savings in the future. The effect of future decarbonisation of energy supply could have a profound effect on future emissions, as could more efficient lighting and M&E equipment installed in future refits. It is argued [8] that the cost of measures to mitigate climate change increase for every year the measures are delayed. For these reasons two methods of weighting future emissions are investigated, which may allow more realistic comparisons to be made between EC and OC.

The first is based on PAS 2050 [2] which accounts for the reduced period emissions are present in the atmosphere during a 100-year assessment period and the weighting factor is given by Eq.(1). This is a simplified version of the approach outlined by the IPCC[9].

$$Weighting\ factor = \frac{\sum_{i=1}^{100} X_i(100-i)}{100} \qquad (1)$$

Where i is the year in which emissions occur and X is the proportion of total emissions occurring in that year i.

The second approach is based on the UK Government Markal-Med model scenarios for decarbonisation of the electricity supply over the period 2010 to 2050 [10]. Mean values of the scenarios considered have been used to give reduction factors to be applied to each of the annual Oc and the future Ec. These factors apply to future electricity supply but for the purposes of this study they are applied to energy supply as a whole.

2.3. Operation emissions (Oc)

The predicted annual 'Building Emission Rate', provided by the building designers, is $20kgCO_2/m^2$. This gives a predicted annual Oc of $231tCO_2$ for the whole building.

2.4. Embodied emissions (Ec)

The process of determining embodied carbon, although simple in principle, is not straightforward in reality due to uncertainty and lack of information on emission factors for

all the materials and processes involved. There is considerable variability between the currently available databases for emissions from materials alone and there are a plethora of software tools and online 'carbon calculators' available purporting to provide whole life assessments. In many cases it is unclear exactly where the assessment boundaries have been drawn and which data sources have been used.

For these reasons Ec in this case study has been assessed using the authors own estimates of embodied CO_2 for materials from 'cradle to grave' using 'as constructed' data. Reference has been made to published UK and global figures from a variety of sources to achieve this [11], [12], [13], [14], [15], [16], [17], [18].

2.5. Transport

Transport emissions were determined using the UK Government published figures [19] and actual travel distances from suppliers to site, where this was known. Distances could be determined for the majority of the large quantity materials, but estimates were made where this information was not available.

2.6. Construction and demolition

Emissions from construction and demolition works on site were assessed using UK Environment Agency base data [12], the actual construction period and an estimate of the period required for demolition.

3. Results

3.1. Relationship between Ec (structure and non-structure) and Oc

Table 1 shows the relationship between Ec(structure), Ec(non-structure) for the different scenarios considered in the study.

Table 1. Case study building: proportions of Ec and Oc

	unweighted		PAS 2050		PAS 2050 + Markal	
	Cradle to site	Cradle to grave	Cradle to site	Cradle to grave	Cradle to site	Cradle to grave
Ec						
structure	17%	18%	19%	18%	35%	35%
non-structure	10%	14%	12%	14%	22%	22%
sub total	27%	32%	31%	32%	57%	57%
Oc	73%	68%	69%	68%	43%	43%
Total	100%	100%	100%	100%	100%	100%

The range of Ec as a percentage of the total emissions was found to be 27% to 57%, with structure 17% to 35%. Ec(structure) was always greater than Ec(non-structure).

The two extreme cases are shown as pie charts in Fig. 1 and Fig. 2 together with calculated values of tCO_2.

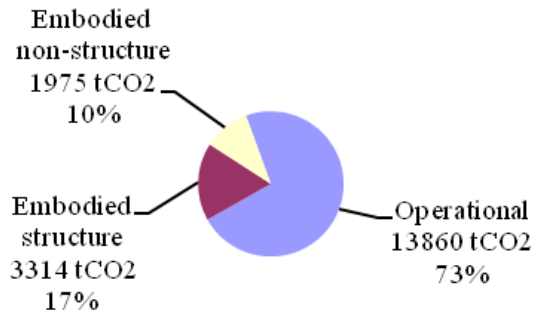

Figure 1. Case study building: embodied and operational emissions (cradle to site, unweighted)

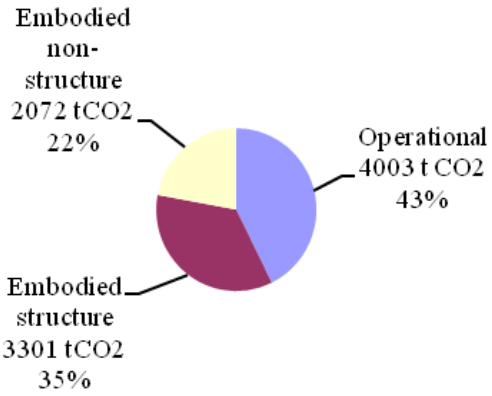

Figure 2. Case study building: embodied and operational emissions (cradle to grave, PAS 2050+Markal)

3.2. Structural benchmarkingc

The range of values of Ec(structure)/m^2 of floor area was found to be between 260kgCO_2/m^2 ('cradle to grave', unweighted) and 286kgCO_2/m^2 ('cradle to site', PAS 2050 and PAS 2050+Markal).

3.3. 'Cradle to site' and 'cradle to grave'

Overall percentage differences between 'cradle to site' and 'cradle to grave' were relatively modest with a maximum of 5% in the unweighted case. The differences reduced if future emissions were weighted. However, for a comparison of individual materials, the end of life scenario can be significant, which indicates that material choices base purely on 'cradle to site', can give misleading results.

3.4. Weighting of future emissions'

Fig 3 shows CO_2 emissions for the case study building lifetime phases.

	Cradle to gate	Transport to/from site	Const-ruction	Oper-ation	Demo-lition	Transport to/from site	End of Life	Total cradle to grave
1. unweighted	4823	519	414	13860	52	102	-438	19332
2. PAS 2050	4756	518	413	11748	36	71	-307	17235
3. PAS 2050+Markal	4466	512	407	4003	2	4	-19	9376

Figure 3. Case study building: lifecycle CO_2 emissions

Applying the PAS 2050 reduction factors has a relatively small impact, whereas applying the PAS 2050+ Markal reduction factors has a large effect. The emission profiles over the building lifetime are clearly demonstrated in Fig. 4. This indicates that Ec is equivalent to approximately 23 and 25 years of Oc respectively in the unweighted and PAS 2050 cases and more than 60 years in the PAS 2050+Markal case.

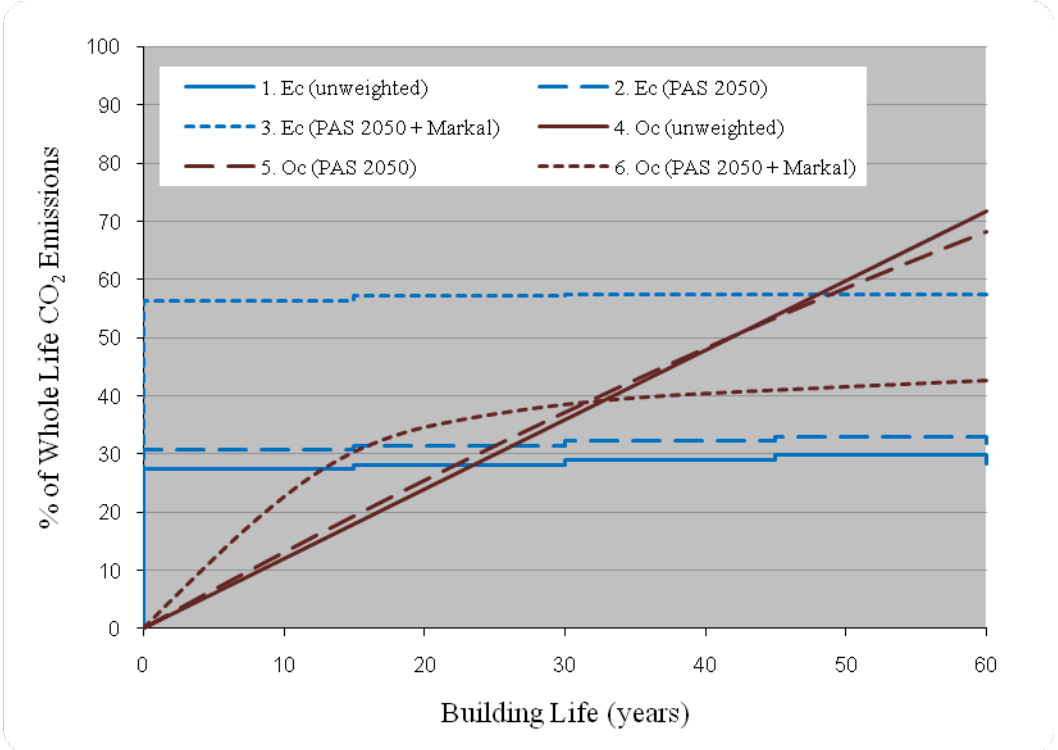

Figure 4. Case study building: Ec and Oc (cradle to grave) as a percentage of whole life emissions

4. Discussion and conclusions

The case study indicates that Ec can be an important consideration in lifecycle CO_2 emissions from buildings, and that in this case the structure was responsible for more than half of the Ec.

A review of other previous case studies [7] indicated that Ec varied between 79% and 108% of Oc for warehouse buildings and was as low as 2% for some other buildings. In this study the range was found to be between 27% and 57% demonstrating that different assumptions and boundary conditions can produce widely differing results and confirming the need for standardisation of Ec data and assessment methods. Assessment of lifecycle carbon emissions should not be considered a precise process due to the many uncertainties and assumptions that have to be made. Nevertheless, it can be a useful tool in assessing where emission reductions can be made most effectively.

An indicative structural benchmark for the building is between 260kgCO_2/m^2 and 286kgCO_2/m^2.

Oc in this case study is based on predicted values. The building was only completed in October 2010 and, therefore, there is currently no data available to assess their accuracy, although these will be available for future updates of the study.

Weighting of future emissions appears to be an important factor to consider. The PAS 2050 reduction factors, to reflect the period emissions are present in the atmosphere during a 100-year assessment period, had only a modest effect, possibly due to the relatively short building life. Longer life buildings would increase this effect but would conversely tend to reduce the Ec proportion of the whole life emissions. In contrast, weighting due to decarbonisation of the energy supply has a large effect, although a more detailed analysis of whether the rate of decarbonisation of the electricity supply will be reflected in the overall energy supply is required before the method used in this study can be validated. No attempt has been made to include discounting based on the cost of measures to mitigate climate change increasing with time but is considered that it would be useful to investigate this issue further.

It is considered that the results of this case study make a useful contribution to the overall bank of data on Ec in buildings.

From a passive to an active house

Tel: +46709-708377, E-mail: charlotta.isaksson@ped.gu.se

Abstract: This paper presents a study on how the energy concept for passive houses is interpreted and used in the daily life of householders. It examines the gradual process by which householders both adapt to and shape passive house technology in their material and social context, thus creating a comfortable home. The theoretical concept of domestication was used in order to understand this process. The empirical material was based on qualitative interviews with residents of passive houses in Sweden. Two rounds of interviews were conducted with 22 informants from 16 households and 21 informants from 15 households. The results show that from a user perspective, the passive house is an active house. An active house has event-based heating. The indoor temperature changes in relation to the household's daily routines and rhythms, their everyday activities and use of appliances. Event-based heating creates different conditions for individual households and alters the meaning of many daily chores. Another result shows that domestication of the passive house concept is a dynamic and long-term process, where the view of indoor temperature and use of technologies change over time. Examining the domestication of passive houses leads to a more informed design process and an opportunity to educate new residents.

Keywords: *Passive houses, Domestication, Households, Space heating*

1. Introduction

Passive houses have been highlighted as an important solution to the problems associated with high energy use for heating in the built environment [1] [2]. The last ten years have witnessed a considerable increase in the market for passive houses in north and central Europe, which is proof of the value of this energy concept. In other words, it has passed the trials connected with its use. The energy use of passive houses has been found to be far below the average and papers have been published about satisfied residents, containing descriptions of comfortable climate conditions [3]. However, the results often show a static product which may be misleading for new residents. Expressed differently, a common impression is that the user simply and immediately adapts to what is offered. The users are seen as passive receivers of the technology. As with any new technology, residents of a recently acquired passive house are confronted by unfamiliar features, to which they have to accustom themselves in one way or another. This paper presents a study of how the energy concept for passive houses is interpreted and used in the daily life of householders. It examines the gradual process in which the householders both adapt to and shape the passive house technology in their material and social context, thus creating a comfortable home. The focus is on the energy concept for heating these buildings:

There are three main factors that affect the amount of energy required for heating a building: 1) the quality of the envelope of the building, including heat exchange. 2) The efficiency of the heating system and 3) the householders' activities, preferences and needs related to heating [4]. Considering the first factor, typical components and requirements for a passive house are a very well insulated and tight building envelope combined with a ventilation system equipped with an efficient heat exchanger. With regard to factor two, the heating of the building is supposed to be mainly managed by "passive" sources such as solar irradiation, human body heat and the residents' use of appliances and lighting [3]. In the case of the energy concept of passive houses, a grouping between factors two and three is made. Through their body heat and use of household appliances, the members of the household constitute a

major part of the heating system. The research questions are: How is the energy concept for heating the building interpreted from a user perspective? How do the residents become accustomed to the energy concept of passive houses? The paper specifically contributes to an understanding of the passive house concept from a user perspective. It provides an understanding of the dynamic yet gradual process of domesticating new technologies. The paper begins with an introduction of the concept of domestication, which is used to describe how passive house technology is gradually integrated into the everyday life of users. The next section outlines the empirical method and data. Thereafter, the results of the two research questions are presented. Finally, conclusions are drawn that highlight the importance of examining the gradual implementation of energy efficient technology.

2. Theoretical approach

This paper examines the domestication of the energy concept in passive houses. In the concept of domestication, the users are regarded as active agents in shaping the way technology is used and, in the long term, its future development [5]. In this paper domestication is regarded as a process, in which the individual both *adapts to* and *shapes* the novel technology in his/her social and material context [6] [7]. The user undertakes both practical and symbolic work in relation to the technology as well as learns how to handle it in an appropriate way. In this process, the reciprocal influence of the user and the technology is not totally predictable. Thus, the passive house concept leads to a change in how the heating of buildings is achieved. This change is ultimately manifested in the social environment where the technology is used and particular meanings are assigned [8].

In this process the users´ relationship to the technology changes over time. For instance, Silverstone et al. analysed the domestication of new technology by means of four non-discrete phases [5]. The first phase occurs when the technology is introduced to the domestic environment. The second is when the technology is assigned a physical space in the home, where norms and values attached to the technology are highlighted, and the initial use begins. The third phase emphasises the subsequent use of the technology and how it is incorporated and fitted into the routines of daily life. Finally, the fourth phase describes the communication between the household and the outside world. By demonstrating different phases, Silverstone et al. highlighted the integration of a new technology as a dynamic and changeable process, where the users´ relationship to and strategies associated with the technology vary. Thus, the interplay with technology is reviewed and reassessed over time [7]. In a similar vein, Lehtonen interpreted the domestication of new technologies, although he studied the phases of domestication as a set of trials in which the capabilities of the users and the technologies were tested in multiple ways [9]. For instance, one type of test is the process of learning what the technologies can do and what the user can do with them, while another is the process of judging that the technology is no longer of any value. In this paper, I will examine the gradual integration of the energy concept for passive houses in relation to the householders' previous situation and collective norms in society. Passive house technology provides a new way of heating buildings, and these features are compared with what the residents were used to in their former accommodation and the houses of others.

3. Methodology

In-depth interviews were conducted with residents living in the first passive houses in Sweden situated south of Gothenburg. The buildings, which were completed in 2001 and were sold as co-operative flats, consist of 20 terraced houses divided into four blocks. Each house is 120 m² and comprises a ground floor, an upper floor and an attic. The south side of the houses has

large window areas, while the north facing side has smaller windows. The passive house standard has a maximum space heating load of 10W/m² [10]. In these buildings a 900 W integrated heater connected to the supply air is intended to cover some of the space heating demand during cold periods. Moreover, solar collectors were installed on the roofs to cover parts of the hot water demand. The measured mean values from all of the passive houses during the second year, show an indoor temperature of 23 ºC (from two measuring points central in the buildings). The occupants stated that the average temperature was about 20-21ºC [11]. It is worth noticing that these temperatures do not say anything about the heat sources used.

The interviews were conducted in two sessions, 2002 and 2005, with 22 members of 16 households and 21 members of 15 households. (During both rounds of interviews one of the apartments was uninhabited and used for research and demonstration purposes). The interviews took place in the householders' homes and lasted between one and two hours, depending on how many family members were present. In six of the interviews, both in 2002 and 2005, two adults from each household were present, while one adult participated in the remaining interviews. In total, 31 informants took part in the study and 12 were interviewed twice. The interviews were audio-taped and later transcribed for analysis. A quoted informant is referenced by an assumed name and the interview year, since they participated anonymously in the investigation [12].

Qualitative interviews were chosen, since they are successful for promoting a user-centred approach where the point of departure is the residents' own perception of how they use and relate to the technology. The strength of qualitative interviews is their ability to capture a variety of opinions and provide a multifaceted and comprehensive picture of the phenomenon studied [13]. The main topic of the interviews was heat comfort and different ways of managing the heating in passive house apartments. Investigations and evaluations of heat comfort often fail to consider the residents' perceptions and activities, instead relying on physical measurements or different statistical standards. Thus, the users are seen as passive recipients of an indoor climate achieved by means of installations such as heating systems [14]. However, this paper is more in line with the so called "adaptive approach" where the residents actively adapt to certain conditions with the help of building technologies and other resources such as clothes, slippers, candles etc [15]. Moreover, the users' management of heating is situated in a social and cultural context that shapes their handling of the heating and what they consider to be an acceptable indoor temperature [14].

4. Result

In the energy concept of passive houses, the residents are explicitly described as being part of the heating system by means of their use of household appliances and human body heat. The first section briefly considers how this heating system is interpreted from a user perspective, whereas the second analyses its gradual integration into the everyday life of householders.

4.1. Event-based heating

When addressing how the households perceive indoor temperature, some dominant features become evident. One of them is *fluctuating* indoor temperatures [16]. The temperature in passive houses changes during the day. In the morning when the household wakes up, it is warmer on the second floor where the bedrooms are situated, but colder on the first floor where the living room and kitchen are located. Nevertheless, the temperature increases rather quickly when the family gathers on the first floor and household appliances are used for

making breakfast. The temperature decreases after the members of the household leave the building for work and school, but rises again shortly after they return to the building in the afternoon. Whether it is warmer on the second or first floor in the evening when everybody is at home appears on first sight to be an issue of where the family members *usually are*. This is interesting, as the passive house concept seems to change the way the indoor temperature is normally perceived to function.

In a cross-cultural study between Norway and Japan, Wilhite et al. identified differences in how buildings are heated [17]. Norwegians tend to heat the whole building and have a relatively constant indoor temperature, whereas the Japanese, only tend to heat the room they occupy. The culture in Sweden is closer to that of Norway, but the energy concept has led to a change. This partly means a shift from heating the whole building to heating the room in which one usually finds oneself. However, the indoor temperature in passive houses does not only fluctuate during the day. Another striking feature is the difference in temperatures *between the weekend and weekdays*, since to a large extent the members of the household are at home during the weekend: ”When one is at home and doing things, washing, using the dish washer, cooking and suchlike, I think that there is good heat circulation and it feels warm” (Frida 02). Frida’s description does not really coincide with the heating culture mentioned above. It indicates something different from generating heat for the rooms that the family members normally use, namely a heating system made up of human activities; an event-based heating system. Heat is supplied when they are engaged in daily activities such as cooking and cleaning, or when they have guests for dinner, thus the term “passive house” is misleading. From a user perspective, it is an *“active house”*, where the heat is generated from the everyday activities of the residents.

Two different tendencies can be discerned within event-based heating. One is that the more activities the household members engage in, the warmer it becomes. That is, people and their participation in everyday activities at home “add” heat for the benefit of each other. The other is that it becomes cooler when there is no one or only a few household members at home or at the times when the household members change location in the house to a place where they have not been for a long time. This mainly concerns going from the second to the first floor or vice versa, such as in the example above when the householders come down to the first floor in the morning.

The concept of domestication underlines the fact that the use and meaning of the technology is integrated and shaped by the social milieu, everyday rhythms and routines of the households [5]. Domestication of the energy concept for passive houses gives rise to an event-based heating that is highly dependent on the social milieu and activities of the households. An event-based heating *creates different conditions* for different households. Smaller households may not generate enough body heat or heat from human activities. Moreover, the result shows that households in which members perform many activities outside the home will have difficulty making the energy concept work adequately, i.e. it does not fit their daily routines and rhythms. In addition, there is a relatively large difference between living in an apartment located at the gable end and living in the middle apartment of the passive house, since heat was better retained in the middle one. In conclusion, the concept generally better fits a four-person household in a middle apartment when the residents spend a considerable amount of time at home. However, the individual conditions of those living in the apartment are also important to consider. For instance, an addition to the family means more body heat as well as increased use of household appliances, which makes it warmer indoors.

Simultaneously, the responsibility that comes with the new family member often leads to a demand for a warmer indoor climate.

4.2. Domestication of the energy concept for passive houses

The following subsections consider the gradual process by which householders both adapt to and shape the content of the event-based heating by means of four types of interplay between their previous experience and the new way of handling heating. In particular, the first three reveal how the householders use of technologies and their view of the indoor temperature changes over time.

4.2.1. Re-creating an acceptable heat comfort

In the 2005 interview session, when the residents looked back on their years in the passive houses, the first two were described as more troublesome, slightly cooler and sometimes too cold. The resources offered by the energy concept were simply not regarded as sufficient to create a comfortable indoor temperature at home. This led to frequent use of other resources – not compatible with the energy concept – such as external electric heaters: ”We used fan heaters. We had one downstairs and one upstairs with the timer set for three times per day. Because we didn’t have the temperature we wanted” (Maria 02). Maria’s family was used to a temperature of around 23-24ºC from her previous home, which she tried to *re-create* in the passive house with the aid of electric heaters. The term re-creating indicates that the difference between the new way of heating the building and the household members´ previous experience is large and also perceived as such and that the members somehow try to recreate the former conditions.

Furthermore, the resources used for re-creating a comfortable indoor temperature were not limited to external heaters. Domestication of technology may give rise to meaning and usage not intended by the producers [5]. One such consequence of the event-based heating is that it alters the meaning of many daily chores at home, such as washing dishes and drying clothes: “If I put the dishwasher on it gets warm” stated Hanna (05), one of the informants. The tumble drier is “really nice and warm” said Maria (02). The dishwasher and the tumble drier were not only appliances that could dry clothes and clean dishes, they also meant a warm and comfortable indoor temperature during the cold winter months. In general, this “double meaning” of the use of household appliances did not stimulate the conservation of energy and an opposite tendency was found. For example, households sometimes washed clothes or turned on the oven, not because they needed to wash or cook, but because the appliances contributed to a comfortable indoor temperature. Use of other resources compatible with the energy concept, such as extra clothing, was not acceptable to these residents.

4.2.2. Re-evaluation of the indoor heat

Thus during the first year, the households where unfamiliar with living in a passive house and many felt that the indoor temperature was to some extent too low. However, while the use of external radiators occurred relatively frequently during the first and second winter in many of the apartments, they became much less common in the following years. In addition, as time passed, the indoor temperature was perceived as normal. A change in how they related to the event-based heating obviously occurred: I think that I have got used to the temperature, that it’s a little cooler. It is really too hot at work” (Hannes 05). As Hannes put it, the change in perception also involved an aspect of *re-evaluation* of the indoor temperature where previous conditions were regarded as less favourable in the light of the present ones.

One interesting reason for this change can be found in what Berner defines as a "perceptual and bodily adjustment" [18]. Berner, who studied industrial workers´ interaction with machines, described it as a process where the human being is forced to "filter out" what one would normally notice in a new environment, such as smell, sound and the speed of new machines etc. It happens simultaneously, as one has to learn how to recognize and act on the basis of new phenomena of which one was previously unaware. The perceptual adjustment to event-based heating occurs by living in the passive house and noticing how the indoor heat changes in relation to the activities and daily rhythms of the household. Moreover, by comparing the heat generating capacity of various technologies and appliances, the household becomes aware of the most suitable method of heating the building. This was demonstrated by Nina who reported that "the effect is better with the candles than with household appliances" or when Johanna compared the use of candles with that of electric light, concluding that the former was more effective. Such comparisons probably facilitate the handling of the heating in the passive house. Other reasons for the change in how the energy concept of passive houses was interpreted are the household's increasing competence in handling the integrated heater in the ventilation system and improved functioning of the energy technology installations. (During the first two years, the ventilation system sometimes malfunctioned). Moreover, some of the informants mentioned the damp remaining from the construction of the houses, which they said gradually vanished. These issues are beyond the scope of this paper, but they all point to the fact that the interplay with technology is reviewed and reassessed by the residents over time [7].

4.2.3. Familiar circumstances

One explanation for their *re-evaluation* of what an acceptable indoor temperature should be is found in the references to other people's homes, and what is considered a normal indoor climate. "They [the cold floors] made me react a little at first but on the other hand they are cold in other houses too and I don't think they are colder here than in other terraced houses" (Caroline 02). Here, the *similarities* between the heat comfort in passive houses and other buildings were highlighted, pointing to the existence of *ordinary and familiar* aspects in the confrontation with the new way of handling heating. The term ordinary indicates that the routines for handling indoor comfort, such as the use of slippers and cardigans, as well as the perception of the indoor temperature are similar to what the household members are used to or are common in society in general.

4.2.4. Innovative ways of managing indoor heat

A re-evaluation of the indoor temperature also highlights positive differences. Although the differences between the household members' previous ways of handling heating and the passive house energy concept are large, they are not necessarily seen as negative. As Bakardjieva who studied the use of internet stated, technologies are often used as innovative tools for changing the present circumstances [19]. Thus, passive house technology becomes interpreted as an *innovative* tool for changing previous ways of handling indoor heat and creating a more pleasant and comfortable indoor temperature. For Paulina, this was the case from an early stage: "As I left a house that was really very warm I thought that it was more comfortable to live in a house where I can put extra clothes on instead of a house where it's too hot" (Paulina 02). The differences outlined above are overcome by the fact that the energy concept for passive houses leads to a desirable change. In addition, resources such as clothes, slippers and blankets are regarded as "nice and cosy" and as a prerequisite for a healthier and comfortable indoor climate.

Other examples of new routines, or new ways of thinking about indoor climate in buildings, are keeping the heat inside by quickly closing the door when entering and seldom airing. This is a new habit that is partly due to the limited possibilities of heating the passive house. Moreover, as highlighted above, the household appliances have become "producers of heat." Another aspect of this is that the householders utilized the heat from the appliances, for instance by facilitating the spread of heat by opening interior doors. These activities are not a "passive" adaptation to the circumstances in a passive house. From the perspective of the householders it is an active process and interpreted as the most appropriate way to handle indoor heat. Other desirable changes that come with the passive house energy concept are an improved economic situation as well as environmental protection. The former included feelings of participation in fulfilling the intentions of the product developers in the creation of an energy efficient home.

5. Conclusion

This paper has examined the domestication of the energy concept for passive houses. Using the term 'event based heating' I have highlighted some important features that newcomers to passive houses may encounter. The gradual process of getting used to the energy concept has been explored by means of four types of interplay between the householders' previous experiences and the new way of handling heating influenced by the energy concept. In a sense, these types reflect what users may be confronted by when leaving old technology behind and experiencing new. Some features are missing, which the householders try to compensate for, whereas others are improved or fairly similar to what they were used to. Nevertheless, their relationship to these features is changeable and might be re-evaluated over time. It is important to identify the content and development of the reciprocal influence between the energy related technology and the user. For instance, does living in passive houses give rise to non-energy efficient routines in relation to household appliances? The result of this study indicates that it does, which in part questions the establishment of a maximum space heating load of 10W/m². However, there are also long term tendencies that demonstrate the creation of a more environmentally friendly view of indoor temperature as well as routines in line with an energy efficient way of life. By examining the domestication of the energy concept in passive houses, an improved understanding of user practice in these buildings can be developed. This would lead to a more informed design process as well as an opportunity to provide information to new residents of passive houses.

Abstract: The integration of Phase Change Materials (PCMs) into the building envelope provides a higher thermal inertia that, combined with the thermal insulation effect, can reduce the energy consumption.
Using a 2-dimensional simulation model based on the enthalpy formulation, a latent heat storage system has been numerically designed and parametrically optimized to take advantage of solar thermal energy for buildings space heating during the winter in Coimbra, Portugal. The main purpose of this study is to show the potential of incorporating PCMs in structural cells of shading elements associated to southward façade windows.
In view of the low thermal diffusivity of the Phase Change Material (PCM) chosen, the distance between metal fins is directly proportional to the energy storage/release capacity of the system. The results of the parametric study also show that solar radiation flux has a strong effect on the melting/charging process. On the other hand, the indoor temperature and the indoor heat convection transfer rate, during the night, play an important role in PCM solidification/discharging process.
In conclusion, an optimal thermal storage system – PCM shutter – can be designed for any given location and characteristic climatic data during the winter. The optimum depends strongly on the thermophysical properties of the PCM and on the internal boundary conditions considered.

1. Introduction

As referred by many authors [1-5], the thermal energy storage systems using PCMs have been recognized as one of the most advanced energy technologies to enhance the energy efficiency and sustainability of buildings. An interesting feature of PCMs is that they can store latent energy as well as sensible energy. Their high latent heat storage capacity combined with friendly energy systems employing endogenous energies, such as solar thermal energy, can reduce the energy consumption of buildings in a passive and sustainable way. The systems incorporating PCMs benefit also from the isothermal nature of the phase change process. For a review, see [1-5]. At the same time as the demand for thermal comfort in buildings in Portugal increases, so does the energy consumption for buildings' indoor environmental control, particularly, for space heating during the winter. The main goal of the present work is

to design a latent thermal energy storage system incorporating PCM, taking advantage of solar energy, which is an abundant resource in Mediterranean climates, for space heating during the winter season in Coimbra, Portugal. The numerical simulation of the system is performed using a code specifically developed for this purpose, based on a 2-dimensional model following the enthalpy formulation.

The enthalpy formulation has been extensively employed by many authors in the modelling of phase change problems [6-11] and it is one of the most popular fixed-domain methods for solving the Stefan problem [4]. The problem of predicting the behaviour of phase change is difficult due to its nonlinear nature at the moving interface and, in addition, to the fact that the material at the two phases has different thermophysical properties. When the PCM undergoes a phase change, both the solid and the liquid phases are present and are separated by a moving interface between them. The difficulty in solving a phase change problem is the presence of a moving boundary or region in which heat and mass balance conditions have to be met.

2. Methodology

2.1. System Descriptions

The scheme of the architectural configuration of the system is shown in Fig. 1a. It consists of 2 shutter panels, each 0.5 *m* by 1.5 *m* and composed of a set of several aluminium rectangular cavities filled with the PCM. The horizontal walls of the cavities are supposed to act as a fin arrangement and enhance the rate of heat transfer to the PCM. To compensate the low thermal conductivity of PCM, the use of metal fins in a latent heat storage system has been studied by many authors [7-11]. The insulation layer on the back surface of the shutter is essential to enable the control of the direction of the stored heat delivery, especially during the thermal discharge of the system.

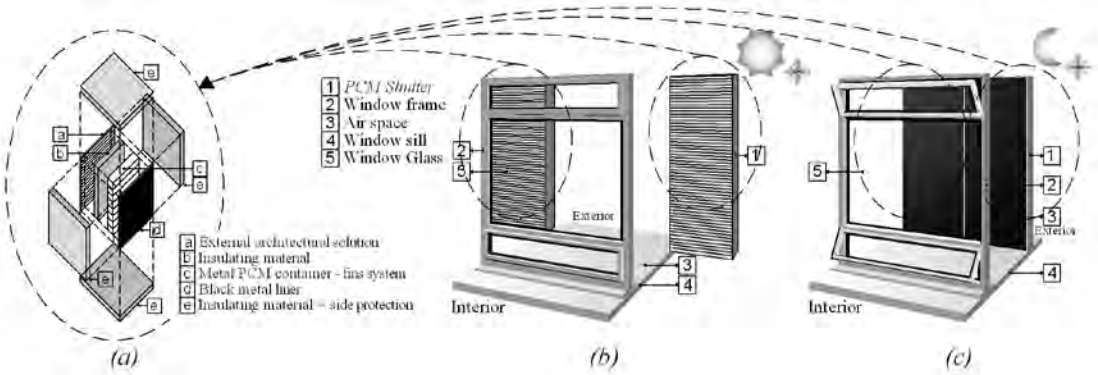

Fig. 1. (a) Schematics of the latent heat storage system; (b) Schematics of the functioning of the PCM shutter during a winter day – PCM charging when the system is opened; (b) Schematics of the functioning of the PCM shutter during a winter night – PCM discharging when the system is closed.

The rationale of the system operation during a consecutive day and night in winter is sketched in Figs. 1b and 1c. The system must operate cyclically, reflecting the ongoing cycles of the daytime and of the PCM phase change process (from solid to liquid and *vice versa*) and, at the same time, enabling the storage and release of thermal energy. The system is to be opened during the day to maximize the solar direct gains through the glass window and the charging of the system – PCM melting. During the night the system must be closed to minimize the heat losses through the glazing and to allow the discharging of the system by releasing the thermal energy indoors through the window arrangement – PCM solidification. During the night the window must be somehow opened to ensure the ventilation of the air cavity separating the window glass and the PCM shutter promoting the heat release indoors.

Many authors have considered the design and analysis of a system with the same goals as the one we propose here, particularly Costa *et al.* [7] and Brousseau and Lacroix [8]. Both works define and study latent heat thermal energy storage systems designed to store the off-peak electrical energy in the form of thermal energy via PCM phase change processes. Using off-peak electricity, a PCM can be melted to store electrical energy in the form of latent heat thermal energy, and the heat is then available when needed for space heating, during the period when the electricity is most expensive. The system proposed in this work aims to take advantage of the solar energy, instead of the electrical energy, to melt the PCM.

2.2. General Assumptions

The chosen PCM for this simulation is similar to an n-Octadecane – CH3(CH2)16CH3. The thermophysical properties of this PCM and of the heat exchanger material (aluminium) are given in Table 1. One uses all of n-Octadecane's thermophysical properties, except for the melting temperature, which shall be considered lower than that of n-Octadecane and closer to indoor comfort temperature in wintertime.

Table1. Thermophysical properties of the system materials.

Thermophysical properties	PCM	Aluminium
Latent heat of fusion ($J\ kg^{-1}$)	243500	-
Density – solid ($kg\ m^{-3}$)	865	2707
Density – liquid ($kg\ m^{-3}$)	780	-
Specific heat – solid ($J\ kg^{-1}\ ^oC^{-1}$)	1934	896
Specific heat – liquid ($J\ kg^{-1}\ ^oC^{-1}$)	2196	-
Thermal conductivity – solid ($W\ m^{-1}\ ^oC^{-1}$)	0.358	204
Thermal conductivity – liquid ($W\ m^{-1}\ ^oC^{-1}$)	0.148	-

The main reference outdoor conditions, Eq. (1), are the external air temperature, $T_{e,ref}$, and the solar radiation in a vertical South facing wall in Coimbra in January, $\dot{q}_{rad,ref}$, both calculated according to the climatic data of SOLTERM® during the period when the system must be opened – from 9 am until 5 pm. The external convection heat transfer coefficient considered is $h_e = 25\ W\ m^{-2}\ ^oC^{-1}$.

$$\begin{cases} T_{e,ref} = 8.2 - 5.5\sin\left(0.32t\right) \\ \dot{q}_{rad,ref} = 160.0 - 350.0\sin\left(0.385t\right) \end{cases}, \text{ with } t \text{ in hours and } \theta \text{ in rad} \qquad (1)$$

The indoor air temperature, T_i, is influenced by outdoor conditions, by the internal loads and by the buildings envelope constitution. However in this study, during the time when the system must be closed – from 5 pm until 9 am – the average indoor air temperature is considered fixed and equal to 15 ^oC. The internal convection heat transfer coefficient, h_i, can vary according to the model chosen for its determination, as explained below.

2.3. Numerical Simulation and Numerical Solution

The model was developed using the enthalpy formulation, as sketched in Fig. 2. In the discretized energy conservation equation, the volumetric sensible enthalpy, h, is the dependent variable and the latent energy rate involved in the phase change process is considered in the source term, which in turn is expressed in terms of the local fraction of melted PCM. The main advantages of this method are: (*i*) the dispense of a condition to be

satisfied at the solid-liquid interface (as it automatically obeys the interface condition), (*ii*) the existence of a mushy zone between the two phases in each control volume, (*iii*) the fact that the energy conservation equation is similar to the one of the pure heat diffusion model (without phase change) and (*iv*) that this method guaranties the isothermal nature of the phase change process. This model is meant to solve the problem of heat diffusion associated to the PCM phase change in a 2-dimensional domain. The differential equation governing the underlying physical phenomenon is integrated using the finite-volume method proposed by Patankar [12]. The system of equations is iteratively solved by a tri-diagonal-matrix algorithm and the evolution in time is modelled according to a totally implicit formulation. Further details concerning the numerical implementation of present enthalpy method may be found in the previous work of the authors [13].

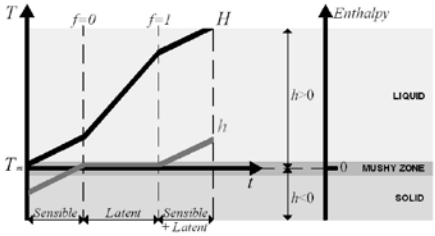

Fig. 2. Sketch of the enthalpy formulation.

3. Results and Discussion

This section is devoted to the identification of the optimal PCM volume, and of the optimal PCM melting temperature, T_m. The first part shows the existence of the optimum PCM volume and its calculation for a specific case. The following parts are concerned with the estimation of the impact of some parameters: outdoor condition, indoor conditions and PCM thermophysical properties. Finally, the optimal configuration is discussed.

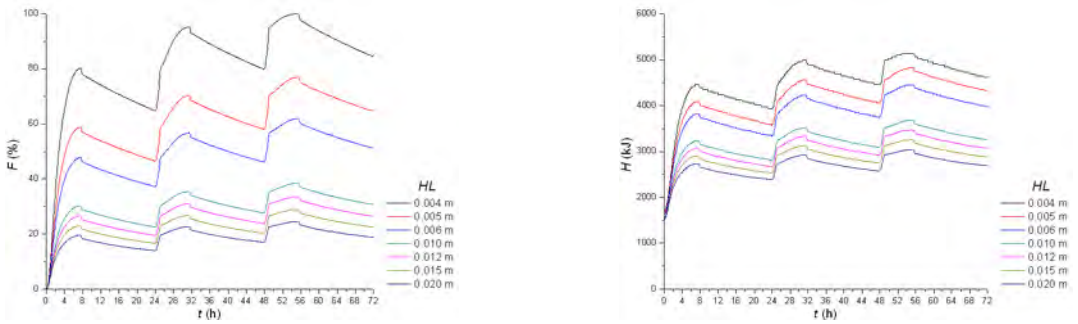
3.1. Determination of the PCM volume

Case of: $\begin{cases} T_m = 18\ ^{o}C,\ L = 243500\ J\ kg^{-1},\ h_i \text{ estimated by natural convection over vertical surface} \\ T_i = 15\ ^{o}C, h_e = 25\ W\ m^{-2}\ ^{o}C^{-1}, T_e = T_{e,ref}, \dot{q}_{rad} = \dot{q}_{rad,ref}, CM = Rvi = 0.002\ m, FL = 0.03\ m \end{cases}$

In order to find the optimal PCM volume to incorporate in the shutter, a set of numerical experiments was held using the methodology presented in Section 2.3, for the test case described in Section 2.1 and for the values above. The optimum PCM volume corresponds to the one that can be totally melted during the charging period (daytime) and totally solidified during the discharging period. Due to the low thermal diffusivity of the PCM, the total volume melted and solidified is strictly related with the distance between the metal fins.

For a given inter-fins distance *HL*, the enthalpy of the system, *H*, and the total PCM melted fraction, *F*, were computed. Figure 3a shows that the PCM can be totally melted considering *HL* = 0.004 *m*. This means that the total volume of PCM with which the container described in Section 2.1 can be filled represents 40 % of the total volume of the system. Results with higher PCM volumes (larger distances between fins) are not so attractive because they cannot be totally melted during the day, and so, the enthalpy of the system is smaller (Fig. 3b) and the PCM potential as a latent heat material is overvalued. The results considered in Fig. 3a and in Fig. 3b were obtained for three consecutive day cycles numerically simulated, starting from a condition of no PCM melted and the whole system at a uniform temperature T_m.

For the PCM volume corresponding to $HL = 0.004\ m$ the discharging process is not completed during the night, which can mean that there will be an enduring melted PCM fraction overvaluing the potential of PCM as a latent heat material. In order to enhance the discharging of the system and the solidifying process of the PCM, indoor forced airflow must be induced in the air gap between the shutter and the glass to enhance heat convection in that period.



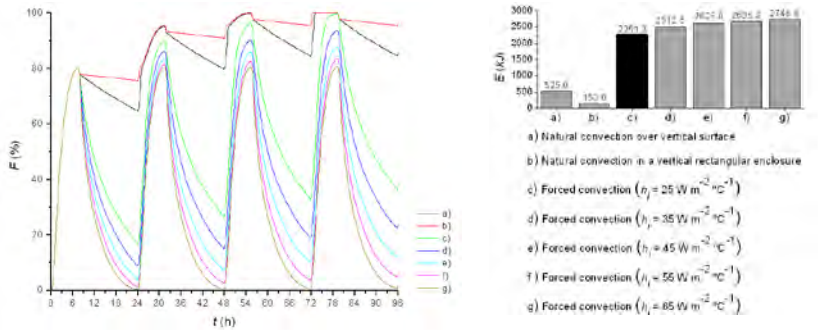
(a) *(b)*

Fig. 3. Evolutions (a) of the total PCM melted fraction, F, and (b) of the enthalpy of the system, H, during three consecutive day cycles simulated.

3.2. Impact of the internal heat transfer coefficient

Case of: $\begin{cases} T_m = 18\ ^{o}C,\ L = 243500\ J\ kg^{-1},\ T_i = 15\ ^{o}C,\ h_e = 25\ W\ m^{-2}\ ^{o}C^{-1} \\ T_e = T_{e,ref},\ \dot{q}_{rad} = \dot{q}_{rad,ref},\ CM = Rvi = 0.002\ m,\ FL = 0.03\ m,\ HL = 0.004\ m \end{cases}$

A set of numerical experiments was held in order to evaluate the influence of the h_i value on the total energy stored in the system via the PCM phase change from solid to liquid and released by the system to the indoor air via PCM phase change from liquid to solid. The different values for h_i considered in the simulations are shown in the legend of Fig. 4.



(a) *(b)*

Fig. 4. (a) Evolution of the F value, during the first four numerical cycles for different values of h_i; (b) Evaluation of the E value during the fourth simulated cycle for the different models considered for h_i.

The results presented in Fig. 4a were obtained for the first four numerical day cycles simulated, the point in time when steady cyclic behaviour was achieved. The values of the total energy stored and released indoors by the system during a complete day cycle, *E*, showed in Fig. 4b, correspond to those of the fourth day cycle simulated. By matching the results of Fig. 4a and Fig. 4b one can see that the *E* value is proportional to the fraction of PCM solidified during the discharging period. The larger the value of h_i the larger is the fraction of PCM solidified during the night and the heat released to the indoor space. For very large values of h_i the system is totally discharged but the PCM volume cannot be totally

melted during the day. Fixing $h_i = h_e = 25\ W\ m^{-2}\ ºC^{-1}$ one can enhance the performance of the system during the night without compromising the melted fraction during the day.

3.3. Impact of the indoor temperature

Case of: $\begin{cases} T_e = T_{e,ref}, \dot{q}_{rad} = \dot{q}_{rad,ref}, h_i \text{ estimated by natural convection over vertical surface} \\ h_e = 25\ \mathrm{W\,m^{-2}\ ºC^{-1}}, L = 243500\ J\ kg^{-1}, CM = Rvi = 0.002\ m, FL = 0.03\ m, HL = 0.004\ m \end{cases}$

In order to evaluate de impact of the indoor temperature considered, T_i, a set of numerical experiments was held with a range of values for T_i and T_m. The results are shown in Fig. 5. One can see that the E value grows proportionally to the difference between T_m and T_i. That is because the driving potential for the heat flow rate to the inside is enhanced and the release of energy during the night is improved while the PCM changes phase from liquid to solid.

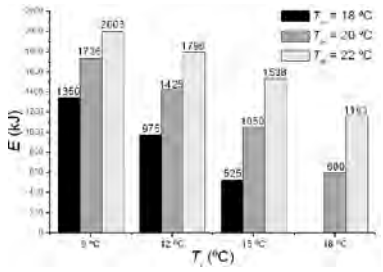


Fig. 5. Evaluation of the total energy stored and released by the system, E, during the fourth numerical day cycle for the different values considered for T_m and T_i.

3.4. Impact of the outdoor conditions

Case of: $\begin{cases} L = 243500\ J\ kg^{-1},\ T_m = 18\ ºC,\ h_i \text{ estimated by natural convection over vertical surface} \\ h_e = 25\ W\ m^{-2}\ ºC^{-1},\ T_i = 15\ ºC,\ CM = Rvi = 0.002\ m,\ FL = 0.03\ m,\ HL = 0.004\ m \end{cases}$

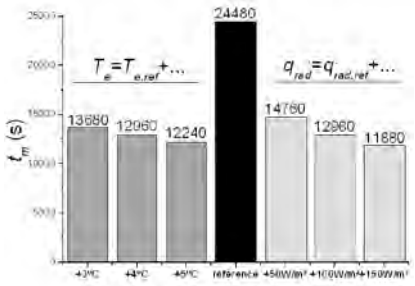

Fig. 6. Evaluation of the time needed to melt all the PCM volume, t_m, considering the reference outdoor conditions and 3 different sinusoidal swing approaches to calculate T_e and $\dot{q}_{rad}$ evolutions.

The impact of the outdoor air temperature, T_e, is evaluated through the time needed to melt all the PCM volume, t_m, using three different sinusoidal swing approaches to estimate the T_e evolution during the time when the system must be opened, and comparing them with the reference sinusoidal curve presented in Section 2.2. The same methodology is carried out for the solar radiation, $\dot{q}_{rad}$. The results are presented in Fig.6 showing that the higher the outdoor air temperature and the solar radiation are, the less time it takes to melt all the PCM volume.

3.5. Impact of the PCM melt temperature

Case of: $\begin{cases} L = 243500\ J\ kg^{-1},\ T_i = 15\ ºC,\ h_i = h_e = 25\ W\ m^{-2}\ ºC^{-1} \\ T_e = T_{e,ref},\ \dot{q}_{rad} = \dot{q}_{rad,ref},\ CM = Rvi = 0.002\ m,\ FL = 0.03\ m,\ HL = 0.004\ m \end{cases}$

The total energy stored and released by the system, *E*, is strongly influenced by the melt temperature of the PCM, T_m. When it is lower than the optimum T_m, the charging process is faster and less time is needed to complete it, thereby melting all the PCM mass. On the other hand, if the difference between T_m and T_i is very small, the discharging process of the system is compromised and the time needed to complete it is larger than the time available (period of system closed). When T_m is higher than the optimum temperature, the discharging process is more efficient. However, the charging (melting) process will not be completed in the time specified by the operating conditions. Figure 7 illustrates the influence of T_m in the *E* value.

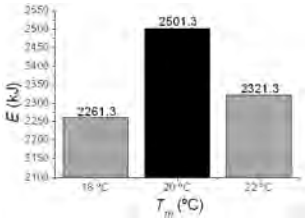

Fig. 7. Influence of T_m in the total energy stored by the system during the day-time and released to the interior during the night in a complete day cycle under the same operating conditions.

3.6. Existence of the optimum

Case of: $\begin{cases} T_m = 20\ ^{o}C,\ L = 243500\ J\ kg^{-1},\ T_i = 15\ ^{o}C,\ h_i = h_e = 25\ W\ m^{-2}\ ^{o}C^{-1}, \\ T_e = T_{e,ref},\ \dot{q}_{rad} = \dot{q}_{rad,ref},\ CM = Rvi = 0.002\ m,\ FL = 0.03\ m,\ HL = 0.004\ m \end{cases}$

The reference test case above shows an optimum configuration for the system. The total energy stored and released by the system, *E*, during a complete 24 hours day cycle is compared with that of other 0.03 *m* thick building materials under the same operating conditions. The results are shown in Fig. 8.

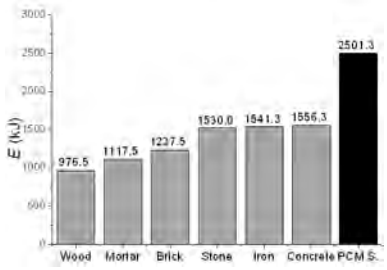

Fig. 8. Total energy stored and released by the system during a complete day cycle, E, compared it with that of other 0.03 m thick building materials under the same operating conditions.

4. Conclusions

The outdoor air temperature and the solar radiation flux play an important role during melting and consequently have a strong effect on the time needed to melt the PCM volume. On the other hand, the indoor temperature and the convection heat transfer rate on the inner side of the shading element, during the night, play an important role for the PCM solidification and have a strong effect on the energy release indoors. To enhance the discharging of the PCM a ventilator must be adjoined to the inner side to increase the internal heat transfer coefficient.
In conclusion, using the numerical simulation as carried out, an optimal system configuration, with an optimal PCM melting temperature, can be found for any given location and characteristic climatic data during the winter season. The results for stored and released energy in a complete day cycle, using a 0.03 m thick layer of different materials, show the

enhancement of the thermal inertia of the building envelope obtained by using the system described. The Tm value has a strong influence on the energy storage capacity of the system. The optimal melting temperature of the PCM to be incorporated in the system for the location of Coimbra is 20 ºC. According to the present predictions, the total energy stored and released by the optimum system during a complete 24 hours day cycle can reach 2501.3 kJ.

Further work has to be done to assess the behaviour of the system in a physical testing – prototype and cell test. A building dynamic simulation has also to be carried out to evaluate the influence of the latent heat loads in the thermal behaviour of the building.

Abstract: Research shows that, as a result of poor energy efficiency, a significant amount of the UK's total energy expenditure is wasted. Changing building occupants' behaviour could help to prevent this energy loss and considerably cut carbon emissions per year. This paper presents an overview of the impact of occupants' behaviour on the energy performance of non-domestic buildings. It further introduces Halcrow's current research project on how to improve the energy performance of their recently refurbished and occupied Headquarters in London, while increasing the satisfaction and well-being of their employees. An employee benchmark survey was conducted at the pre-occupancy stage. The purpose of this survey was to identify the employees' level of satisfaction with their current workplace and, also, to indicate employees' motivation and energy awareness level. The mean score of 2.98 indicates that the majority of the respondents are neither satisfied nor dissatisfied with their current workplace. The results of this survey also show that employees who work in cellular offices on their own are less satisfied than those who work in open-plan offices. Regarding employees' sustainability awareness, most of the respondents said that they were not fully aware of Halcrow's sustainability targets. This paper provides the results of this survey in detail.

Keywords: *Energy Awareness, Non-domestic Building, Sustainability, Refurbishment, and Carbon Reduction*

1. Introduction

About one fourth (25%) of carbon emissions in the UK, which is about 100 million tonnes of CO2 per year, are generated by non-domestic buildings [1]. Considering the fact that 60% of the total non-domestic buildings in 2050 exist today [2], sustainable building refurbishment can significantly contribute to meeting the UK government's target. Every day about £7 million, which is about 21% of the UK's total energy costs, is wasted in UK industry due to poor energy efficiency [3]. In comparison, it is estimated that changing buildings users' behaviour could save this money for the companies and cut carbon emissions by 22 million tonnes per year [4].

It is argued that green technologies such as efficient lighting and advanced ventilating systems will enhance interior environmental quality and therefore be beneficial to human well being and productivity.[5]. Technologies which are designed to improve the energy efficiency of a building must engage with the users, or the building will underperform and energy savings will be limited [6]. Organizational scientists pay little attention to the physical environment, despite its impact on social behaviour [7]. Working space affects the user's performance [8], and productivity is also believed to be associated with the provision of high quality interior environments [9]. However, there is little understanding of how such benefits might be achieved by a satisfactory work environment.

Halcrow Group Ltd has recently refurbished a leased 1930's, 5-storey office building in Hammersmith, London. This building is now occupied by about 450 people who have moved from Halcrow's previous offices (Vineyard House (VH) and Shortlands) adjacent to the site. As staff satisfaction has a central place in social sustainability, Halcrow wishes to investigate innovative interventions currently available to reduce their energy consumption in their new HQ, while increasing their employee's satisfaction and well-being. To do this, a survey was carried out at the pre-occupancy stage to understand employees' needs and expectations

regarding their work environment. The findings from this questionnaire were considered at the design stage of the new building and also used as a benchmark for evaluating the new building's performance. This paper demonstrates some of the findings from the questionnaire.

2. Methodology

An employee survey was conducted to collect data regarding employee satisfaction, needs and expectations. This benchmark survey was used as a tool to enable the employees to confidentially express how they felt about their work environment. The first part of the questionnaire included items concerning demographic factors such as age, sex and employment status. Also, in this part, employees were asked to specify their modes of transportation to work and their willingness to work at home. In the second part, employees were asked to indicate their levels of satisfaction with their workplace physical environment, use of interior space, indoor facilities and current policies. For these questions, 5-point response scales were used, where: 1= Strongly Agree, 2= Agree, 3= Neither Agree nor Disagree, 4=Disagree and 5 = Strongly Disagree. In the latter part, employees were asked to state whether they were aware of Halcrow's sustainability targets and whether they felt personally responsible for contributing to Halcrow's sustainability objectives. This survey was sent via internet to all employees in Vineyard House (VH) and Shortlands buildings and stayed open for two weeks. Initially, 197 completed surveys were returned, (representing 34% response rate). Having excluded data from ineligible participants and questionnaires with missing data on more than 70% of items on "satisfaction with workplace" questions, the final sample consisted of 189, 162 from VH and 27 from Shortlands.

3. Results

This part of the paper illustrates the findings from the pre–occupancy employee survey, for VH employees only.

3.1. Demographic Questions

Over two-thirds of the 162 VH respondents were male, 32.7% (53) were female. Most respondents, 41% (66), were between 26 and 35 years old, 5.6% (9) were 25 years old and under, 23.6% (38) were between 36 and 45, 16% (26) were 46 and 55 and 13.7% (22) were over 55 years old. In terms of employment status, the majority of the respondents, 95.1% (154), were full-time. More than 70% respondents (115) indicated that they were based in VH 75%-100% of the time.

3.2. Mode(s) of Transport

About 98% (159) respondents answered this question. Their responses are shown in Table 1.

Table 1: Mode(s) of transport you normally use to commute to your office

	Frequency	Percent
Bus/Train/Underground/Foot/Bicycle	64	40
Car (in combination with other modes)	27	17
Bicycle (in combination with other modes)	32	20
Foot (in combination with other modes)	79	49
Bicycle (only)	5	3
Foot (only)	11	7
Car (only)	7	4

3.3. Working from Home

Of 154 respondents, 47.4% (73) indicated that they already worked occasionally from home; while 39% (60) said that they would consider working from home given the opportunity. Among the latter, 7 respondents reported driving to work for part, or the whole of their journey, with a total mileage of 9701.379 km per year.

3.4. Working in the Office after Office Working Hours

The majority of respondents, 57.1% (92), specified that they rarely worked after 7.00pm (0-1 evenings/ month). However, a good number - 40% (65), indicated that they needed to work in their office for 2-10 evenings/month. Only 2.5% (4) needed to work for more than 10 evenings/ month.

3.5. Using the Canteen in VH

About half the respondents (81) specified that they rarely used the canteen facilities in VH.

3.6. Office Set Up:' Where You Sit in the Office'

The majority of the respondents, 76.4% (123) worked in an open plan office with more than 5 people, 17.4% (28) worked in a multi-occupant cellular office (5 people or less), 5.6% (9) had their own single cellular office and only 0.6% (1) of the respondents hot-desked in an open plan office.

3.7. Employees' Satisfaction with Their Workplace

Physical Environment

Approximately 86% (139) of participants answered all the questions (8) in this category; the results are illustrated in Figure 1.

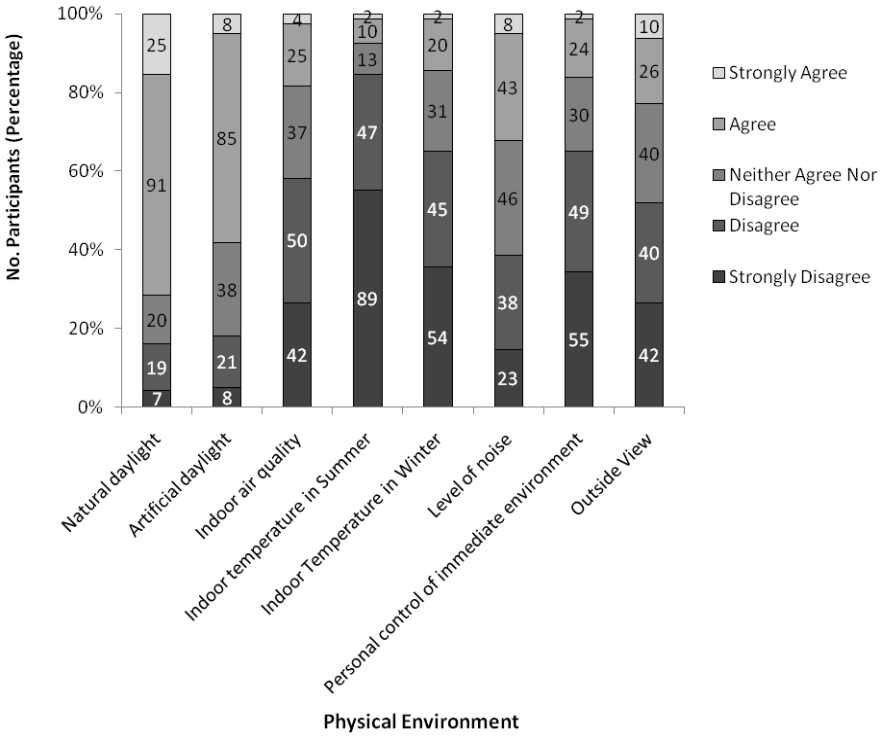

Figure 1: I feel satisfied with the physical environment of my workplace

Use of Interior Space

Approximately 84% (136) of the participants answered all the questions (13) in this category; the results are illustrated in Figure 2.

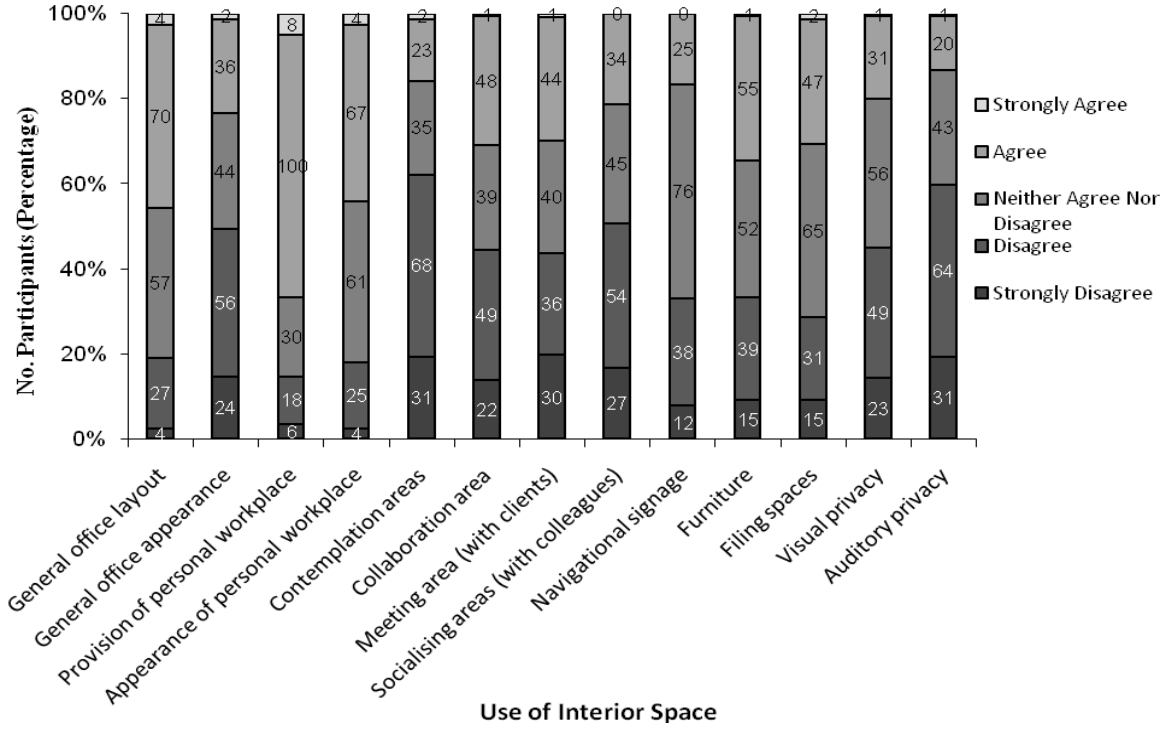

Figure 2: I feel satisfied with the use of interior space in my workplace

Indoor Facilities

Approximately 92% (149) of the participants answered all the questions (5) in this category; the results are shown in Figure 3.

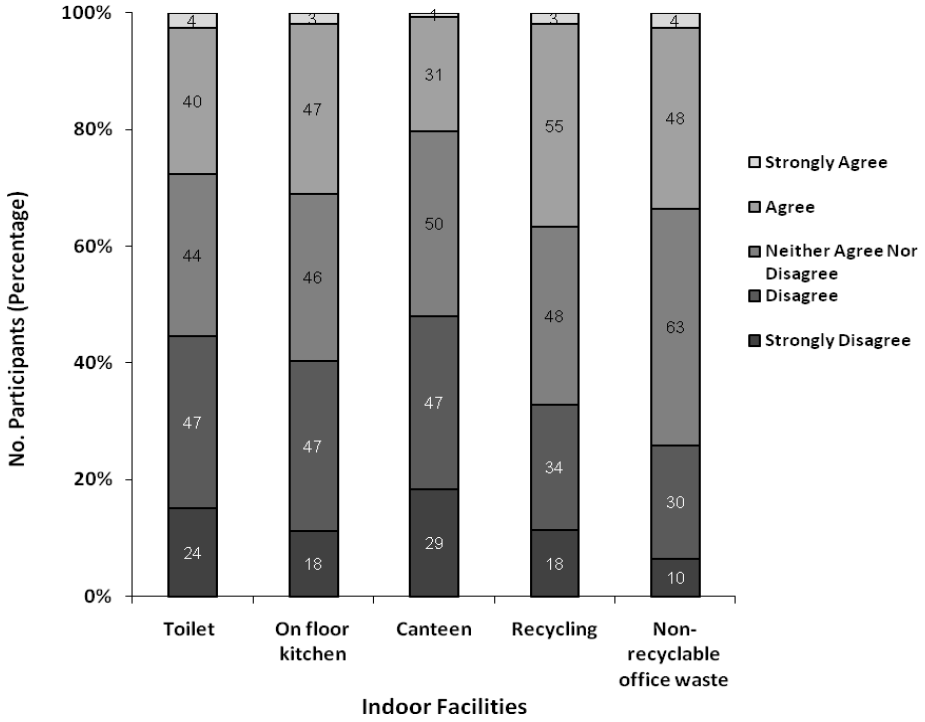

Figure 3: I feel satisfied about the indoor facilities in my workplace

The Policies

Approximately 98% of participants (159) answered this question; the results are shown in Figure 4.

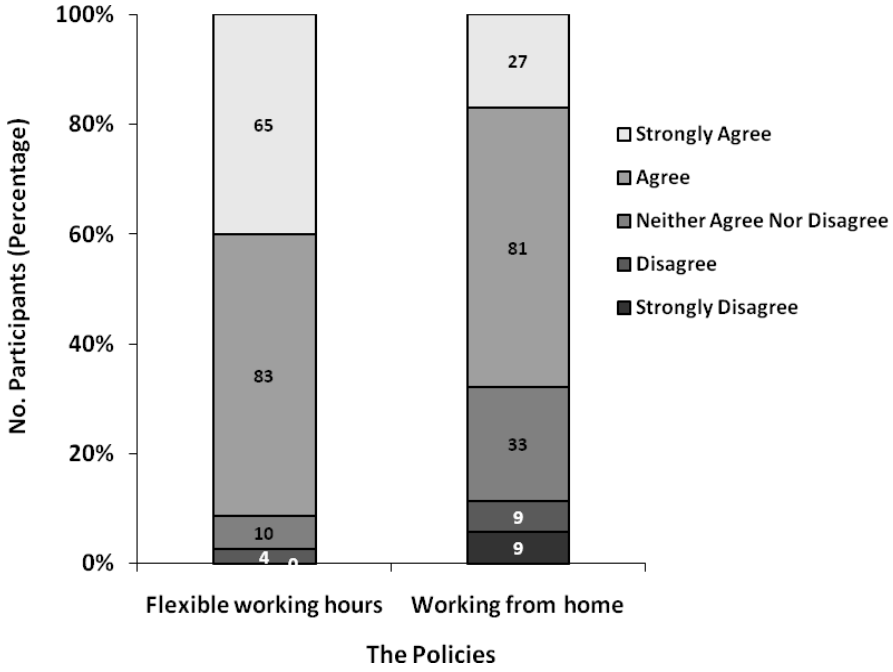

Figure 4: I feel satisfied with the policies available at my workplace

Table 2 shows the mean employees' satisfaction level in each category. The 4 items together showed a satisfactory level of reliability (Cronbach's alpha = 0.89), so overall satisfaction scores could be derived; overall satisfaction mean scores are also shown in Table 2.

Table 2: Mean Scores for Employee's Satisfaction

	Physical Environment	Use of Interior Space	Indoor Facilities	The Policies	Overall Employees' Satisfaction Level at VH
Frequency	139	136	149	159	111
Mean	3.45	3.18	3.20	2.02	**2.98**

Analysis was conducted to assess whether overall satisfaction differed between office set-ups (e.g. open plan, cellular offices, etc) (see Figure 5 overleaf). Overall satisfaction of respondents in single cellular offices (Mean=2.61, Std. Error of Mean=0.14) was higher than that of those in open-plan offices (Mean= 2.98, Std. Error of Mean=0.047). This difference was significant, t (92) = -2.104, p=0.038.

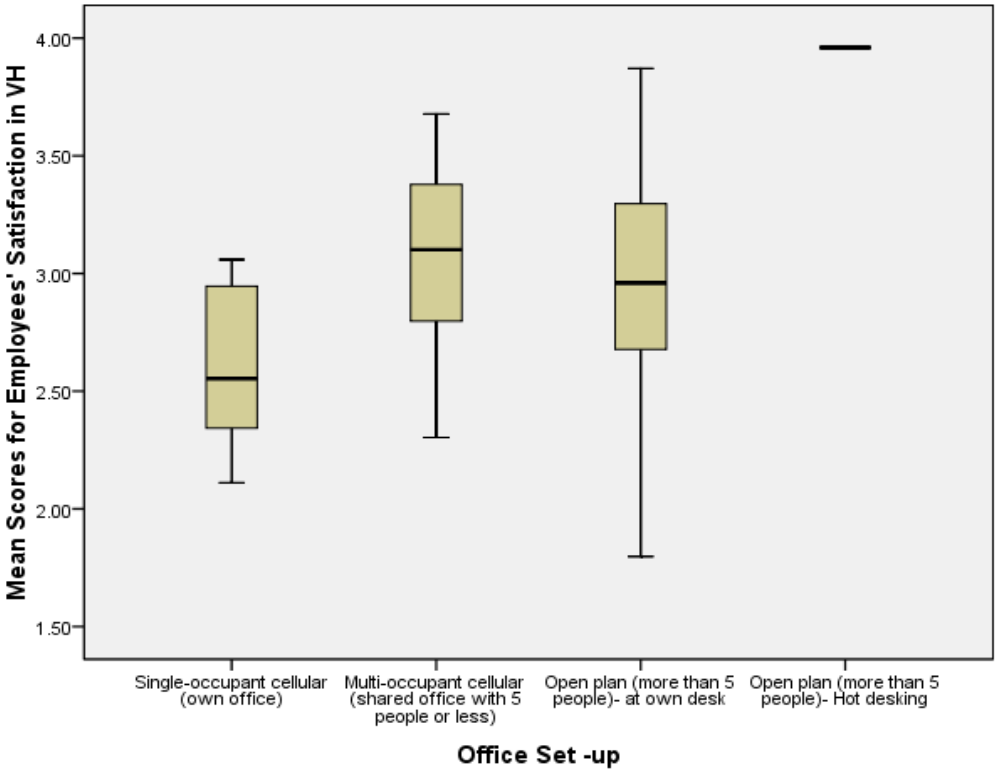

Figure 5: VH Employees' Satisfaction in different office set-ups.

3.8. The Positive Effect of Office Environment on Employees' Productivity, Well-being and Enjoyment

Figure 6 indicates the degree to which respondents felt that their current workplace had a positive effect on their productivity, well-being and enjoyment at work. The overall mean score (Cronbach's alpha = 0.902) was 3.07.

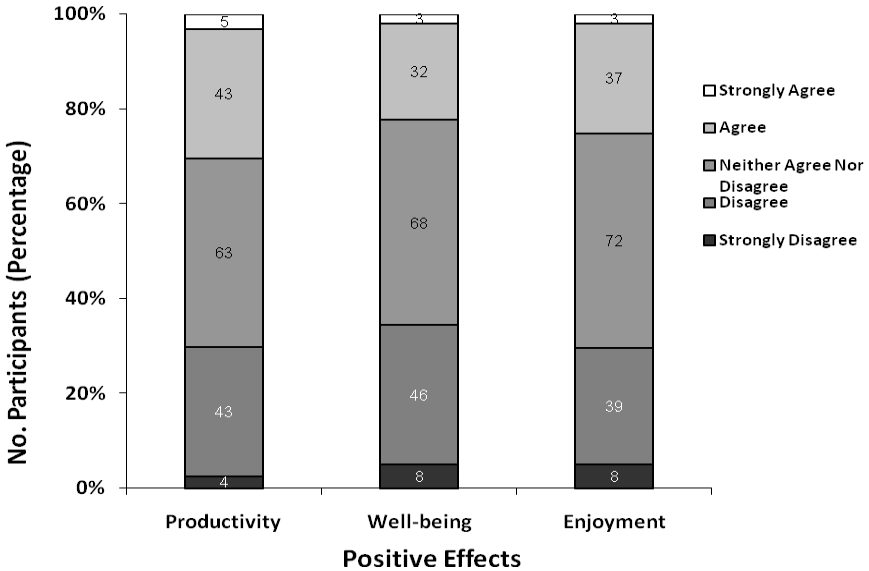

Figure 6: The Positive Effect of VH Environment on Employees' Productivity, Well-being and Enjoyment

An analysis was performed to assess the correlation between employees' overall satisfaction in VH and the positive effect of VH environment they perceived. A significant positive correlation ($r = 0.602$, $p < 0.001$) *was found*, indicating that satisfaction was positively associated with perceived positive effect

3.9. Employees' Awareness of, and Attitudes towards, Halcrow's Sustainability Targets

Figure 7 shows the level of employees' awareness of Halcrow's sustainability targets and whether they felt personally responsible for contributing to these targets.

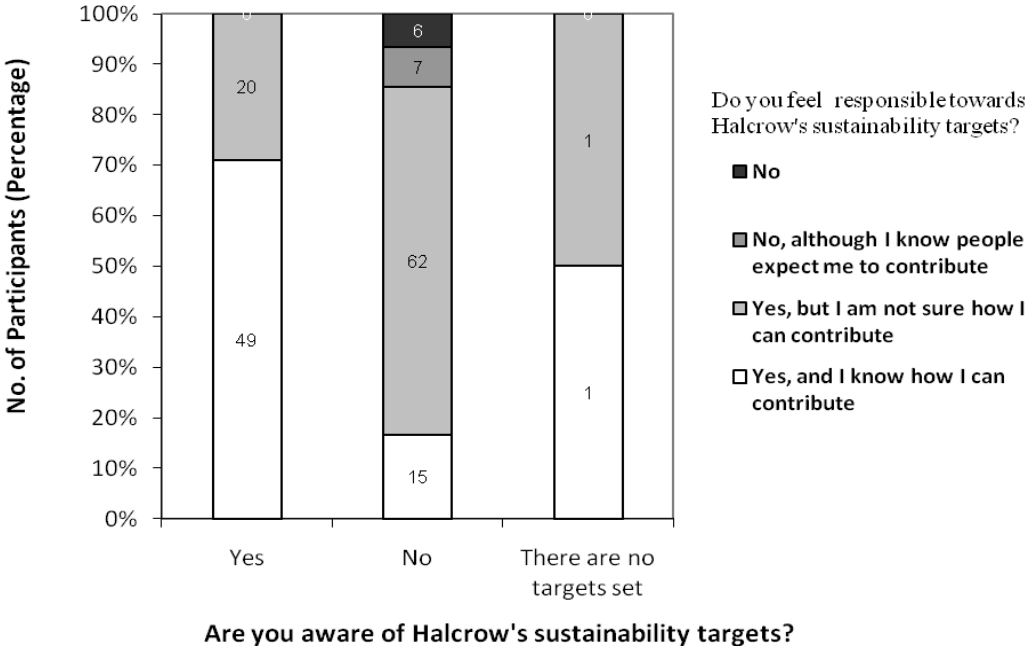

Figure 7: Employees' Awareness of and Attitudes towards Halcrow's Sustainability Targets

4. Discussion and Conclusions

A sustainable workplace is no longer just about technical fixes. Now, it is felt that behavioural intervention is perhaps going to be the key and that physical work environment might help drive certain behaviours. In this study, an employee survey was used as a tool to improve workplace sustainability by engaging the building's occupants.

The sample of respondents was broadly representative of the employees at VH, as indicated by responses to the demographic questions and the question regarding office set-up.

The overall employees' satisfaction score indicated that the respondents, on average, were neither satisfied nor dissatisfied with their workplace. Considering the four categories of employees' satisfaction separately, the respondents, (as was expected due to the poor air conditioning system in VH), were not satisfied with their workplace indoor temperature, indoor air quality and opportunity for personal control of the immediate environment. Inappropriate thermal conditions affect dexterity and increase physiological stress [10]; therefore, it was important to consider these issues in the building's refurbishment. Regarding the use of interior space, most of the respondents were not satisfied with the availability of contemplation areas and also with the auditory privacy of the individual workspace. Providing spaces for different work-styles, in the new building, was considered at the design stage.

The data presented in Table 1 (Modes of transport) indicate that the majority of the employees used sustainable modes of transport to commute to work. Giving the home-working opportunity to those who drive to work could save about 20.6 tCO2/year.

About half the respondents indicated that they rarely used the canteen facilities in VH. This was expected, as the canteen was too small to accommodate the number of the employees in VH and was not a welcoming place for the employees to socialize during their lunch breaks.

As is shown in Figure 5, and as confirmed by t-test, respondents who worked in single cellular offices were more satisfied than those who worked in open plan offices. However, it should be borne in mind that the sample size for single cellular offices was small compared to that for the open plan offices. Figure 7 indicated that the majority of the respondents did not know about Halcrow's sustainability targets and most reported that they did not know how to contribute towards Halcrow's sustainability objectives. This could be because the channels of communication were ineffective

This survey and the post-occupancy survey will indicate whether the refurbishment is meeting expectations that the new building is more sustainable than the old HQ building, and guide thinking on the need for new technical, behavioural and policy changes that are necessary to maximise sustainability performance within the budget and other practical constraints that have been identified.

Abstract: Environmental problems caused by energy usage threaten the world. High CO_2 emission emitted into the atmosphere by combustion of fossil fuels cause global warming. As a result of combustion of fossil fuels used for heating buildings, air pollution occurs. E ffective thermal protection in residential sector playsan important role towards the reduction of energy consumption for space heating. Insulation reduces fuel consumption, undesirable emissions from the burning of fossil fuels, and increases thermal comfort by minimizing heat losses from buildings. In this study, the four different cities of Turkey, Antalya, Istanbul, Eskişehir and Erzurum are selected to determine the optimum insulation thickness of the external wall of buildings. Optimum insulation thicknesses for two different energy sources (coal and natural gas) by using extruded polystyrene as an insulant are calculated and compared to each other. Annual savings in energy consumption and CO_2 emissions have been determined after optimization of insulation thickness. The result proved that when the optimum insulation thickness was used, the energy consumption and the emission of CO_2 decreased.

T_0	*Mean daily temperature (°C)*
U	*Overall transfer coefficient, (W/m²K)*
x	*Insulation thickness, (m)*
η	*Efficiency of the combustion system*

1. Introduction

In recent years, the amount of the energy consumption is increasing depending on t he development of technology, social and economic life. Although this shows the welfare of the society level, increase in energy consumption has brought environmental problems. One of the most crucial impacts resulting of consumption of variety of energy resources is changing the global climate which is known as the greenhouse effect or the global warming. During the recent years, greenhouse gases concentration has occurred continuous increase in the atmosphere. Turkey has a dynamic economic development besides its rapid population growth and industrial developments. Therefore, energy consumption has dramatically increased. Both the increase in energy need and the environmental problems make it

necessary to utilize energy in the most efficient way. In the "climate change report" announced by the UN, it is indicated that global warming has been created in the last 50 years by the human being [1]. Among the order of countries emitting carbon dioxide- the US(5.5 billion tons), Russia(2.8 billion tons) and Japan(1.3) billion tons-, with carbon dioxide emmision of 294 million tons annually, Turkey was annnounced to be 13th. CO_2 emission in Turkey results 42% from industry, 30% from residences, 20% from transportation, 5% from agriculture and 3% from consumption out of the energy. The importance of environmental problems originating from residences will be better understood, when the amount of consumed energy for heating is considered in the portion of total energy. CO_2 emissions produced by the fuels for heating in residences will be reduced by insulating the buildings. When the insulation in optimum thickness is applied to the outer walls of the building, CO_2 emissions will be reduced 30% by status of uninsulated.

Dombaycı et al [1] calculated the optimum insulation thickness for Denizli by using two different insulants and five different fuel types. Dombaycı [2] further calculated the optimum insulation thickness of external walls of buildings in Denizli by using the expanded polystyrene insulant and coal. He determined that with a decrease of 46.6% in fuel consumption. CO_2 and SO_2 emissions dropped by 41.53%.

Çomaklı and Yüksel [3] calculated the optimum insulation thickness for Erzurum which is the coldest cities in the IV. degree-day zone of Turkey in accordance with the TS Standard no 825 on Rules of Heat Insulation in Buildings. He has been determined that CO_2 emissions amount decreased 50%

Ucar A. and Balo F.[4] calculated the optimum insulation thickness of the external wall, energy cost savings over a lifetime of 10 yr, and payback periods for the four different wall types in Elazığ. It is found that when the optimum insulation thickness is used, the amount of fuel consumption and the emissions of CO_2, SO_2, NO_x, and CO are decreased depending on the wall type.

For this purpose in this study, the optimum insulation thicknesses of external walls were calculated by using two different fuel types (coal and natural gas) for heating and expanded polystrene as the insulation material in buildings at selected cities of Turkey in four degree-day zones such as Antalya, Istanbul, Eskişehir and Erzurum, respectively. Annual savings in energy consumption and CO_2 emissions have been determined after optimization of insulation thickness.

2. Methology

Turkey is divided into four climatic zones depending on average temperature degree days of heating. Table 1 shows the degree-day values with reference to an equilibrium temperature of 18°C in provinces within the four degree-day zones of Turkey as per the TS Standard no 825 on Rules of Heat Insulation in Buildings [5].

Table 1 Degree-day values with reference to an equilibrium temperature of 18°C [6]

Region	Provinces	Degree-day value
I	Antalya	1083
II	Istanbul	1865
III	Eskişehir	3049
IV	Erzurum	4827

2.1. The Heat Loss Calculation For External Walls

Heat losses in buildings generally occur through external walls, windows, roof, floors and air infiltration. In this study, the optimum insulation thickness has been calculated in consideration of heat losses only occurring in the external walls.

The external wall of a building is an externally-insulated wall composed of a 2 cm internal plaster. 13 cm bricks, insulant and a 3 cm external plaster. Physical characteristics of constituents of the wall are given in Table 2. In calculations, only the heat losses occurring in external walls were considered to calculate the optimum insulation thickness.

Table 2 Physical properties of the materials of external wall

Constituent	Thickness(m)	k (W/mK)	R (m^2K/W)
Internal Plaster(Lime-based)	0.02	0.87	0.02
Bricks	0.13	0.45	0.28
External plaster(cement-based)	0.03	1.4	0.02
R_i			0.14
R_o			0.04
$R_{wall\ total}$			0.50

In the study, extruded polystyrene (k=0.032 W/mK) was used as an insulation material. The price of insulation material is 158 $/m3.

The heat loss per unit area of external wall is

$$q = U \cdot (T_b - T_0) \tag{1}$$

The annual heat loss in unit area,q, can be determined using the degree days,DD asoccurring in unit surface is calculated by using U and the degree-day value [6].

$$q_{year} = 86400 \cdot DD \cdot U \tag{2}$$

The annual energy requirement can be calculated by dividing the annual heat loss to the efficiency of the heating system η:

$$E_{year} = \frac{86400 \cdot DD.U}{\cdot \eta} \tag{3}$$

where U is the overall heat transfer coefficient for a typical wall that includes a layer of insulation is given by

$$U = \frac{1}{R_i + R_{wall} + R_{insulation} + R_o} \tag{4}$$

R_i and R_o are the the inside and outside air film thermal resistances respectively and R_{wall} is the total thermal resistance of wall layers without insulation. $R_{insulation}$ is the thermal resistance of the insulant and calculated as follows:

$$R_{insulation} = \frac{x}{k} \tag{5}$$

Total resistance of the non-insulated wall layer $R_{wall.\ total}$ is

$$R_{wall,total} = R_i + R_{wall} + R_o \tag{6}$$

As a result, the annual heating load is then given by

$$E_{year} = \frac{86400 \cdot DD}{\left(R_{wall,total} + R_{insulation}\right) \cdot \eta} \tag{7}$$

Annual energy cost for unit surface C_{year} is calculated with the following equation:

$$C_{year} = \frac{86400 \cdot DD \cdot C_{fuel}}{\left(R_{wall,total} + R_{insulation}\right) \cdot Hu \cdot \eta} \tag{8}$$

The price and lower heating values of fuels and efficiencies of heating systems used in these calculations are given in Table 3.

Table 3 The parameters used in calculations

Parameter	**Value**	**Parameter**	**Value**
Natural gas		**Coal**	
Chemical formula	CH_4	Chemical formula	$C_{7.078}\ H_{5.149}\ O_{0.517}\ S_{0.01}\ N_{0.086}$
Hu (J/kg)	$34{,}526.10^6$	Hu (J/kg)	$29{,}295.10^6$
η	0,93	η	0,65
C_{fuel} ($/m^3)	0,72	C_{fuel} ($/kg)	0,2216
Interest rate (i)		%7	
Inflation rate (g)		%10	
Life cycle (N)		10 years	
Present Worth Factor (PWF)		11.67	

The life cycle cost analysis method was used in calculating the optimum insulation thickness. Annual energy cost was calculated based upon t he present worth factor and the lifetime determined [1]. The interest rate adapted for inflation rate r is given by if

$$i > g \rightarrow r = \frac{i-g}{1+g}$$

$$i < g \rightarrow r = \frac{g+i}{1+i} \tag{9}$$

The present worth factor is calculated based upon the inflation and interest rates as follows:

$$PWF = \frac{(1+r)^N - 1}{r \cdot (1+r)^N} \tag{10}$$

Insulation cost is calculated as follows:

$$C_{insulation} = C_y \cdot x \tag{11}$$

Ultimately, the total heating cost of an insulated building as per the life cycle cost analysis is calculated as follows:

$$C_{insulation,\,total} = C_{year} \cdot PWF + C_y \cdot x \tag{12}$$

Energy savings ($/m^2) obtained dring the life time of insulation material can be calculated as follows:

$$A_{year} = C_{total} - C_{t\,ins} \tag{13}$$

where, C_{total} and C_{tins} are the total heating costs of the building when insulation is not and is applied, respectively.

Pay-back period

$$pp = \frac{C_{total}}{A_{year}} \tag{14}$$

the fuel consumption per year as follows:

$$M_F = \frac{86400.DD}{(R_{wall,\,total} + R_{insulation})\eta \cdot Hu}\,(Kg/year) \tag{15}$$

2.2. Calculation Of Annual Combustion Gases Amount

Building lose heat through the wall and insulation reduces this heat loss giving increased comfort conditions and fuel consumption reduced. The general chemical formula of combustion for fuel is given by

$$C_x H_y O_z S_p N_q + \alpha A(O_2 + 3.76N_2) \rightarrow xCO_2 + \left(\frac{y}{2}\right)H_2O + p.SO_2 + B.O_2 + D.N_2 \tag{16}$$

The constants A, B and D calculated from the oxygen balance formulas given in (17), (18)and (19) respectively:

$$A = a + \left(\frac{b}{4}\right) + e - \left(\frac{d}{2}\right) \tag{17}$$

$$B = (\alpha - 1) + \left(a + \frac{b}{4} + e - \frac{d}{2}\right) \tag{18}$$

$$D = 3.76\alpha\left(a + \frac{b}{4} + e - \frac{d}{2}\right) + \frac{f}{2} \tag{19}$$

Total emission of CO_2 products resulting from the burning 1 kg of fuel can be calculated by

$$M_{CO_2} = \frac{x.CO_2}{\dot{M}} = \text{kg } CO_2 / \text{kg fuel} \quad (20)$$

$\dot{M}$ is the weight of mol for fuel which can be calculated using,

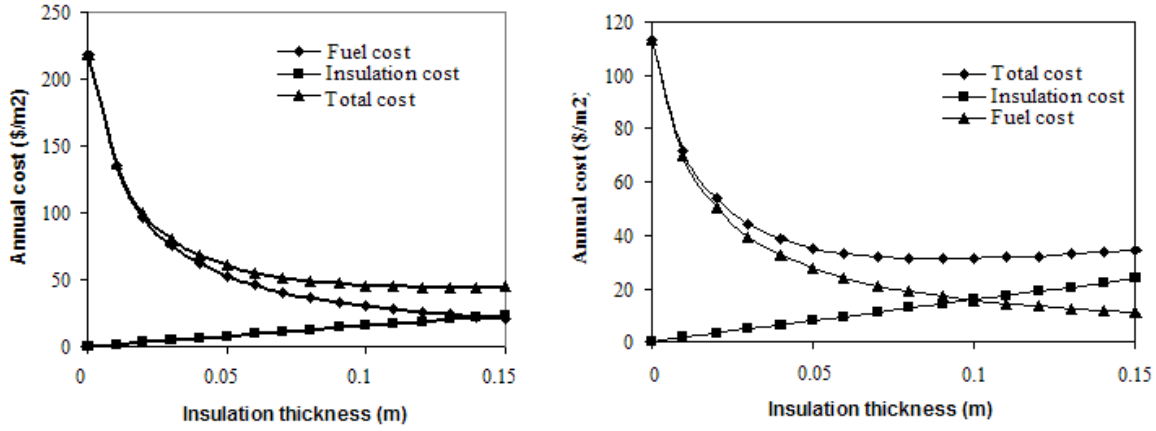
$$\dot{M} = 12x + y + 16z + 32q + 14p \text{ kg / kmol} \quad (21)$$

2.3. Results

In this study, the optimum thickness of insulation with heating load for four different walls used for the buildings in turkey is determined. The effect of insulation thickness on total cost, fuel cost and investment cost for Antalya, Istanbul, Eskişehir and Erzurum province has been calculated. Optimum insulation thickness, pay-back period and energy saved over a period of 10 years calculated for two different fuel types are shown in Table 4. The effect of insulation thickness on the total cost over the lifetime of 10 year in Erzurum,which is the coldest city in Turkey, is given in Figure 1a-b. As shown in the figure 1, while the optimum insulation thickness for Erzurum with extruded polystyrene used for the insulation of the external wall within a natural-gas fuelled heating system is 14 cm, it is 9 cm when coal used as a fuel.

Table 4. Optimum insulation thickness, pay-back period and energy saving for different fuel types

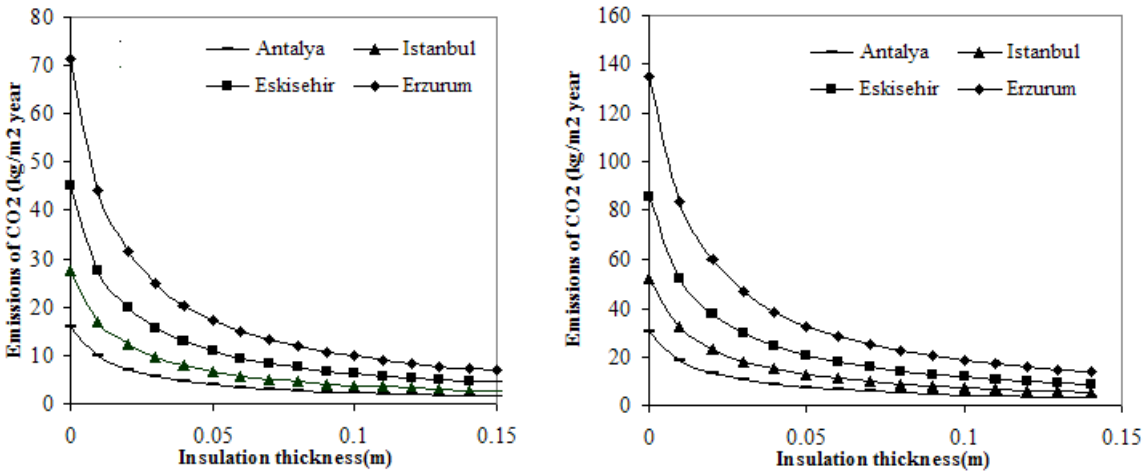
	Insulant	**Extruded polystyrene**		
City	**Fuel type**	**Thickness (m)**	**Pay-back period (year)**	**Energy Saving (10 years) ($/m^2)**
Antalya	Coal	0.03	2.14	11.84
	Natural gas	0.05	1.67	29.22
Istanbul	Coal	0.05	1.73	25.28
	Natural gas	0.08	1.46	57.69
Eskişehir	Coal	0.07	1.51	47.22
	Natural gas	0.09	1.3 4	102.93
Erzurum	Coal	0.09	1.38	82.03
	Natural gas	0.14	1.26	173.5



(a) (b)

Fig. 1 Effect of insulation thickness on total cost for Erzurum a) natural gas b) Coal

The variations of the emissions of CO_2 versus insulation thickness for a $1m^2$ external wall of a building for four different cities of Turkey are shown in Figure 2 a by using natural gas and 2.b by using coal respectively.



(a) (b)

Fig. 2 Emissions of CO_2 versus insulation thickness a)For natural gas b) For Coal

As shown in the figure 2, CO_2 emission release from coal is greater than the natural gas when the coal is fired in Erzurum, located in the 4th climate region.The use of low- quality coal will increase the air pollution in particular. CO_2 emissions produced by the fuels for heating in residences will be reduced by using insulate the buildings. As shown the figures 2a, if we apply 14 cm insulation, which was found to be the optimum when natural gas is burned, the emission rates of fuel 7 kg/m^2. If insulation was not applied, CO_2 emission rate would be 71 kg /m^2. Similary, if we apply 9 cm insulation, which was found to be the optimum when coal (Figure 2b) is burned, the emission rates of fuel 20 kg/m^2. If insulation was not applied, CO_2 emission rate would be 135 kg /m^2.

Conclusion

As energy sources of our country are limited and foreign-dependent, conservation and efficient use of energy particularly in housing sector where energy is intensively consumed, and heat losses are much gain more significance day by day. In this study, optimum insulation thickness for external walls with two different fuels in four climatic zones of

Turkey have been calculated. The life cycle cost analysis method has been used in the calculations. Though variable by the fuel used selected, pay-back period of insulations applied to buildings are usually too short. Investments in insulation shortly pay off and contribute to diminishing the dependency of our country in terms of fuel sources. At the present, where fuel and energy costs drastically increase, this situation becomes vitally important. It is found that when the optimum insulation thickness is used, the amount of fuel consumption and the emissions of CO_2 decreased depending on the fuel. The highest values of the CO_2 emission rates is reached for coal. The results indicate that the optimum insulation thicknesses show significant variation due to fuel and climatic conditions.

Overheating risk evaluation of school classrooms

Despoina Teli[1,*], Mark F. Jentsch[1], Patrick A.B. James[1], AbuBakr S. Bahaj[1]

Abstract: This paper presents a pilot study which considers the overheating risk of classrooms in school buildings. Four schools in Southampton in the South of the UK, constructed during the period of the 1950s-1980s were used as case study examples. The schools were studied in terms of the parameters or the combination of parameters that may drive classroom overheating. Topographic features, built-up area, urban density, adjacency to roads and parks and other characteristics such as building form and materials were assessed, looking at the urban, building and classroom scale. In addition to this a questionnaire survey was conducted to assess the teachers' perception of their classrooms' thermal environment. The survey responses are discussed and compared to the outcomes of the school parameter analysis, also considering the limitations of the survey approach. It was found that gaining an understanding of the occupants' perception of the thermal conditions in a school's classrooms is essential for developing recommendations for addressing overheating. The study appears to indicate that individual perception of overheating may outweigh the objective influence of urban design and construction parameters on the indoor thermal conditions.

Keywords: *School buildings, Overheating, Microclimate, Refurbishment, Classroom.*

1. Introduction

Over recent years, children and teachers in the UK have been experiencing uncomfortably warm thermal conditions inside school classrooms during non-heating periods [1]. This potentially has implications on learning outcomes since it has long been understood that an increase in the indoor temperature may lead to a decline in the productivity of students [2].

Some school buildings constructed between the 1950s and the 1980s are unsuitable for hot summer periods, due to characteristics such as low thermal mass and highly glazed facades. Building performance simulations of typical UK school building types have shown that their overheating risk is likely to be exacerbated under the predicted future climates [3]. Due to cuts in public budgets new school projects have been cancelled in the UK [4] and the life of the majority of the existing school building stock will have to be extended further. In terms of internal thermal comfort, summer overheating could be addressed by installing air conditioning systems, a solution which has been widely adopted in southern Europe over the past decades [5]. The adaptation of such a measure would however conflict with the goal to reduce building related greenhouse gas emissions [6]. It would also set a precedent where air-conditioning would become the expected norm.

The aim of this study is to investigate methodological approaches for evaluating the overheating risk of school buildings. It considers the schools' characteristics and the teachers' perception of their classroom's thermal conditions.

2. Parameters that drive overheating

The thermal conditions inside a building are determined by the interactions between the external climate and the building, the building shell and the internal space and the internal space and the occupants [7]. Accordingly, the parameters which influence the risk of overheating in buildings are:

- The external climatic conditions, i.e. the air temperature; solar radiation; rainfall; relative humidity and wind velocity.
- The microclimatic profile, i.e the local scale climate which is affected by the surrounding surfaces (albedo, thermal capacity); topography; vegetation; soil structure and urban form (industrial processes, transportation, buildings, human metabolism) [8].
- The building shape and form, i.e. the geometric relations (envelope area to volume ratio, building height) which determine the building's exposure to solar radiation and the ambient air [9].
- The building fabric properties, i.e. the thermo-physical properties of its construction materials (U-values, g-values and albedo, thermal capacity).
- Internal gains, i.e. the sensible and latent heat emitted by human bodies, lighting, computing and office equipment, electric motors and appliances [10].

During the last 30 years, there has been a trend towards warmer summers [11]. This trend is likely to continue as projections for the future UK climate in the 2020s, under a medium emissions scenario, predict about 1.5 ºC higher summer mean temperatures and up to 3 ºC higher summer mean daily maximum temperatures, relative to a modelled 1961–1990 baseline period [12]. This can be expected to further drive the occurrence of summer overheating in buildings.

3. Methodology for overheating risk assessment

Four primary schools in Southampton on the South coast of the UK were chosen as case study examples in order to evaluate overheating risks of existing school buildings. Primary schools were selected as the teachers and students remain in the same classroom during the school hours ensuring uniformity in terms of occupancy. The study consisted of two components: (i) an aerial photo analysis of the schools and their surrounding environment and (ii) a questionnaire survey of the teachers.

3.1. Aerial-photo analysis

The aerial photo analysis, which is highlighted in Fig.1 for three of the schools discussed in this paper, included:

- the surrounding urban environment (urban density level, building heights, adjacency to roads/parks/fields/water).
- the school ground (density level, greenery/hard surfaces, location of the building within the school ground, shape of the school ground in relation to the orientation)
- the building (form, shape, roof cover)
- the classrooms (materials, window/wall ratio, shading conditions)

The area within 100m around the schools was studied since the local microclimate of this area was considered as influential for the building performance.

3.2. Questionnaire survey

The teachers of the 4 schools were requested to complete an 11 question survey investigating their perception of their individual classroom's thermal environment. In case they had been in that classroom for less than 1 year, they were asked to answer for their previous classroom (within the same school). Most of the questions were closed type questions (fixed-response). The survey forms were filled in face-to-face with the respondents in an interview style. The aim of the questionnaire was to identify the following:

- when, where and under which circumstances overheating occurs
- the duration of overheating occurrences in the school/classroom
- the teachers' understanding of the factors which cause overheating
- the mitigation measures taken to date with respect to overheating
- the teachers' perceived impact of overheating on students

The pilot study of four schools has highlighted limitations of the survey which need to be taken into account in the analysis of the results. These limitations are:

- the subjective perception of individuals
- the possibility of an established view in each school about the thermal conditions in the classrooms
- the expectations of individuals based on their perception of the outside climatic alterations throughout the year.

4. Aerial photo analysis of the four investigated schools

The four schools used in this study are denoted as A, B, C and D in Fig.1. They share their school grounds in pairs and are surrounded by residential areas of a relatively low density with detached 2-storey houses. The schools are not shaded by surrounding buildings or trees. Vegetation is limited to grass surfaces with few trees in the school grounds. The outdoor space material surrounding the buildings is mainly tarmac, covering 58 and 68% of the open spaces for schools A, B and C,D respectively (excluding sports fields).

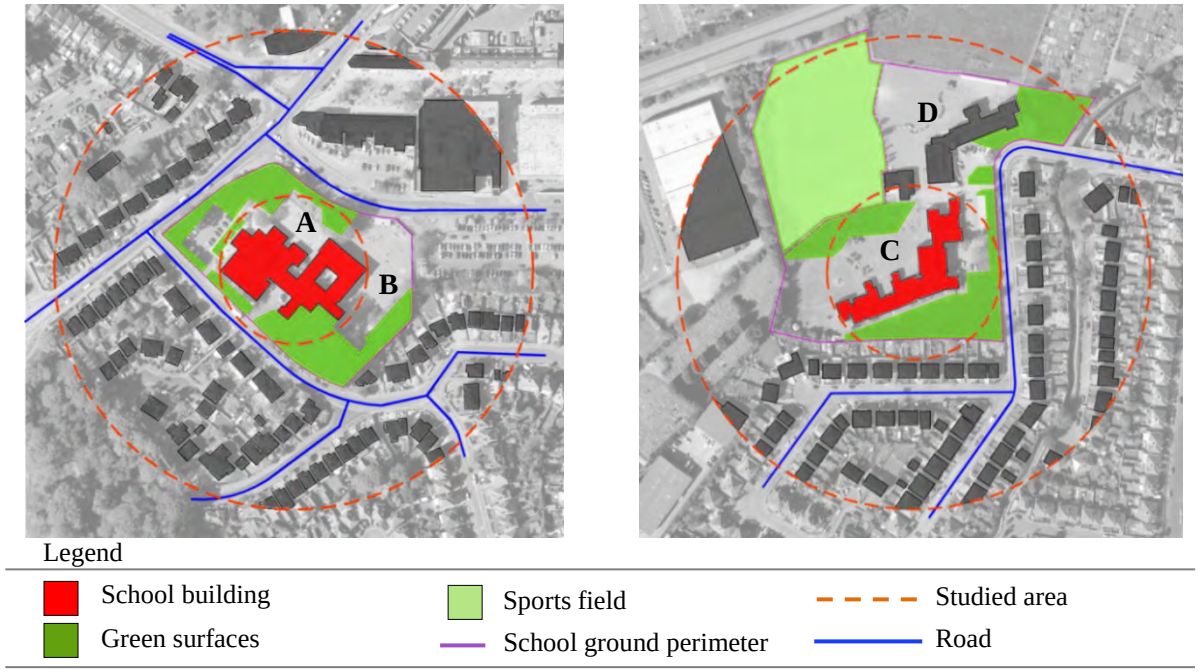

Fig. 1. Analysis of the main urban characteristics of three of the studied schools

School A is a compact one-storey building with an assembly hall in the centre and the classrooms located around it. School B consists of two parts which create an enclosed yard, a 2-storey L shaped building housing the classrooms and a 1-storey building with the remaining school spaces. Schools C and D both consist of linear sections. The building parts which face southeast (SE) accommodate the classrooms. In school D the classroom part has 2 storeys.

Schools A and B were built in 1978 using a light-weight construction with steel frames and pre-fabricated concrete panels. The other two schools (C and D) were constructed in 1950 using a brick cavity wall system. 40 to 60% of the façades are glazed in all four schools (Fig.2). Windows in schools A and B are single glazed whilst they are double glazed in schools C and D. All buildings are internally shaded with blinds or curtains. In schools C and D most classrooms face SE while in school A most classrooms open to two orientations and in school B half of the classrooms face northeast (NE) and half southeast (SE). This is shown in Fig.3.

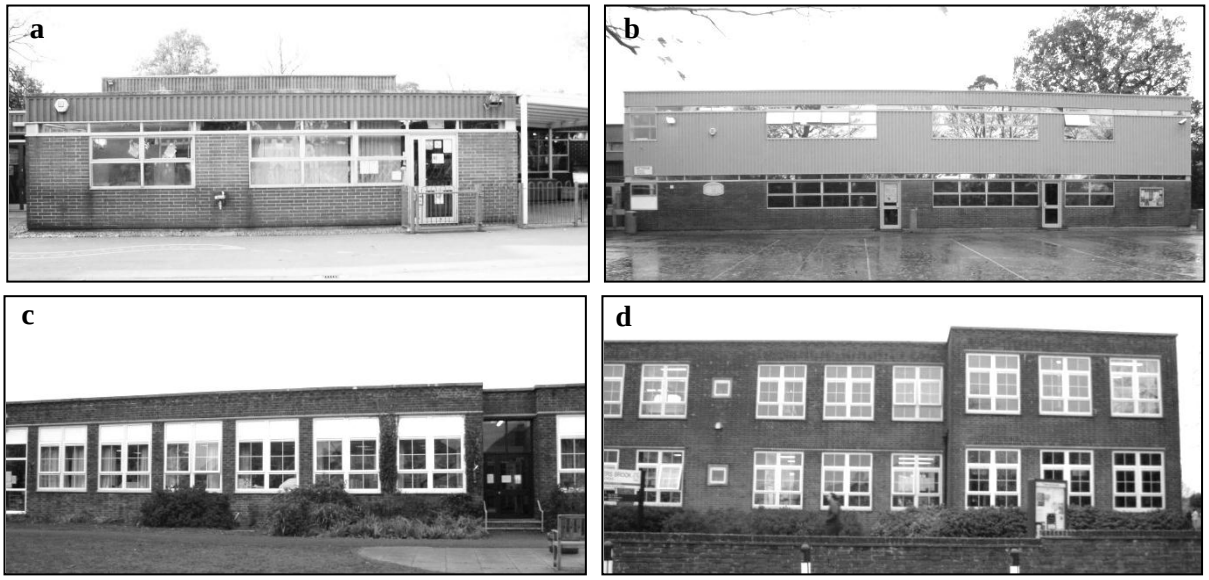

Fig. 2. Schools' facades: a. Northeast elevation of school A, b. Southeast elevation of school B, c. Southeast elevation of school C and d. Southeast elevation of school D.

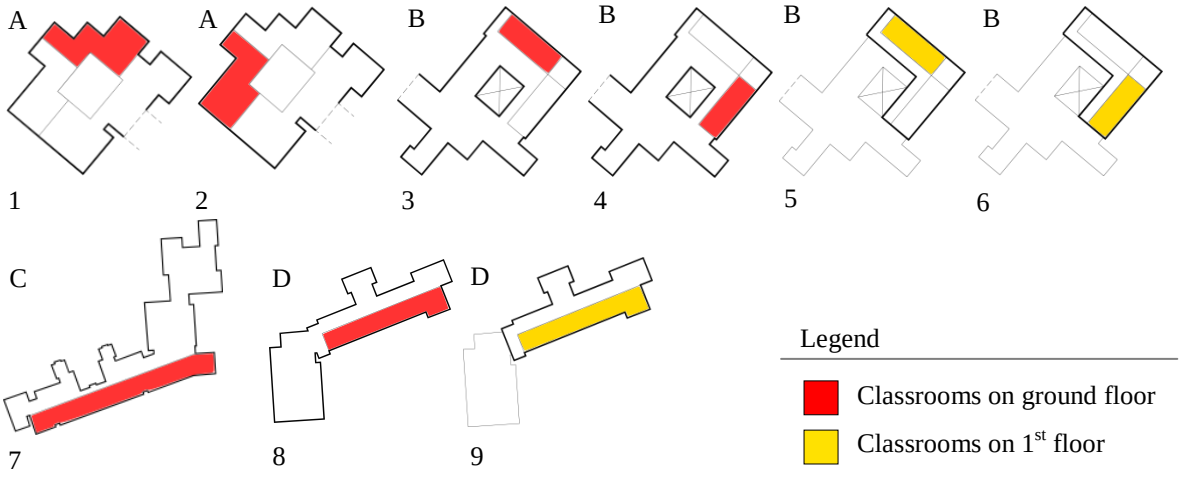

Fig. 3. Classroom clusters of the case study schools

From the aerial photo analysis 9 classroom clusters were identified based on construction, orientation, storey and surrounding environment (Fig.3). Clusters 5 and 6 (school B) appear to have the highest potential risk of overheating. Their NE and SE orientation in combination with the outdoor tarmac surfaces, a flat bitumen roof, a light-weight construction, single glazing and a lack of wind exposure are parameters which may drive overheating in the classrooms. Ground floor clusters 3 and 4 have the same characteristics like 5 and 6 apart from the missing heat absorption from the roof. In school A (clusters 1 and 2) the classrooms

benefit from 2 facades due to the building form which increases their ventilation potential. Cluster 2 is adjacent to a small green area and it is relatively exposed to prevailing SW winds. However, the light-weight construction, single glazing and flat roof indicate a high risk of summer overheating later in the day. Schools C and D (clusters 7-9) benefit from the cavity wall system and double glazing but the large SE oriented windows and the lack of ventilation and shading suggest high penetration of solar radiation.

5. Questionnaire survey results of the four investigated schools

50 teachers completed questionnaires across the 4 schools for their individual classroom. Their responses are analysed below and subsequently compared with the outcomes of the aerial photo analysis.

5.1. Thermal performance of the classrooms

The teachers were asked to evaluate their classroom's thermal performance for the occupancy period from April to October 2010. As shown in Fig.4, June and July are considered as the months with the greatest overheating occurrence, whilst in May and September are perceived as less problematic, yet with about half of the teachers stating that the classroom is either 'warm' or 'too warm'. April and October are generally perceived as acceptable. It should be noted however that the teachers might be influenced by the general perception of the climatic alterations throughout the year.

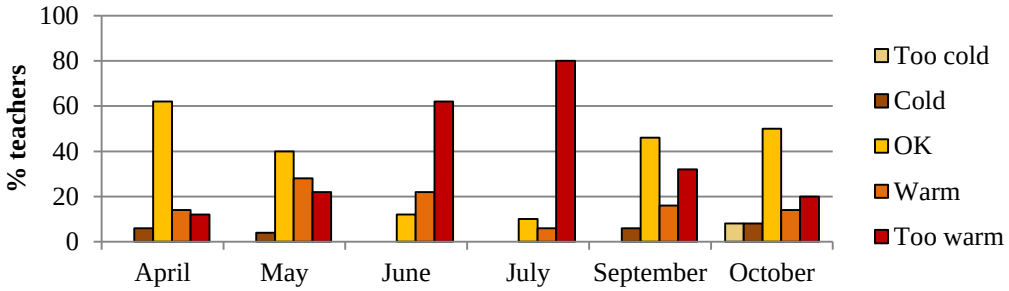

Fig. 4. Perceived classroom temperature conditions from April-October

When comparing individual responses in relation to the clusters described in section 4, a high variation in responses on a single façade orientation was identified for the months of April, May, September and October. In some cases the temperature of adjacent classrooms with exactly the same characteristics was assessed as 'OK' by one respondent and as 'too warm' by another. This suggests that in the spring and autumn months individual variation in perception appears to be more significant for overheating perception than absolute classroom temperatures.

5.2. Overheating occurrence

The teachers were asked about the magnitude and duration of overheating in their school and classroom. As shown in Fig.5, 80% of the teachers stated that in the non-heating season more than 60% of their school's classrooms experience overheating. In winter the responses vary. One of the reasons for this variation was found to be that in schools A and B the heating system is controllable and some teachers switch it off when temperatures are too high.

Almost 60% of the respondents answered that overheating occurrences in the non-heating season last for more than a week (Fig.6). For the heating season the responses are less clear. 30% of the teachers voted for 'not applicable' and about 25% for 'more than a week'.

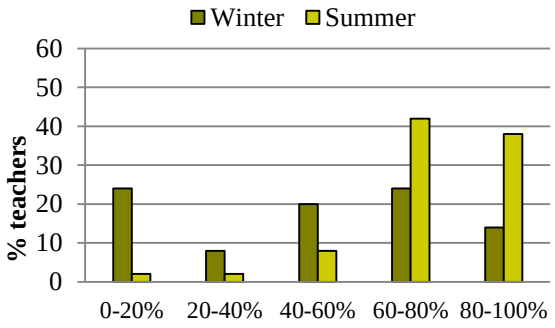

Fig.5. Perceived percentage of the school's classrooms that have experienced overheating

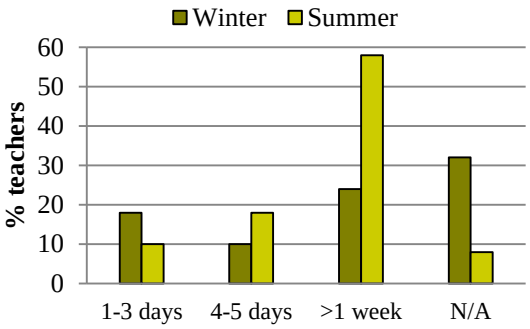

Fig.6. Perceived duration of overheating occurrences in the teachers' classrooms

The teachers were also asked to assess the frequency of overheating occurrences in various school spaces (Fig.7). For the classrooms, 80% of the teachers agreed that overheating occurs very often while for the assembly hall, circulation areas and library the responses are less pronounced. This difference in perception may be related to the characteristics of the classrooms (high occupancy density, large windows, small window openings, internal gains etc) but it may also be due to the stronger concern of the teachers for the spaces where most of the school activities take place.

Fig.8 shows the months which are perceived to cause greatest classroom overheating during the school occupancy periods. As expected, June and July were indicated by almost all respondents as the two months with the greatest overheating problems.

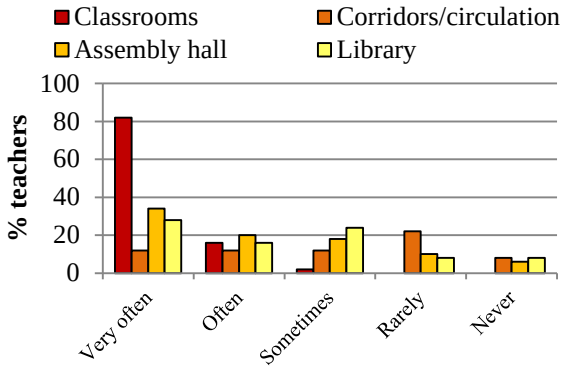

Fig.7. Perceived overheating occurrence in different school spaces

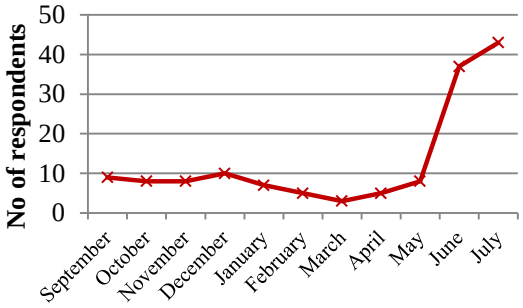

Fig.8. Months perceived to cause greatest overheating (School year: Sept '09-July '10)

5.3. Possible causes of overheating and mitigation measures applied by the teachers

In an open question the teachers indicated the factors which they believe to drive overheating in their classroom (Fig.9). Poor ventilation, a poorly controlled heating system and the number of students were the most frequent answers followed by room size and not-openable windows.

Achieving appropriate ventilation is a problem in many classrooms as cross ventilation is not possible. Also, in all 4 schools the windows open only to a certain extent and the internal shading obstructs the air flow. The heating system was often highlighted as an issue because some teachers cannot control it in their classroom or they weren't aware that they could.

The students' habits and behaviour towards heat stress were identified as a point of concern. According to some teachers, children may be clearly too warm and yet do not take off their jumpers or ask for help. Teachers felt that children's perception of heat is different from adults and that this should be taken into account when school buildings' thermal conditions are studied. This furthermore indicates that more research is needed addressing the perception of children, looking at temperature thresholds from a children's perspective and the implications of classroom overheating for their learning experience.

Fig.10 shows the measures taken by the teachers when overheating occurs. The question was fixed-response with the opportunity to add further measures. All teachers selected window opening and almost everyone drinking of water.

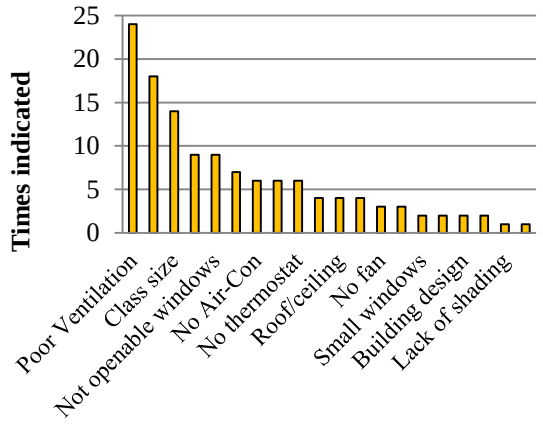

Fig. 9. Causes for overheating of their classroom according to teachers' responses

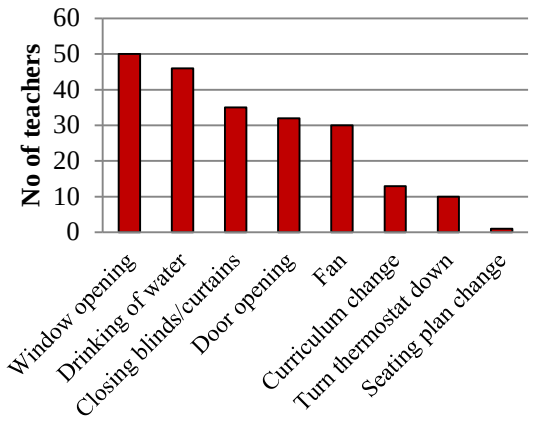

Fig. 10. Mitigation measures taken by teachers when overheating occurs

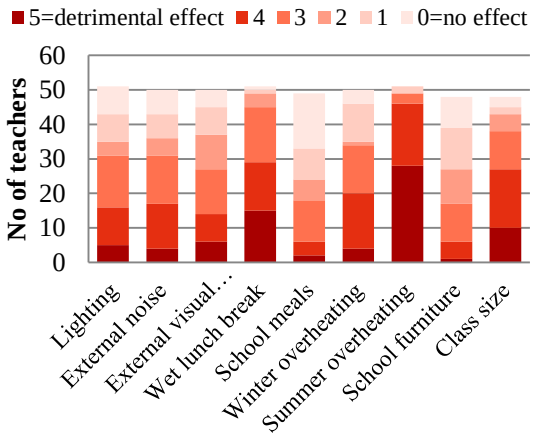

Fig. 11. Perceived effect of different factors on students' learning experience

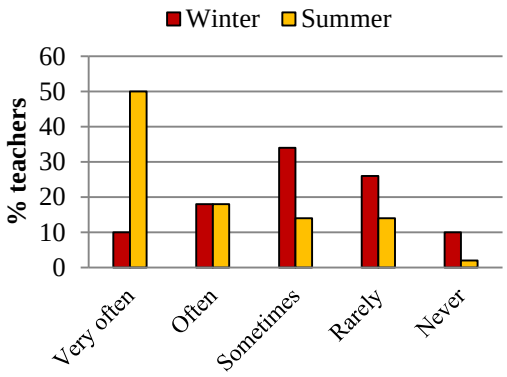

Fig. 12. Complains from children about excessively high temperatures in classroom

5.4. Impact on students

The teachers were asked to rate 9 factors in terms of their impact on students' learning experience, using a scale of 0-5, 0 representing no impact and 5 standing for a highly detrimental impact. As shown in Fig.11, summer overheating gathered the largest number of 5 and 4 rates. This is followed by a wet lunch break and the class size (number of occupants in classroom). However, it should be taken into account that this result may have been affected by the specific interest of the survey in summer overheating.

Teachers were also asked whether students have complained about excessively high temperatures (Fig.12). 50% of them said that this was 'very often' the case during the non-heating season and some noted that children may not complain even though they feel discomfort.

6. Discussion

This work investigated the overheating risk of four UK schools through an aerial photo analysis and a questionnaire survey of the schools' teachers. The aerial photo analysis suggested a high overheating risk within all 4 schools which was verified by the teachers' survey responses. However, a detailed comparison at the classroom level showed variations in individual responses for the spring and autumn months. This appears to indicate that the individual perception of thermal comfort may outweigh the impacts of the building's design and its surrounding landscape conditions on indoor temperatures. The teachers' observations that children may have a different thermal perception to adults suggest that more work is needed looking at the relation between children's perception and building overheating.

The study furthermore highlighted that teachers are often not aware of how their classroom operates (widow opening, heating system). Therefore, low-cost measures such as training may be an effective way to address hot classroom conditions and should be explored prior to taking any retrofitting measures.

Energy retrofit and indoor environmental requalification of existing school buildings. Method and tools for operating procedures

Paola Boarin[1,*], Pietromaria Davoli[1]

Abstract: Within the existing building stock, schools occupy a large segment of public real estate but are rarely involved in widespread retrofit investment plans. For example, according to Italian statistics, two thirds of existing schools are hosted in buildings constructed between 1940 and 1990, many of which have not undergone substantial changes and transformations over time. Verifications made by Public Administrations and users demonstrate that these structures have many building problems related to the consumption of resources, the well-being and security of users and, not least, the management by local government units.
Operating substantially and in a scheduled way on existing school buildings, by adapting the physical environment and optimizing the use of resources, would, on the one hand, increase the quality of construction and conditions of use (and then last but not least the effectiveness of the educational system) and, on the other hand, improve the economic management of resources by local government units.

Keywords: *Existing educational buildings, Energy retrofit technologies, Indoor climate enhancement, Operating procedures.*

1. Introduction

Within the Italian existing building stock, schools occupy a large segment of public real estate (throughout the country there are about 42,000 schools). Schools host a very sensitive group, but currently don't provide the necessary well-being and use a large amount of resources. Nonetheless, they are rarely involved in widespread investment projects of national interest. The national annual reports provided by Legambiente [1] show that about 1 out of 3 buildings needs urgent maintenance because of many problems related to resource consumption, indoor environmental quality, security conditions and management by Public Administrations.

The present paper presents the results of a syudy aimed at establishing planned, systematic, substantial and integrated operating procedures for energy retrofit and indoor environmental quality enhancement on existing school buildings to increase construction quality, reduce energy consumptions and optimize economic management of resources by the Owner. Even if this topic has already been developed on the international landscape (IEA ECBCS Annexe 36 [2] is one of the most important experience), it hasn't found a pragmatic approach yet in Italy where, because of the low qualification of the public technical staff and of the few economical investments by the Owners, it is (and even more will be in the next few years) a real problem for Public Administrations from the economical, management and security points of view.

2. Methodology and phases

Given that the Ministry of Education or Local Goverments do not provide any comprehensive technological database concerning building elements and plant systems, it has been decided to directly investigate an existing school building stock by studying a sample of buildings that has been considered to be representative of the wider national situation (different climatic conditions, various building technologies and plant systems, different energy contracts and management). The survey procedure has been essential to define energy benchmarks and technological state of the art that has been compared with best practice projects, choosen from national and international landscape and concerning exemplary and innovative requalification

processes on existing school buildings. The direct results of the study sample survey have been compared with the performance requirements coming from national regualtions and lows that are considered to be the minimum level of success of the future retrofit strategies. Retrofit measures has been defined through: energy and environmental goals (from the previous survey and best practice analysis), needs-performance framework (from low and regulations) and best technical solutions for energy and quality enhancement (referring to the outcome state of the art of the surveyed study sample).

The operating procedure has been systematically developed to support decision-makers during the retrofit strategy choice, considering performance targets, technological (energy saving and environmental quality enhancement) and economical (payback period optimization) aspects, people involved (technical staff, Owners, Designers, Energy Managers) and in order to obtain an appropriate management of the existing school building stock.

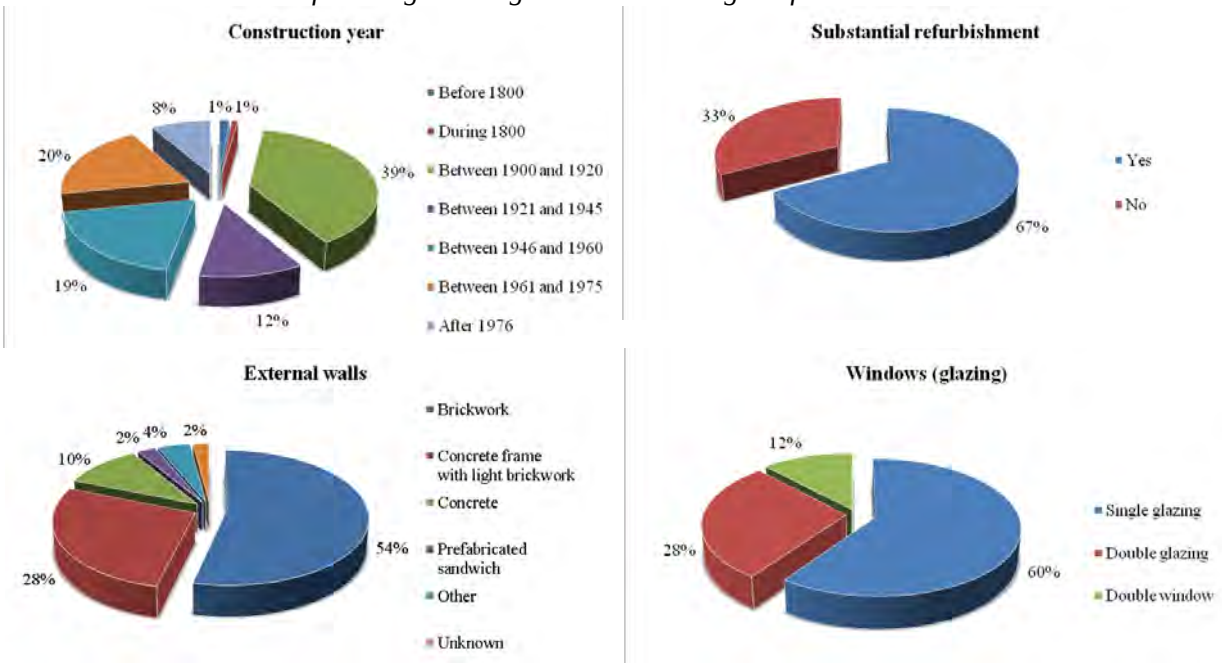
3. State of the art: the technological point of view

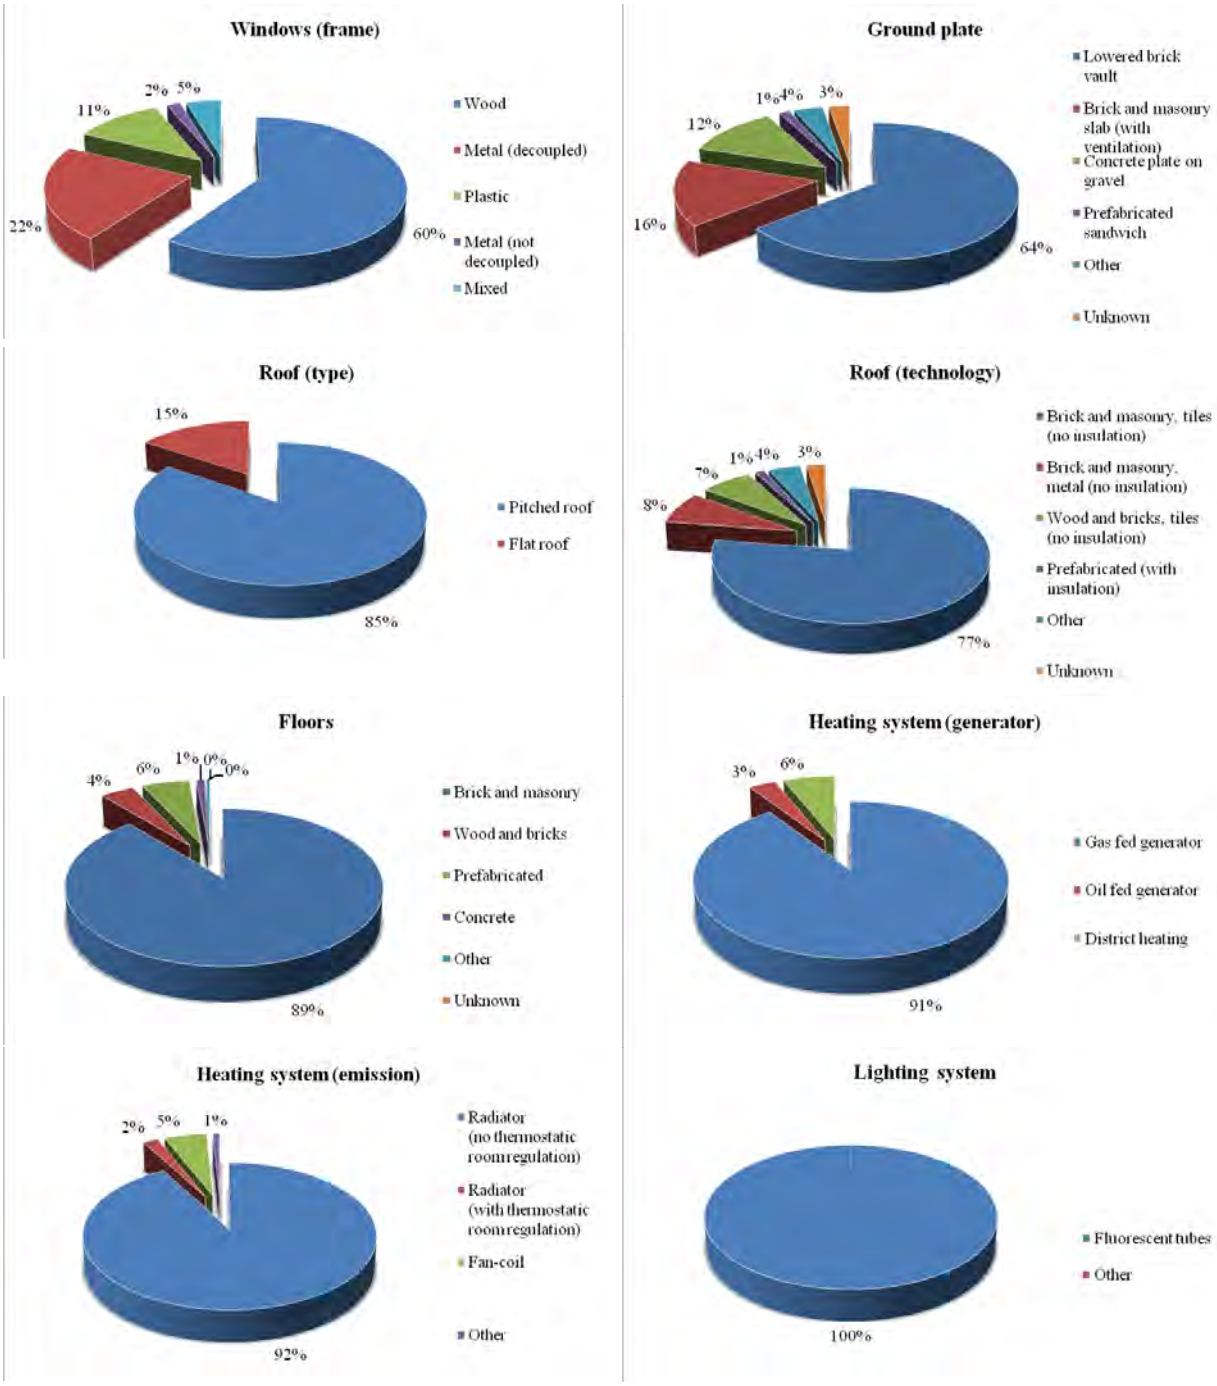
The study sample has focussed on the municipalities and provinces of Rovigo, Ferrara and Modena and has been composed of 232 buildings. The abovementioned municipalities and provinces have been chosen because of the information available and their geographical location, in a temperate area requiring more attention in the building and plant system design. The survey shows that existing school buildings of the study sample are in a critical situation.

Table 1 List and geographical distribution of the study sample.

Municipality or Provincial Administration	Number of investigated buildings
Municipality of Ferrara	53
Province of Ferrara	27
Municipality of Rovigo	25
Province of Rovigo	24
Municipality of Modena	69
Province of Modena	34
Total	232

Table 2 Overview results of existing buildings actual technological features.





3.1. Building envelope

From an energy point of view, heat losses through the building envelope are mainly due to the lack of thermal insulation in walls, roofs and ground floors. Traditionally, Italian constructions have a strong brick enclosure, which can be single layered or combined with other materials (concrete blocks, plaster, stone and wood), and whose performance is particularly poor in buildings dating from the Fifties and Seventies.

Even windows and glazed systems have a very low performance. This aspect is particularly relevant because school buildings have many large window areas in order to archieve lighting targets. The study sample also has a low proportion of low-emissivity glass (most of the buildings are single-glazed) and frames, which are primarily wooden but without seals, or

metal but not thermally decoupled. Importantly, however, windows replacement is the owner's first item of intervention.

3.2. Heating system

Investigated school buildings have traditional heating plant systems (consisting of boilers which are mainly powered by natural gas) with no zoning. The output terminals in classrooms are large radiators, mostly made by cast iron, which, with rare exceptions, don't have any thermostatic control valves or any room regulation. Because of the amount of air to be heated, mechanical ventilation systems (without any heat recovery) or plants heaters (fan-coils) are often used in larger rooms (gymnasiums, lecture halls, laboratories). The employment of air heating system (air vents) is much more limited in classrooms, because of noise transmission, air movement and filter maintenance. Mechanical ventilation systems are also rarely used and are almost completely absent in the existing school buildings which have been evaluated.

3.3. Summer air conditioning system

Since school buildings are used in Italy from September to June, air conditioning systems are quite rare and the study sample has confirmed this trend. The only exceptions to be found are school staff offices where low-performance and high-consumption independent air conditioning units which are not connected to the centralized system have been installed.

3.4. Lighting system

The investigation demonstrated that schools are only lightened by fluorescent tubes without any occupancy sensor (for example in hallways or bathrooms) or automatic dimming of light intensity according to the amount and distribution of natural light in classrooms.
Beside the absence of energy saving devices, a comprehensive design based on different lighting needs in classrooms (especially to avoid glare and to promote a homogeneous distribution of natural light) and in other parts of school buildings is also lacking.

3.5. Energy sources

Natural gas is currently the most widely used energy source, but few buildings still use diesel. Usually, these are isolated buildings located in the outskirts of cities and villages which are not yet served by the distribution network because of local conditions. A good practice is the connection to the district heating network, but it is still incomplete and quite limited in some areas. Renewable energy sources (mainly photovoltaic and solar thermal) have begun to be used only in recent years, particularly in structures with continuous use and extra-curricular functions.

4. The operating procedure: application phases

Enery and environmental analysis of the study sample direct survey data have demonstrate how existing educational buildings are distant from the minimum performance requirements given by lows and how uncomfortable many scool buildings are for occupants. The operating procedure minimum level of success is the archievement of the minimum performance values given by national lows and regulations for the parameters that are responsible of considerable variations of energy consumption and environmental quality (air, temperature, humidity, lighting, noise). The further level of success is the archievement of the maximum level of energy saving and indoor environmental quality enhancement (increasing comfort perceived by occupants), together with the optimization of the Owner's economical investment.

Therefore, the operating procedure deals with several topics (technology, energy, economy, management, etc.) which are considered in subsequent and linked phases and should be seen as a decision support tool for recovery strategies of existing educational buildings.

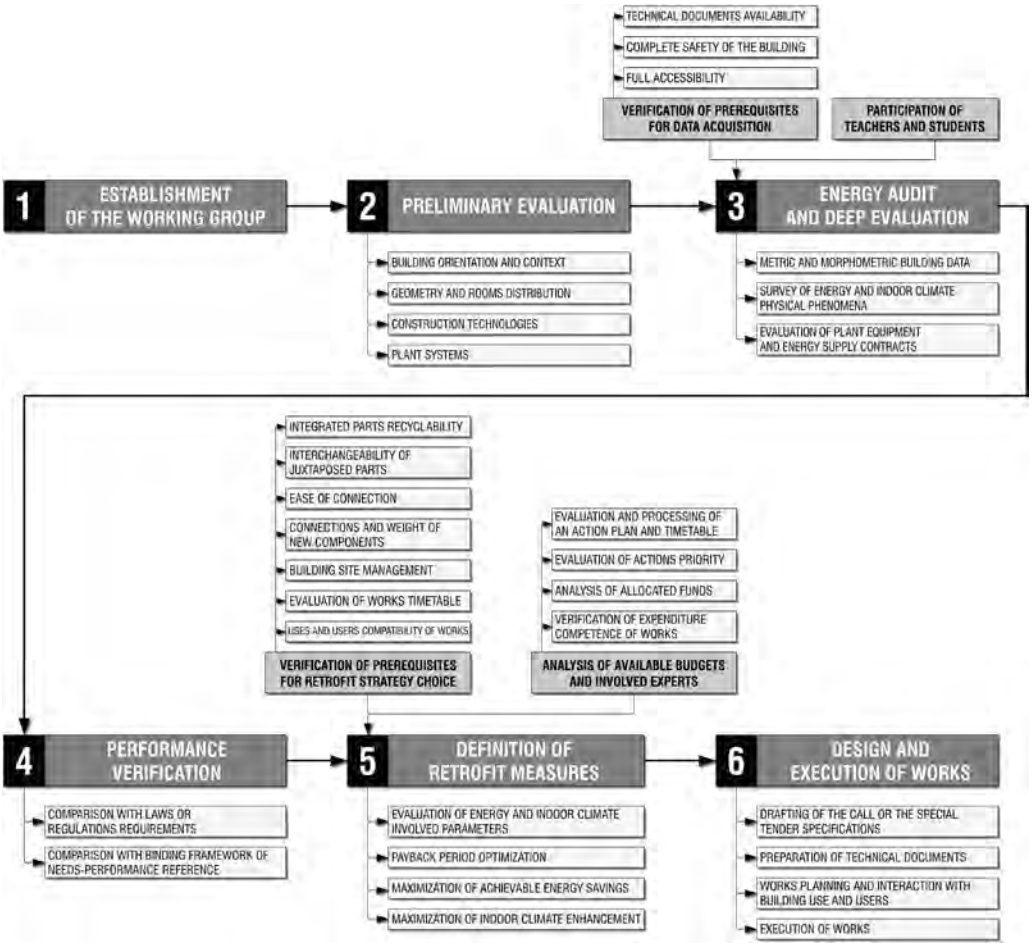


Fig. 1 Operating scheme of energy and indoor environmental refurbishment process.

4.1. Step 1: establishment of the working group

The first step of the procedure is the establishment of a working group composed of people involved in the management, design and educational process. At this stage, several stakeholders meet the Public Agency that promotes the intervention, which ca be the municipality or the province depending on the specific competences on the school building stock; the Educational Institution, that has the double task of informing about the critical problems related to the use and to initiate educational activities to raise awareness among students (for example, daily actions aimed at savings and at the management of energy resources); the Designer, who is tasked with drawing up the project and coordinating the activity; and the Energy Manager, who optimizes energy management in different building redevelopment stages.

4.2. Step 2: preliminary evaluation

The second phase is a preliminary evaluation of the existing building, aimed at identifying morphological features and general technologies which are useful to define the retrofit strategy to be adopted. In particular, the following aspects must be evaluated:

- building orientation and evaluation of the surrounding natural or urban elements that may affect energy and environmental behaviour (shading from adjacent buildings that limit solar direct gains, proximity to noise sources, presence of vegetation shielding, etc.);

- building type (geometry) and internal distribution of rooms. This can be done by reading the project plans with their subsequent modifications and implementations. This information is aimed at finding a first guidance for action based on the savings potential inherent in any type of building;
- existing construction technologies of technical element. Information in this regards can be retrieved in the project documentation submitted during the execution of works (if any), in owner's and manager's databases or through a direct visual examination;
- plants systems. This can be studied basing on the direct experience of Energy Managers or through visual inspection of books and equipment (in this case, the potential for savings depends not only on the optimization of the plant system, but also on the verification of the supply contracts, especially in the context of energy market liberalization).

The most critical part of this phase is the definition of the technological features, due to owner's or managers' lack of knowledge about construction techniques and plants systems of the building heritage. Public Administrations do not usually have any monitoring tools to manage the building stock and leave the transmission of information to the "historical memory" of the contractors carrying out maintenance.

4.3. Step 3: energy audit and deep evaluation

This phase may require external professional support to evaluate parameters that affect energy and environmental building behaviour. There are three main subtasks:

- determination of metric and morphometric building data for calculation of gross floor areas, heated volume and dispersant surface, aimed at energy evaluations;
- survey of physical phenomena related to energy and environmental building behaviour concerning the whole technological system (enclosures and internal partitions), by studying the main factors affecting energy consumption and indoor comfort (air, temperature, humidity, lighting, noise);
- evaluation of plant equipment and energy supply contracts (which may cause consumption not attributable to the efficiency of plant system).

Since this phase requires where direct investigations on the building several conditions must be met to be able to gather data, such as:

- full accessibility to different parts of the building, including basement, attics and spaces normally closed to the public;
- guarantee of the complete safety of the building;
- availability of technical original and subsequent versions of design documents, as a basis for the determination of the status quo.

4.4. Step 4: performance verification

The fourth phase, which is closely linked to the previous one, is a comparison between measured performance and laws or regulations requirements in relation to the parameters involved in energy consumption and indoor environmental quality. By comparing the actual performance and with the binding framework of needs-performance reference for each building element, the main critical elementsd of the existing building are identified.

4.5. Step 5: definition of retrofit measures

The people involved are the same as in the preliminary working group but the Designer is definitely the emerging personality. He is tasked with coordinating the different needs and defining technically and morphologically relevant design solutions.

Before planning any activity, the presence of some prerequisites has to be verified, as:

- compatibility of works with building uses and users;

- evaluation of the works execution timetable and its relationship with school activities;
- management of building sites (possibility of storage of materials, accessibility, etc.).
- connections and weight of the new components compared to existing structures;
- ease of connection of any new elements to existing structures;
- interchangeability of juxtaposed parts related to future opportunities for interventions;
- recyclability of integrated parts.

Apart from these considerations, the Designer shall, in collaboration with the Promoter, verify and analyze the available budget and experts involved through:

- a preliminary verification of expenditure competence of the works
- an analysis of the funds allocated by the local Administration or the Owner;
- the evaluation of the actions to be performed depending on the priority and urgency of interventions;
- the evaluation and development of an action plan accompanied by a timetable.

Once these steps are completed, the most appropriate intervention strategy can be chosen basing on the evaluation process (preliminary or in-depth), the issues raised during the performance evaluation (energy and environmental factors involved), the Owner's budget or investments availability and the main features of the building site. Given that these involved factor are several and complex, it has been decided in the study to define a panel of retrofit measures [3], aimed at finding the best technical solution for the specific case and based on the need-performance requirements. Therefore, the action to be identified are those which can optimize the payback period (expressed in years), maximize the energy savings (expressed by the percentage reduction of primary energy consumption compared with the previous condition) and enhance the environmental quality to the greater extent (expressed by an occupant's sensation scale from 0 – neutral to +2 – considerably perceived; action with negative influence on occupants' perceived comfort will not be taken into consideration).

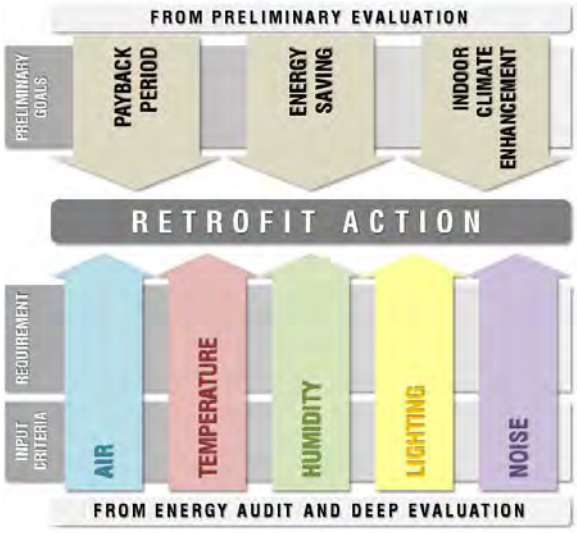

Fig. 2 Main criteria involved in the definition of operating procedure's retrofit actions, starting from preliminary or deep evaluation of existing educational building.

4.6. Step 6: design and execution of works

This phase includes the following:

- drafting of the call or of the special tender specifications;
- preparation of technical documents in collaboration with other experts and stakeholders involved (the document will be entirely drafted by the Administration in case of internal procedure, otherwise they will be contracted out to Designers);

- works planning taking possible interaction with building use and users into consideration;
- execution of works.

The drafting of the documents containing the technical specifications of the project and for the tender is the most critical point of this phase. This phase may be rather long because of the high number of experts to be involved and the unexpected prolongation of the timing of the tender. In addition, the organization of timing and of the different phases of the works, together with the potential overlapping with school activities, may lead to moving classes in other temporary structures, is another complex aspect in this phase.

5. Further suggestions

5.1. The potential of integrated and optimized procedures for morphometric and energy data collection on existing buildings

The current research in the field is even more focussed on the definition of integrated and optimized procedures for data gathering by integrating experimental acquisition methods and instruments (advanced survey). Consequently, proper planning and scheduling of all survey phases is crucial, with the aim of determining an optimized sequence of steps for acquisition, processing and management of data. Each phase is not independent and autonomous, but functional and closely related to the others. Thanks to technological innovation and economic competitiveness, the more advanced techniques are reaching levels that make them comparable with traditional ones, but with the addition of the features of the advanced survey, especially in terms of productivity because they significantly increase the amount of information gathered, reducing the time needed for the survey.

5.2. Importance of post occupancy evaluations and participatory management

Once works have been executed, it is essential to carry on with building management activities, i.e. all operation, maintenance and monitoring phases on the reskilled building aimed at comparing project design criteria to real performances obtained. They include:

- students awareness and training on how to use the building in a proper way in order not to waste energy that would result in a reduction of the achievable savings and, therefore, in the extension of the payback time.
- participatory management of the redeveloped building through the involvement of users;
- post-occupancy evaluation, also through the participation of users (even students and teachers) to data acquisition and monitoring of the building;
- periodic monitoring of contracts for energy management, consumption and counters, to be carried out by an Energy Manager.

Analysing the energy performance of secondary schools in N. Greece

Vagi F. [1], Dimoudi A.[1,2,*]

[1] *Hellenic Open University, MSc 'Environmental Design of Cities and Buildings', Patras, Greece*
[2] *Department of Environmental Engineering, Democritus University of Thrace, Xanthi, Greece*
** Corresponding author: Tel./Fax: +30.25410.79.388, E-mail: adimoudi@env.duth.gr*

Abstract: Aim of this paper is the analysis of the energy performance of secondary school buildings in North Greece and the investigation of proposals for their energy upgrade. The survey was carried out by monitoring the energy performance of 20 secondary school buildings in the prefecture of Evros in Thrace and by simulating representative school buildings. Energy data both for heating and electricity, together with other information concerning structural details and operational characteristics for a period of 5 years (2001-2005) were collected. The energy data for the secondary schools are presented and compared with data from other regions in Greece. The mean heating energy consumption of secondary school buildings in the prefecture is 70.6 kWh/m^2, with insulated buildings performing with 27% less energy consumption than non-insulated buildings. Simulation of representative school buildings in this area suggests that measures for natural lighting, reduction of infiltration losses, controlled ventilation during the winter, shading and natural ventilation during summer and the effective functioning of heating and lighting system are the major priority for the school building stock. Especially in the 'old school buildings', this type of interventions are necessary not only for achieving energy efficiency but for obtaining thermal comfort conditions in their interior.

Keywords: *Energy efficiency, Schools, Monitoring, Simulations*

1. Introduction

The mean annual energy consumption of buildings in Greece is allocated as : 406.8 kWh/m^2 in hospitals, 273 kWh/m^2 in hotels, 187 kWh/m^2 in offices, 152 kWh/m^2 in commercial buildings and 93 kWh/m^2 in schools [1]. Although the energy consumption in school buildings is lower than other building categories, the overall energy consumption at national level is considered high due to the big number of school units, and the fact that they mainly operate during the heating period - they operate about 9 months -, they are not equipped with cooling systems and the majority of energy is spent for heating. The inadequate energy design of existing buildings, their age (40.9% is older than 30 years), their initial design (87.3% designed for schools), their location and proximity with disturbance sources (33.5% with high traffic roads, 15.9% with manufacturing premises and polluting areas), lack of regular maintenance and refurbishment can lead to education spaces with low thermal, visual and noise comfort, at reduction of pupils educational perception and additionally, at considerable environmental implications as a result of the increased energy consumption [2].

School buildings, due to their specialized operational characteristics and their social/ educational character have special requirements for environmental design for heating, cooling, ventilation and daylighting of their buildings. Collection of reliable energy data can facilitate to creation of a national data base that is useful to support reliable energy certification of school buildings and also to facilitate national energy policy measures to be taken. Aim of this paper is the analysis of the energy performance of secondary school buildings in North Greece and the investigation of proposals for their energy upgrade.

2. Methodology

2.1 Energy Consumption in School Buildings

All school units in Greece are equipped with heating systems (99.9% during the school year 2003-04) and the majority has a central heating system (88.0%). According to the opinion of

the Master of the school units, a portion of 11.1% considered as inadequate the operation of the heating system and in only 1.5% there was lack of heating operation during the years 2003-04 [2]. The energy consumption of school units, irrespective of education level (primary, secondary) based on previous surveys carried out in school units around Greece is reported in table 1. School buildings in Greece consume electrical energy mainly for artificial lighting and during the lasts years, especially in secondary schools, for new technologies (e.g. PCs). The mean energy consumption for heating and electricity in school buildings in other European countries, based on data from EC (Energy, E. C, 2000) [7] and other literature sources [8, 9, 10] are presented in table 2:

Table 1. Mean annual energy consumption in school buildings in Greece

Region / Climate zone	Year of research	No of buildings	Mean heating energy (kWh/m^2)			Mean electrical energy (kWh/m^2)
All Greece [1]	1993	238		67	Difference 40%	26
All Greece [3]	2006	340		68		27
Evros / C Climate zone [4]	2001-2005	10 primary Schools	No-insulated 89.4	72.8 Insulated 56.65	Difference 37%	8.65
Grevena / D Climate zone [5]	2004	9	No-insulated 139	123.31 Insulated 115.38	Difference 17%	14.31
Kozani / D Climate zone [6]	2003-2007	11 nursery 10 primary		135.9 105.8		7.5 9.3

Table 2. Mean annual energy consumption in school buildings of the member states of the European Union [7, 8, 9, 10]

Member States of the European Union	Heating energy (kWh/m^2/ year)	Electrical energy (kWh/m^2 /year)	Mean annual (kWh/m^2/year)
England (Mean value)	137-189	20-27	
Secondary school (Gateshead)	177		
Denmark (Skive)			
Primary school	170-175		
Sweden (Karlskrona)			
Secondary school	210		
Portugal (Agueda/Crato)			
Secondary school	64 /67		
Ireland [8]			96
Italy [9]			110
Slovenia [10]			192

3. Energy monitoring of secondary school units in the prefecture of Evros

The energy monitoring survey was carried out in 20 secondary school units out of 45 in the prefecture of Evros (NE Greece) covering 10 Junior High Schools, that is the 42% of corresponding units in the prefecture and 10 High Schools, corresponding at 48% of the

majority of high schools in the prefecture. The 5 out of the 10 junior high schools were located at the municipality of Alexandroupolis (the capital of the prefecture) thus, corresponding at 83% of the units in the municipality. The 8 out of 10 high schools were also located at the municipality of Alexandroupolis, covering the 63% of high schools in the municipality. During the survey, energy data for 5 years were collected (2001-2005), both for heating and electricity, together with other information concerning structural details and operational characteristics (e.g. no of pupils, heating system operation schedule, etc).

Table 3: Total mean annual energy consumption in 10 junior high schools of Evros Prefecture during the period 2001-05

			Heating energy			Electricity		Total
No	Construction year	Heating floor area (m^2)	Oil cost (Euro)	Oil quantity (kg)	*Heating energy (kWh/m^2)*	*Cost (Euro)*	*Consumption (kWh/m^2)*	*Total energy (kWh/m^2)*
1	1964	2.048.62	6,834	13,524.84	78.69	2,510	12.90	91.59
2	1976	2,300	7,420	14,605.08	75.69	1,724	7.89	83.58
3	1978	2,214	4,835	9,746.52	52.47	1,809	8.60	61.07
4	1978/ 1992	3,089.6*	6,055	12,437.04	78.72	4,339	14.78	93.50
5	1980	902.23	4,761	9,476.04	125.19	975	11.38	136.57
6	1986	809	2,826	5,765.76	85.00	649	8.45	93.45

8	1992	1,613.15	4,008	7,847.28	57.99	1,720	11.22	69.21
9	1996	2,398.5	5,414	10,887.24	54.11	2,023	8.88	62.99
10	1957/1995	2,348.96	5,350	11,340	57.55	1,928	8.64	66.19
		Total Mean Consumption:			72.00		10.14	82.14

* 1,883.15 (1978) + 1,206.45 (1992) = 3,089.6 m^2

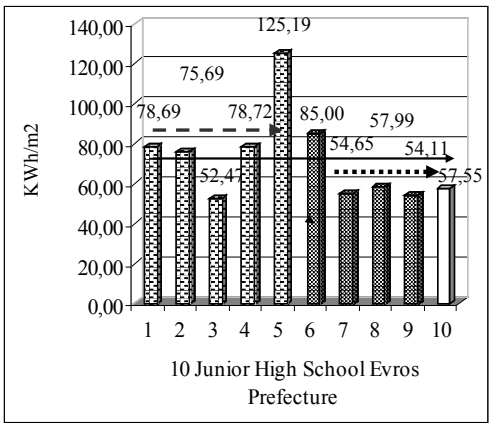

Fig. 1: Mean heating energy consumption in a sample of 10 junior high schools in the Prefecture of Evros for the period 2001-05

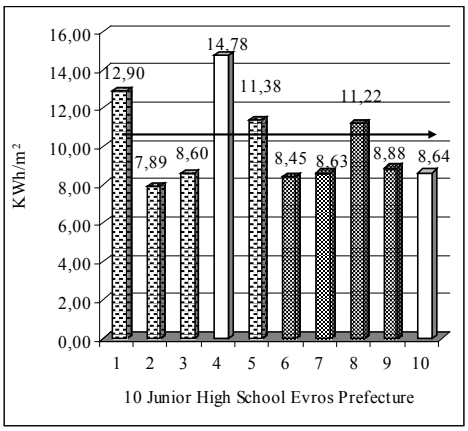

Fig. 2: Mean electrical energy consumption in a sample of 10 junior high schools in the Prefecture of Evros for the period 2001-05

Mean heating energy consumption for:

non - insulated junior high schools (1, 2, 3, 4, 5) :	82.16 kWh/m^2
insulated junior high schools (6, 7, 8, 9):	62.94 kWh/m^2
"Old" with "New" additions in junior high schools (4, 10) :	57.55 kWh/m^2
All junior high schools	72.00 kWh/m^2

The monitored energy consumption data, based on data of 5 years for the period 2001-2005, together with the construction year are summarized at tables 3 and 4 for the junior high schools and high schools respectively. The annual records for heating costs were available in each school and these values were quantified into energy consumption (in kWh/m^2) based on the mean annual price of diesel oil from the records of the Ministry of Development.

It is observed from figure 1 that the heating energy consumption in junior high schools ranges from 52.47 kWh/m^2 up to 125.19 kWh/m^2, with a mean value of 72 kWh/m^2, showing the higher values in 'old' buildings. Building 10 concerns an old building with an addition and its energy consumption is in the levels of the 'new' buildings. Junior high school no 4 is "old" with "new" additions, but the heating energy consumption concerns only the 'old' buildings while the electricity energy consumption both of them.

Table 4: Total mean energy consumption in 10 high schools of the Prefecture of Evros (2001-05)

			Heating energy			Electricity		Total
No	Construction year	Heating floor area (m^2)	Oil cost (Euro)	Oil quantity (Kg)	Heating energy (kWh/m^2)	Cost (Euro)	Consumption (kWh/m^2)	Total energy (kWh/m^2)
1	1970	3,300	10,828	21,215.04	76.63	4,104	13.09	89.72
2	1976	2,100	6,091	12,122.88	68.81	2,126	10.66	79.47
3	1976	4,405	20,103	40,057.92	108.39	7,032	16.8	125.19
4	1977	2,030	7,917	16,136.40	94.75	2,547	13.21	107.96
5	1981	3,500	18,799	39,170.88	133.4	6,595	19.83	153.23
6	1984	1,377	5,866	11,103.96	96.12	1,222	9.34	105.46
7	1985	2,716	7,768	15,333.36	67.3	2,969	11.51	78.81
8	1987	2,067.5	4,057	7,866.60	45.35	3,095	15.76	61.11
9	1996	1,404	3,609	7,203.84	61.16	2,009	15.06	76.22
10	1999	2,398.,5	6,646	12,701.64	63.12	3,523	15.46	78.58
		Total Mean Consumption:			81.50		14.10	95.60

Concerning high schools (fig 3), the heating energy consumption ranges from 45.35 kWh/m^2 up to 133.40 kWh/m^2 with a mean value of 81.5 kWh/m^2, showing the higher values in 'old' buildings. Energy consumption in units no 3 and 5 is increased (table 4 and fig. 3 και 4) as they concern technical high schools, which are equipped with different laboratories (mechanical, computers, horticulture sunspaces, etc), resulting at high energy consumption.

The mean electrical energy consumption is 10.14 kWh/m^2 in junior high schools 14.10 kWh/m^2 in high schools (tables 3 and 4) and 8.56 kWh/m^2 in primary schools in the prefecture of Evros [4]. The electrical energy corresponds only to about the 1/6th of the heating energy (fig. 5 and 6), mainly in the 'old' buildings', while in the new 'ones', electrical energy has a higher merit at the overall energy balance as the heating energy is reduced due to the improved building construction.

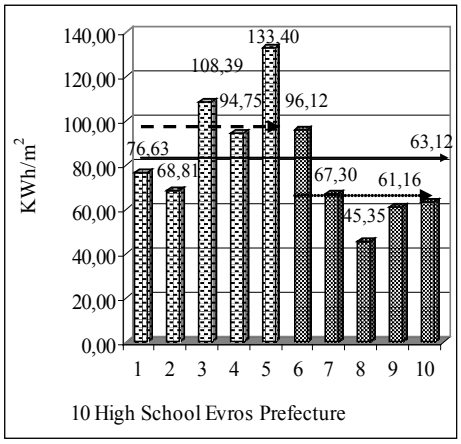

Fig. 3: Mean heating energy consumption in a sample of 10 high schools in the Prefecture of Evros for the period 2001-05

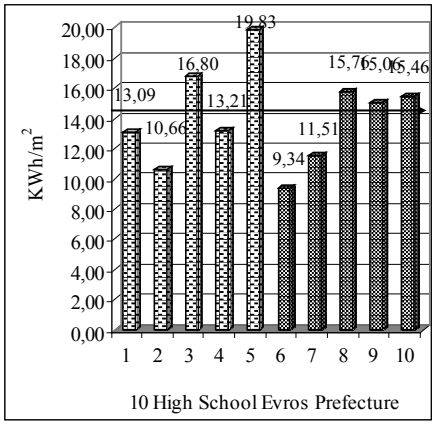

Fig. 4: Mean electrical energy consumption in a sample of 10 high schools in the Prefecture of Evros for the period 2001-05

Mean heating energy consumption for:

non-insulated high schools (1, 2, 3, 4, 5) :	96.40 kWh/m^2
insulated high schools (6, 7, 8, 9, 10):	66.61 kWh/m^2
All high schools	81.50 kWh/m^2

The mean heating energy of the school units in the region (Climatic zone C) corresponds at the 85% - 88% of the total energy consumption, compared to 72% that was recorded from previous studies [1] for all grades school buildings around Greece. This may attributed at the low temperatures recorded at this climatic zone and consequently the increased heating needs of the buildings, at the old age of buildings and lack of envelope insulation, at the fact that existing insulation in some buildings may be deteriorated, at the inadequate maintenance of the envelope and of the mechanical installations.

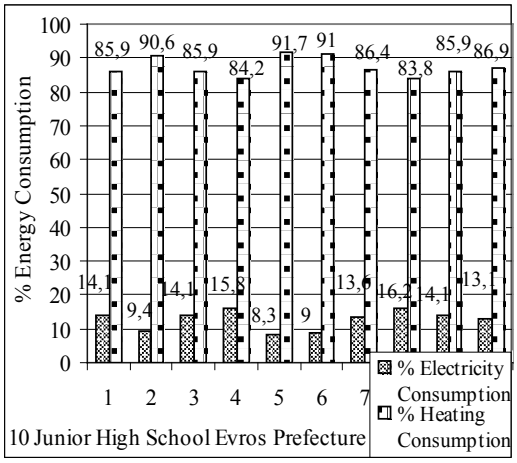

Fig.5: Mean energy consumption for heating and electricity (in %) in junior high schools in the Prefecture of Evros

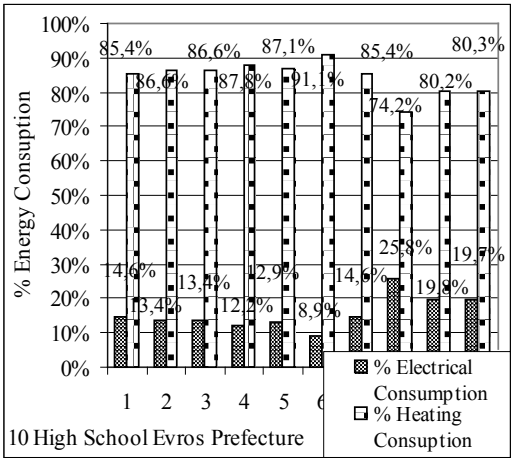

Fig. 6: Mean energy consumption for heating and electricity (in %) in high schools in the Prefecture of Evros

Analyzing the energy performance of all secondary school buildings in the prefecture of Evros (climate zone C) (fig. 7) the mean heating energy consumption is 70.6 kWh/m^2, with insulated buildings ('new') performing with 27% less energy consumption than non-insulated ('old') buildings. The 100% of insulated buildings show an energy consumption less than 100

kWh/m^2, compared to 70% of the non-insulated ones (table 3 & 4). In an older study of 180 insulated and 58 non-insulated school buildings in different climatic zones [1], the heating energy consumption differs between them by 40%, while the 88% of insulated buildings have energy consumption lower than 100 k Wh/m^2 compared to 79% of the 'non-insulated' buildings [1].

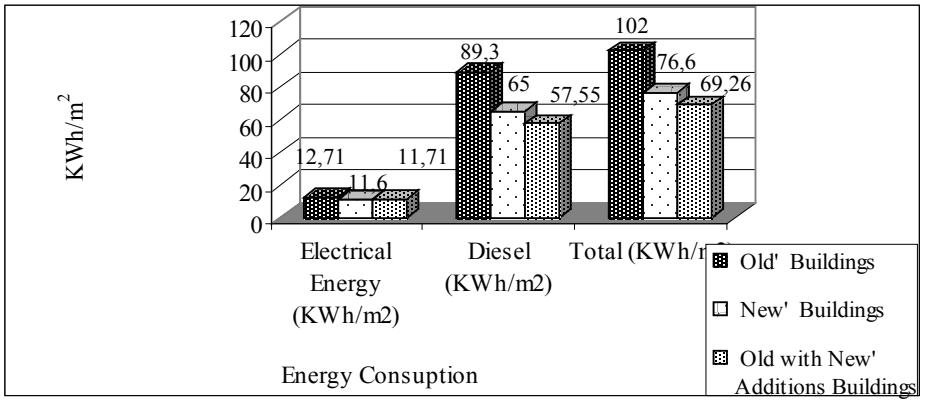

Fig. 7: Mean energy consumption according to the antiquity of 20 sschool buildings

4. Assessment of the thermal performance of 6 school buildings

For the thermal assessment of the school buildings, 6 units were chosen, 5 junior high schools and 1 hi gh school. The 4 junior high schools are located at the municipality of Alexandroupolis, representing 67% of junior high school buildings as well as the high school. From the 6 studied buildings, the 2 are 'old'ones constructed before 1981, and the 4 are 'new' ones, constructed after 1985. The thermal assessment of the studied school building and investigation of alternative energy saving measures was performed with the software tool XENIOS. The XENIOS is a European software tool that was developed in the frame of an Altener programme, partly financed by the EC DG on Energy and Transport. For each building the existing thermal performance was evaluated and alternative scenarios of energy upgrade were investigated.

4.1. Conclusions from the thermal analysis

4.1.1. Heating period

The following conclusions were drawn from the thermal analysis of the six buildings:

- Replacement of the windows with new ones and improving their overall transmittance of windows from 5.2 W/m^{2}K to 2.56 W/m^{2}K in the 'old' buildings resulted at reduction of the energy requirements during the heating period by about 12%. Improvement of the thermal properties of the windows in the 'new' buildings from 3.26 W/m^{2}K to 2.56 W/m^{2}K results at reduction from 1% up to 3%.
- Insulation of the external walls results at reduction of the energy consumption up to 12%.
- Insulation of the building envelope, with addition of insulation at the external walls, roof and windows replacement has an energy reduction up to 25% in 'old' buildings. In the 'new' ones a small energy reduction, in the order of 2% to 3% was observed.
- In most school buildings, the heating system is oversized, not well maintained and in the majority, there is no provision for control of their operation [12, p.25]. Improvement of the efficiency of the boiler up to 90% may bring energy savings up to 27% in all school buildings.
- Improvement of the efficiency of the distribution system, with appropriate pipes insulation, especially in they case they pass through unheated spaces, may bring considerable energy reduction, up to 15% in the studied buildings.

- Control of the indoor air temperature with thermostats in classrooms may lead to energy reduction up to 21% in all studied buildings. Installation of time-controllers, low control, room temperature sensors or external temperature based controllers or more advanced control systems (e.g. optimizers) achieving synchronization of the external and internal climatic conditions with the operation of the heating system can achieve indoor thermal comfort and energy savings. A thermostatic valve in the heating system is considered necessary for achieving the desired temperature in a space and achieving energy savings.
- The combined measures of improvement of the efficiency of the boiler and the distribution system and of the control of the indoor thermal conditions can increase the energy savings up to 52% both in the 'old' and the 'new' ones. Taking into account that in most school buildings, the heating system operates for a few hours, manually, with no room air temperature control, irrespective of indoor thermal conditions and outside climatic conditions and considering that the payback period for the improvement of the boiler and the distribution system efficiency is relatively low, it is considered imperative the replacement of the old systems with new ones.
- Applying all the proposed measures in the studied school buildings, an energy reduction from 53% up to 64% may be achieved.

4.1.2. Cooling period

- Insulation of the walls and of the roof would reduce energy cooling demands in 'old' buildings by about 2% in each case separately.
- Painting the outside surface of the external walls with a light colour reduces by 5% and by 3% the energy demand in cooling loads in the "old" buildings while in the "new" buildings only by 1%. The light colour on the roofs does not show a remarkable change in their thermal performance.
- The installation of interior blinds on all openings of the buildings, especially of southern, eastern and western orientation, may conserve energy of up to 61%.
- Installation of ceiling fans in the centre of each classroom, of power 100-200W, is sufficient to create the conditions for thermal comfort, provided that is combined with adequate shading and natural ventilation [12, p.30]. It may result in conservation of cooling energy up to 100% when combined with shading devices and light colored roof and walls. This is due to the fact that while the limit of thermal comfort in a natural cooled space is 27^{o}C, when a fan operates, the heat is dispersed because of air currents and the comfort level is raised over 29^{o}C.
- Also noctumal ventilation in schools is very effective especially during the hot days where the daily ventilation heats the building. It stores coolness in the thermal mass of the building, thereby reducing the thermal burden of the building during the next day. Schools are kept safe all night, so night ventilation can be applied without any risk.
- Energy conservation with implementation of all scenarios can reach up to 100%. At the same time, thermal comfort conditions are created in the classrooms that are considered necessary for the educational process and also contribute to reduction of air pollution with a lot of environmental and social benefits.

5. Conclusions

To ensure the efficient function of a school building and the reduction of problems that usually arise with time and the use of systems, the proper and regular maintenance of the building and its systems is essential. Collection and analysis of their energy data is essential for monitoring their energy performance and to react by taking the appropriate energy saving measures. In a national context, collection of energy data for different building categories can create reliable databases for certification of buildings and for prioritizing energy policy

measures. The assessment of the thermal performance of the school buildings in this study may provide useful conclusions for the actions to be considered in school building of the C' climatic zone in order to improve energy efficiency and achieve comfort conditions in the working space. Actions like planning and monitoring of an energy management plan, maintenance of the electromechanical installation and regulation procedures of natural lighting, reduction of losses from air infiltration, controlled ventilation for the winter period, shading and natural ventilation for the period of cooling and interventions in the exterior building structure particularly in the "old" school buildings are required, both to achieve thermal comfort and conservation of energy.

Abstract: The new recast of the Energy Performance of Buildings Directive (EPBD) calls for all new buildings to be nearly zero energy buildings by the end of 2020. Besides, there are many evolving new definitions of Net Zero Energy Building (NZEB) that need to be fulfilled. To achieve the above mentioned targets is quite challenging. In this paper the author presents his approach for the optimum deign method for NZEBs, which is by using combined simulation-optimisation. The method takes the problem as one-integrated design problem, where all possible components of the on-site renewable production, energy conversion, HVAC systems, building envelope and grid-connection are considered together as options in the design. It is a multi-objective problem, because it is to simultaneously minimise energy, CO2 emission, cost and indoor discomfort. Since these are conflicting objectives, thus it is an optimisation problem. An optimisation example is presented, which is solved by two methods: as a single objective problem and a two-objective problem.

Keywords: *NZEB, cost-optimal design, simulation, optimisation*

1. Introduction

The new recast of the Energy Performance of Buildings Directive (EPBD) calls for all new buildings to be nearly zero energy buildings by 31.12.2020 and two years prior to that for new public buildings. The rest of the energy is to be covered by renewable sources. Achieving the above mentioned targets is quite challenging. In order to fulfil the requirements for a Net Zero Energy Building (NZEB), it is to find the answers to the following question: What are the "best" components to be used in the building (materials of constructions, windows, air-tightness, insulation thickness, daylighting .vs. artificial lighting, shading type, etc), in the Heating, Ventilating and Air Conditioning (HVAC) systems (type of systems and equipments) and in the energy supply (including options for on-site renewable energy sources)? Those "best" components used to fulfil the energy target should not impose very high investment costs; otherwise the concept will not be economically viable. Besides, thermal comfort should also be kept on a high level. In addition, those best solutions will be different according to different definitions of the NZEB Concepts (e.g. NZ Site- Energy Buildings, NZ Primary Energy Buildings, NZ CO2 Emission Buildings, NZ Cost Buildings, etc). This leads us to think about: how to find the "best" components since there many targets to be achieved related to energy, cost, indoor-air comfort etc?

Then about the way to design a NZEB: the conventional way is to go first for minimising the energy demand on the building side and then to introduce on-site renewable energy. So is this the "optimum" approach?

In this paper an overview of the general method proposed by the EPBD, and as described by the Buildings Performance Institute Europe (BPIE), for finding cost-optimal solutions for nearly energy buildings is presented. Besides, the conventional method for designing buildings for the fulfilment of the NZEB definition according to the IEA-SHC Task 40 / ECBCS Annex 52 i s also presented. Then, the author presents his own approach for the optimum deign as a part of his position as a research-fellow of the Academy of Finland (2010-2015). The project aims for developing a combined simulation-optimisation tool for the optimal design of the NZEB's.

2. The EPBD recast 2010 and the IEA-SHC Task 40 Annex 52

2.1. The EPBD recast 2010 [1]

According to the recast of Energy Performance of Buildings Directive (2010/31/EU), all new buildings shall be "nearly zero energy buildings" as of end of 2020, and two years prior to that for the public sector. Such buildings should have very high energy performance. The nearly zero or very low amount of energy required should be covered to a very significant extent by energy from renewable sources, including energy from renewable sources produced on-site or nearby. Minimum energy performance requirements should be set for all existing buildings that undergo any energy relevant renovation. Besides it is to specify the level of minimum energy performance requirements for new buildings and renovations by developing benchmark method to achieve cost-optimal levels.

Overview of the cost-optimal method
The method in brief is:

- To define and select representative reference buildings (residential and non-residential, both for new and existing).
- To define combinations of compatible energy efficiency and energy supply measures to be applied to the reference buildings (packages of measures)
- To assess the delivered energy and primary energy of the selected building
- To find the corresponding global costs
- To develop cost curve(s) and derive an optimum.

The EPBD recast prescribes that the cost-efficiency of different packages of measures (combinations of compatible energy efficiency and energy supply measures) can be assessed by calculating and comparing the energy-related lifecycle costs. From the variety of specific results for the assessed packages, a cost curve (global costs .vs. primary energy) can be derived (Figure 1). Global costs are defined as the net present value of all costs during a defined calculation period (investment costs, maintenance and operating costs, earnings from energy produced and disposal costs). It is first to start with packages of measures that comply with the minimum performance requirements in force, and then to find ambition solutions beyond current minimum requirements up to and including nearly zero-energy buildings. The lowest part of the curve in Figure 1 represents the economic optimum for a combination of packages.

To establish a comprehensive overview, all combinations of commonly used and advanced measures should be assessed in the cost curve. The packages of measures should range from compliance with current regulations and best practices to combinations that realise nearly zero-energy buildings. The packages should also include various options for local renewable energy generation. The variety of solutions will form a "cloud" of data points from which a cost curve can be derived. The minimum energy performance requirements are represented by the portion of the curve that has the lowest cost in Figure 1. The part of the curve to the right of the economic optimum represents solutions that underperform in both aspects (environmental and financial). To prepare for higher energy or environmental targets related to 2020, certain Member States might choose even stricter requirements than the economic optimum (left part of the curve). The distance to the target for new buildings "nearly zero-energy buildings as from 2021" is shown in Figure 1.

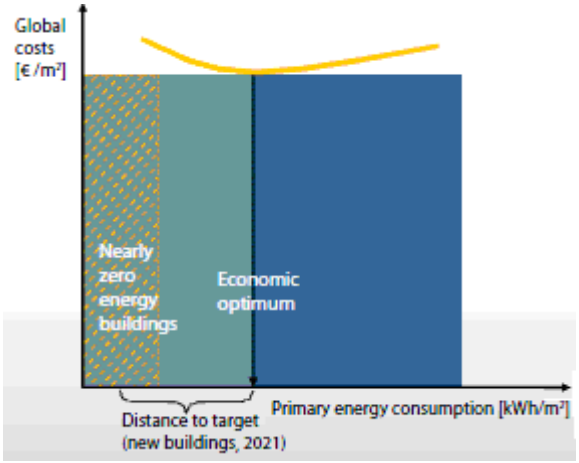

Fig. 1. Cost optimum and distance to target [1].

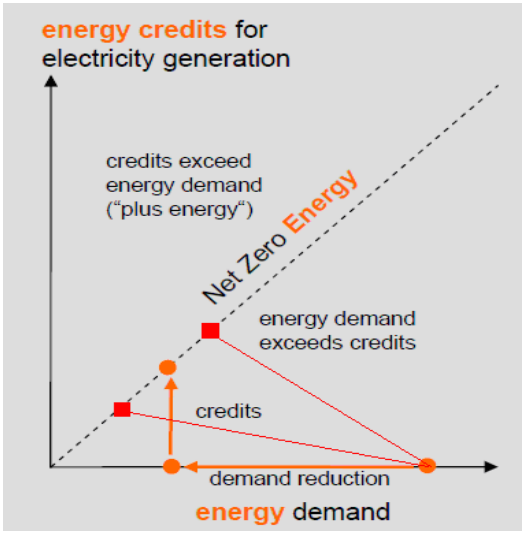

Fig. 2. Conventional way to achieve NZEB [2].

2.2. IEA-SHC Task 40 Annex 52 definition for NZEB [2]

For a NZEB, the balance between energy export (feed-in energy to the grid) and import (delivered energy from the grid) over a period of time must be zero or positive. The following inequality defines a NZEB:

$$Export - Import \geq 0.$$

The balance is normally calculated by means of some credits rather than directly on physical units of energy. The terms of the above inequality are expressed as follows:

$$Import = \sum_i delivered\ energy(i) \times credits(i)$$
$$Export = \sum_i feed\text{-}in\ energy(i) \times credits(i)\ ,$$ where i is the energy carrier.

The credits are therefore the metric used to calculate the balance. Figure 2 gives a graphical representation of the general pathway for the design of NZEBs in two steps (indicated by the orange circles): it is firstly to reduce the energy demand on the building side and secondly to generate renewable energy to get enough credits to achieve the balance.

2.3. Comments on the above mentioned methods

A crucial issue in the EPBD method is how to define the packages of measures (i.e. how can we say that for this package let us take x_1, x_2, x_3 and x_4 as the insulation thickness in the external wall, roof, floor, and the U-value of the window, respectively?). This is also pointed out by the IBPE publication [1]. On the other hand, and even for one package, searching for the optimum values and types of the design variables by making a comprehensive overview of all possible combinations of commonly used and advanced measures is not a simple task. This is because if we make an exhaustive search, the total number of combinations is a result of multiplication of the options for each variable. This will produce a huge number of combinations to be investigated. And then for both EPBD and IEA-Annex 52 methods, the approach should not be split into two steps, firstly reducing the energy demand to nearly zero energy and secondly introducing on-site renewable energy production. This is because if we apply this approach, we will first end-up with an extremely low-energy house or a passive-house before giving a very small chance for on-site renewable energy production to participate in the solution, which is not the best method for all cases (e.g. a case using micro-CHP).

3. Optimum Method for Designing NZEBs

The optimum method is to take the problem as a one-integrated problem, where all possible components of energy production (e.g. on-site renewables), energy conversion (e.g. via heat pumps), HVAC systems, building envelope and grid-connection are considered together as options. It is a multi-objective problem, because it is to simultaneously minimise the targets of energy (heating/cooling energy, primary energy), CO2 emission, cost (investment cost, operating cost, net present value costs), indoor discomfort, etc. Since these are mostly conflicting objectives, thus it is an optimisation problem, where optimal trade-off designs are searched. This holistic approach will produce a huge optimisation problem. However, it could be converted into a manageable size using e.g. problem specifying heuristics and considering most promising components in the building and the HVAC system. An optimisation problem is formulated by specifying the variables and objectives of the problem. The parameters are classified as fixed and variable parameters. These latter we call "design variables", are the ones we seek to find their optimum values that will make the best impact in achieving the objective functions (i.e. targets).

The implemented approach is "combined simulation-optimisation", which is made by coupling the dynamic building simulation program with optimisation algorithms, to find optimal values of the design variables. Figure 3 shows a typical combination of an optimisation program with a simulation program. To perform the optimisation, the optimisation program automatically writes the input files for the simulation program. Then it starts the simulation program, reads the value of the function to be minimised from the simulation result file and then determines the new set of input parameters for the next run. The whole process is repeated iteratively until a p re-defined criterion is fulfilled or a maximum number of iterations is reached. Two optimisation programs are implemented in our studies. In our implementations, we have modified those programs [3, 4], so that we are able to handle single and multi-objective function problems, with or without constraints, having continuous and discrete variables. Discrete design variables are very common in building designs (e.g. different types of windows, walls, shadings, HVAC equipments etc).

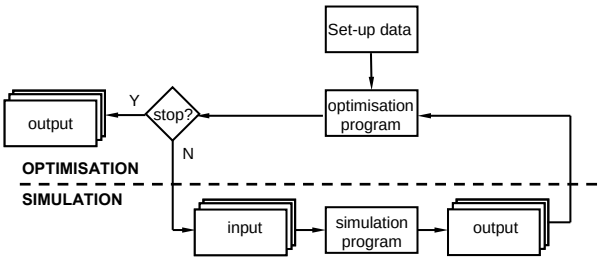

Fig. 3 Combined simulation-optimisation.

Table 1. Design variables and bounds.

	d$X_{extwall}$ (m)	dX_{roof} (m)	dX_{floor} (m)	U_{window} (W/m^{2}K)	*Eff.*
Min. (m)	0	0	0	1.0	07
Max. (m)	1.0	1.0	1.0	Or	or
Step (m)	0.05	0.05	0.05	1.4	0.8
Initial (m)	0	0	0	1.4	0.7

Min. is the lower bound value
Max. is the upper bound value
dX is the additional insulation thickness to be added to the standard
U_{window} is the window's thermal transmittance
Eff. is the efficiency of the heat recovery unit

3.1. Example

To demonstrate the method, a building design example is presented here. In this example, a detached house (floor area 147 m^2) designed according to the Finnish Building Standard-2003 is studied (Standard House). The task is to modify the house by finding optimal values for five design variables that will need minimum investment while making best impact on

lowering the operating energy cost. These variables are: three continuous variables as additional insulation thicknesses to be added to the Standard House (in the external wall, roof and floor) and two discrete variables (types of windows and ventilation heat recovery exchanger). The given bounds for the values of those variables are indicated in Table 1. The problem is solved in two ways, as a single objective problem and a two-objective problem. In this paper, data from [4 and 5] are reproduced to explain the implementation.

3.1.1. Solution as a Single Objective Problem

The objective is formulated as a single objective optimisation problem for minimising of one objective (ΔLCC) (€), the difference in the life cycle cost of the house discounted to net present value compared with its standard design. ΔLCC is defined as

$$\Delta LCC = \Delta IC + \Delta RC + \Delta OC$$

ΔIC difference in the investment cost (€) for the specified design variables
ΔRC difference in the replacement cost (€) due to replaced items (in the building envelope or system) in specified years due to shorter life of those items with respect to the building life.
ΔOC difference in the operating cost (€) due to difference in energy consumption

All above cost differences are with respect to those for the Standard House. This is an optimisation problem because it includes conflicting targets (i.e. increasing the investment cost will decrease the operating energy cost and vice-versa). An exhaustive search method to find the optimal values of the design variables will need a huge number of simulations even for this simple case. For example, if we assume that there is 1 cm step in the additional insulation thickness in Table 1, then the total number of possible combinations to be investigated is $100 \times 100 \times 100 \times 2 \times 2 = 4 \times 10^6$. The combined simulation-optimisation does it in much less number of simulations.

For this example, eight cases were studied [5] with different assumptions for the life-cycle span *n*, escalation in the energy price *e* and the source of the design variable prices. Figure 4 shows the optimisation-simulation iterations for one case (n = 20 years, e = 0.01 and real interest rate = 4.90 %). Only 241 simulations were needed to find the cost-optimal solution using a hybrid algorithm (PSO and Hooke-Jeeves). Each point in the figure is a full-year hourly dynamic simulation. From this figure, it can be seen that the solution has a minimum value of ΔLCC (−2102 €) as a result of the reduction made in the energy cost for space heating ΔOC (−4229 €) when investment is made in the insulations, windows and heat recovery including associated replacement costs ΔIC+ΔRC (+2127 €). Since ΔLCC for the Standard House is 0, therefore the negative value of ΔLCC means lower LCC cost is reached compared with the Standard House. The optimisation results give the optimised values of the five design variables to achieve this target. The simulation-iteration runs, when searching for the optimal solution, are indicated in Figure 5 as ΔLCC .vs. annual space heating energy. From this figure, we can conclude that there is no need to make an exhaustive search and draw the whole energy-cost curve to find the cost-optimal solution because the optimisation algorithm finds shortest ways to that. In addition to minimising the LCC, Figure 5 shows that the annual space heating energy demand at the cost-optimal solution is about 71 kWh/m^{2}a, which is 28% lower than that for the Standard House. This means that the obtained cost-optimal solution achieves both the financial and energy targets. By this method, the optimisation method took the problem as one investigation for minimisation of the LCC, which inherently accomplished the environmental target.

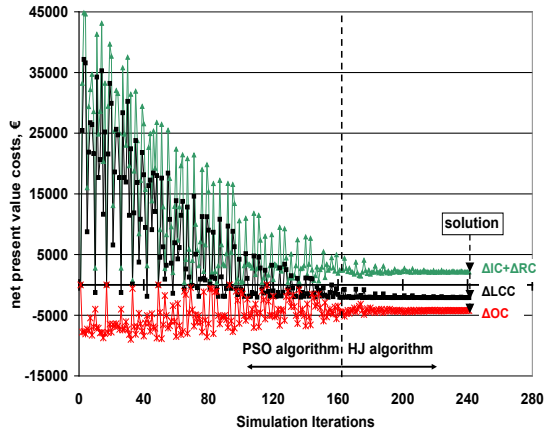

Fig. 4. Simulation-optimisation iterations.

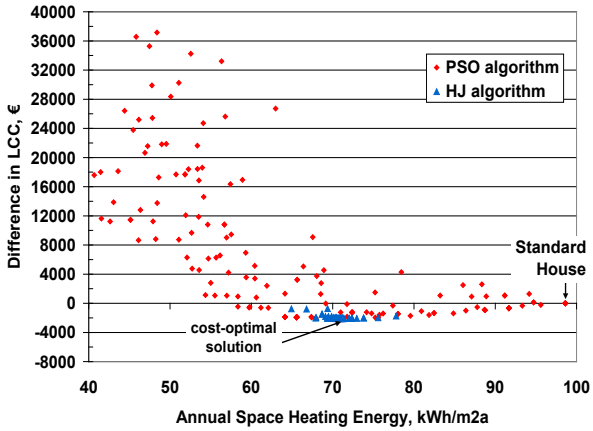

Fig. 5. Finding the cost-optimal solution.

3.1.2. Solution as a Multi-Objective Problem

By taking the problem as a multi-objective optimisation problem, we can draw the cost-curve, find the cost-optimal solution and specify other potential solutions towards nearly zero energy buildings, without making an exhaustive search. To explain this method, the previous example is converted into a two-objective optimisation problem where it is to simultaneously minimise both the difference in the investment cost (ΔIC) and the annual space heating energy demand. Figure 6 shows the optimisation solutions for this two-objective problem using combined simulation and a Genetic-algorithm optimisation [4]. In this figure, the results of an exhaustive search (Brute-force) made on preferable solutions are also shown. The Brute-force search is made by keeping the floor thickness according to the Standard House. This makes the number of variables four. Besides, a maximum value of 0.39 m is considered for ($dX_{extwall}$) and (dX_{roof}). Assuming a 1 cm step in the insulation thickness, the total number of Brute-force candidate solutions is 40×40×2×2 =6400 and as shown in Figure 6. These hints were concluded from the single-objective case results; otherwise a complete exhaustive search will be needed with 4×10^6 candidate solutions. It can be seen that the optimisation solution captures the optimal Pareto-front of the Brute-force, which is an indication of the high accuracy of the optimisation results. Figure 7 presents the difference in the life cycle cost (ΔLCC) based on the data from the optimisation solutions and the Brute-force results from Figure 6. It can be seen from Fig. 7 that the cost-curve is constructed and the cost-optimal solution can be found. In comparison with the single-objective solution, this two-objective solution facilitates assessing potentials for nearly-zero buildings (range of optimal solutions to the left of the cost-optimal in Fig. 7), which is a big advantage over the single objective approach. It is to note that a constraint of 6000 € was applied on (ΔIC) in the optimisation problem to obtain similar range of results as those got from the brute-force search in Fig. 6. We could have got a more complete cost-curve without such a constraint.

Similarly for the NZEB case, the optimisation method can find optimum solutions (indicated by the red squares in Figure 2) without going through the conventional two-step solution method.

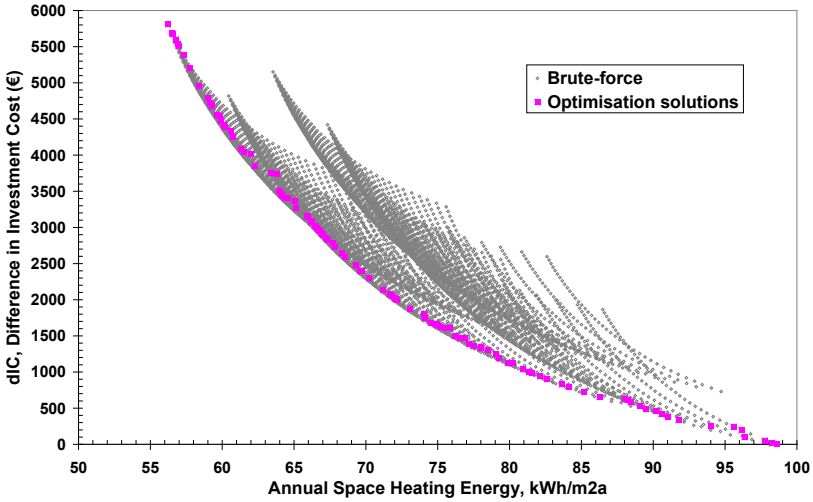

Fig. 6. Two-objective optimisation results and Brute-force candidate solutions [4].

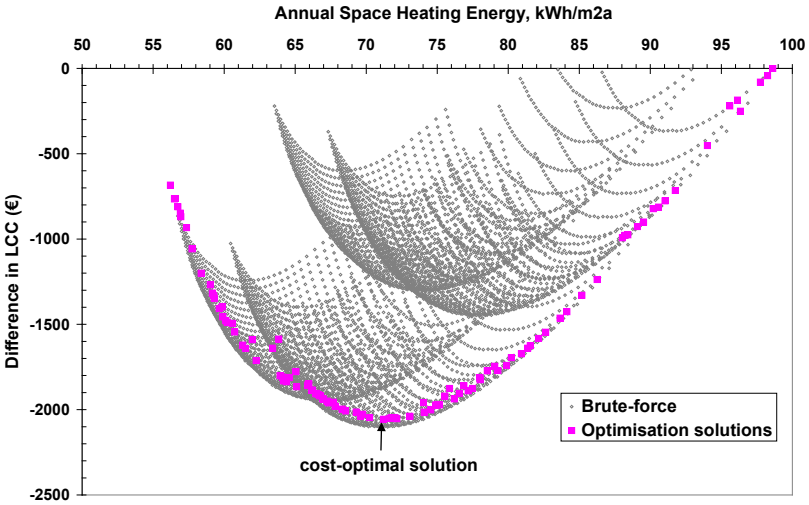

Fig. 7. Cost-curve and cost-optimal solution found from the two-objective optimisation results.

4. Conclusion

It is concluded that optimisation tools have to be combined with simulation tools for finding optimal designs of NZEBs. This is valid for the two methods discussed in this paper: the EPBD recast method and the IEA-Annex 52 NZEB definition. Otherwise it is very difficult for a designer to make a "good" guess at best candidate combinations of measures that will be compared for their cost-energy performance especially when there are many variables in the problem and also due to the nonlinear interaction between the variables. Another way is to make exhaustive searches for each case to define candidate packages, which will then need a huge number of simulation iterations.

The approach should not be split into two steps, firstly reducing the energy demand to nearly zero energy and secondly introducing on-site renewables. If we apply such approach, we will end-up with an extremely low-energy house before giving a very small chance for on-site renewables to participate in the solution, which is not the best method for all cases. For example a house with on-site energy generation from a micro-CHP dose not need to have high quality windows or very thick insulations because of the ample heat accompanied with the generation of electricity. Besides, the selection of the optimal measures should not be only dependent on achieving cost and energy targets, but indoor air comfort should be considered

as target in the problem as well, otherwise overheating could be faced when using more insulations and air-tight envelopes or overcooling could be faced when low-energy value sources are used for heating.

The optimum design method for NZEBs is by taking the problem as one-integrated problem (envelope + HVAC systems + en ergy supply including renewables) using combined simulation-optimisation. The optimisation tool will find the best combinations of measures that will fulfil the objectives of the problem. This approach was applied in the presented example. The problem was solved by two methods. In the first method, the problem was formulated as a single objective LCC minimisation problem, where search was done for finding the cost-optimal solution. In the second method, the problem was formulated as a two-objective problem, where search was done for minimising both energy and investment cost, from which the whole cost-curve was constructed and the cost-optimal and other alternative solutions were found.

Abstract: Unglazed transpired solar collectors are usually mounted on the side of the building that receives the most sunlight. It is a fan-assisted system, whereby air is drawn through the holes into the plenum and the warm air is then ducted into the building. The primary reason for using the unglazed transpired metal plate as the solar collector is not only to absorb the solar heat but also to reduce the convection heat loss. These in return will have higher heat exchange effectives and heating efficiency. Though many research have been carried out to study the Nusselt number correlations, heat exchange effectiveness, wind effects and pressure drop, yet only hand full of research that involved heat transfer study that including the vertical airflow in the plenum. This paper is to assess the heating performance of this system through experimental tests which involve the study of temperature rise along the vertical air flow in the plenum. Results show that the temperature of the air flowing vertically is increasing gradually from the bottom to the top of the plenum. This is contrast with the previous studies which assumed that the temperature of the air in the plenum is constant and same as the outlet air temperature at the top of the plenum. The temperature rise is increasing with solar radiation intensity. Temperature rise along the plenum contributes between 30 to 60% of the total temperature rise at a constant suction velocity. On the other hand, temperature rise is decreasing with suction velocity. Values of temperature rise along the plenum are between 30 to 50% of the total temperature rise for suction velocity of 0.03 to 0.05 ms^{-1} at 600Wm^{-2} of solar radiation. Therefore, this study has proved that heat transfer of vertical airflow in the plenum has a crucial heating effect.

1. Introduction

The heat transfer of the transpired plate occurs at the front-of-plate (the upstream-facing surface), the hole and the back-of-plate. The diameter, pitch and geometrical of the hole together with the porosity of the plate and suction velocity of airflow rate are the key factors for the heat transfer coefficient. However, there are limited studies on transpired plate heat transfer. Kutsher [1] has developed an empirical correlation of Nusselt number which is appropriate for thin transpired plates with porosity less than 2%, low suction flow rates and triangular hole arrays. To-date, this is the only study considering the porosity, hole diameter and crosswind conditions to reach the empirical correlation Nu. The correlation covers heat transfers from the front-of-plate, hole and back-of-plate but excludes the vertical airflow in the plenum. The author ignore heat transfer between the back surface and the vertical airflow because it is believed that the flow in plenum has little effect due to the injection effect on the

back-of-plate side and the air laminarization induced by acceleration. The numerical results show that the heat transfer that occurs at the front surface dominates heat transfer in the hole and on the back surface at suction flow rates of 0.02 to 0.07 kg $s^{-1}m^{-2}$. The crosswind data for the narrow transverse spacing are correlated as $Nu=2.75[(Pit/d)^{-1.2}Re^{0.43}+0.011PRe(U_w/v_s)^{0.48}]$ with $0.001\leq P\leq 0.05$ and $100\leq Re\leq 200$ [1]. Augustus and Kumar [2] use the same Nu correlation in their mathematical modelling of transpired solar collector performance. The assumptions made are the same as Kutscher's [1, 3] and Dymond's [4] studies. The plate is a mild steel absorber coated with black paint with input parameters as follows: $400\leq I\leq 900 Wm^{-2}$, $0.02\leq v_s\leq 0.03 ms^{-1}$, $25\leq \Delta P\leq 80 Pa$, $0.050\leq D\leq 0.150 m$, $0.012\leq Pit\leq 0.024 m$ and $0.00080\leq d\leq 0.00155 m$.

Gunnewiek et.al have studied the airflow in plenum but only considering the vertical direction by using 2D CFD model. The transpiration of air through the plate is modelled as a process occurring through discrete holes. The collector height range is $3.0 \leq H\leq 6.0$ m, and the plenum aspect ratio range is $10 \leq H/D \leq 50$. The results show that different settings of parameters yield different airflow profiles. The nature of the profile depends on whether the flow is dominated by buoyancy or by the forced-flow produced by the fan. When the flow is non-uniform, the code predicts that an important amount of heat transfer can take place from the back-of-plate to the vertical air in the plenum. The non-uniform flow is favoured in flows that are buoyancy dominated. Besides improving the efficiency, non-uniform flow is also keeping the fan power at a minimum, so there is a dual benefit [5]. Poor flow distribution occur in large building applications; this has been shown by infrared photographs [4]. Such poor distribution would cause penalties in performance due to greater radiation and convective heat losses at hotter, flow-starved surfaces. In order to study the uniformity of the airflow, Dymond and Kutsher [4] have developed a computer program to allow designers to predict flow uniformity and efficiency by applying pipe networks concept. The studied range of plenum depth, D is between 5 and 30cm. In terms of the energy balance the authors acknowledge additional heat transfer from the plate to the air in the plenum is possible, which has been indicated by Gunnewiek et. al [5] simulation results. However this part of heat transfer is ignored due to the absence of heat transfer correlation between the back-of-plate and the vertical airflow. Hence, it is assumed that the air temperature leaving a junction is the same as the perfectly mixed temperature of the air entering the junction. The overall results show that the air inside the collector plenum experiences three plenum pressure drops, i.e. acceleration, friction, and buoyancy. The larger the air flow through the collector, the better the heat is transferred away from the collector, which results in a higher collector efficiency.

Though there are quite a number of studies that ignored the heat transfer from the back of the plate, study [5] has proved that this part of heat transfer is possible and the authors [4, 6] also acknowledge this possibility if the collector is vertically tall. Thus, this paper is to discuss the heating performance of this system through experimental tests which involve the study of temperature rise along the vertical air flow in the plenum.

2. Methodology

A chamber is built inside a laboratory. Fig. 1 illustrates the schematic view of the experimental system. The wall of the façade that contacts with the ambient is a black painted aluminium transpired plate which adjuncts with three other solid walls, and so they form a plenum. As shown in Fig. 1. The sandtile wall is made of eight sandtile blocks with the dimension of 0.25m x 0.25m x 0.06m for a single block. The other two adjunction walls that attached to both aluminium plate and sandtile wall are rigid polyisocyanurate foam boards

with glassfibre of 0.07m of thickness and U-value of 0.023W $m^{-2}K^{-1}$. The opening of the air outlet is 0.23m x 1.0m. Two fans are installed at the air outlet. Nine K-type thermocouples are placed on each aluminium plate, the plenum and the sandtile wall as shown in Fig. 2. The locations of thermocouples between the wall and the plate (the plenum) are in line with the thermocouples on the sandtile wall except at the bottom they are in line with the first row of the holes from the bottom. The thermocouples are connected to a computer-controlled data logger. Temperatures data are started to be taken only after the test has begun for 2hours to reach a steady state. Air velocities are measured at the centreline of the plenum and at the outlet of the plenum.

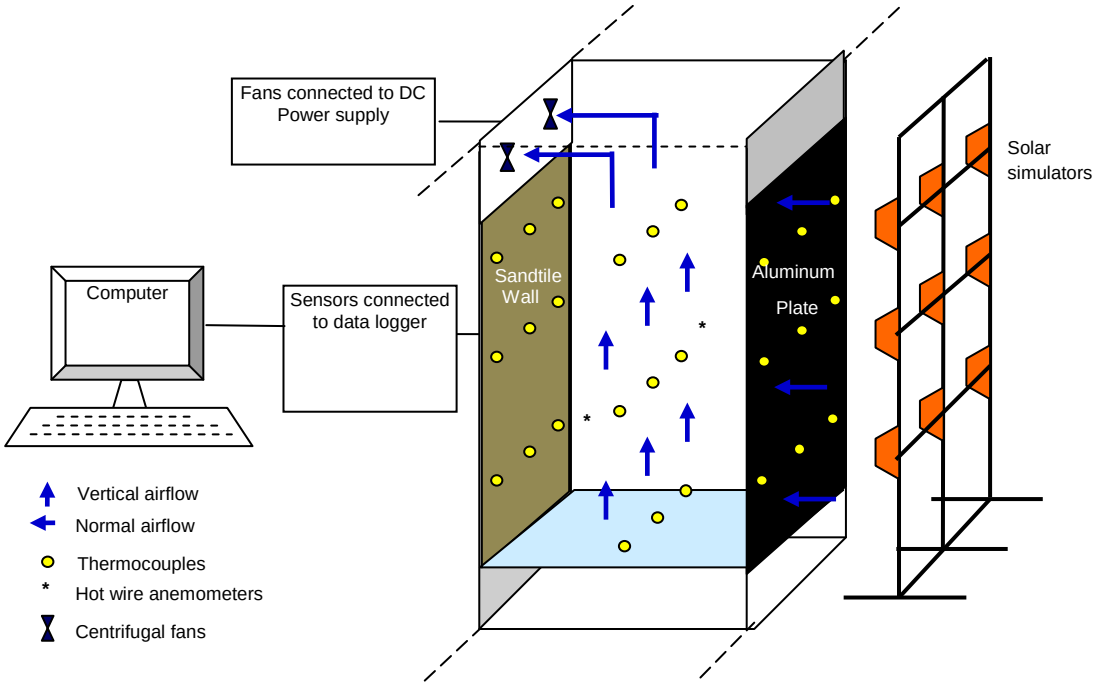

Fig. 1. Schematic view of experimental set up.

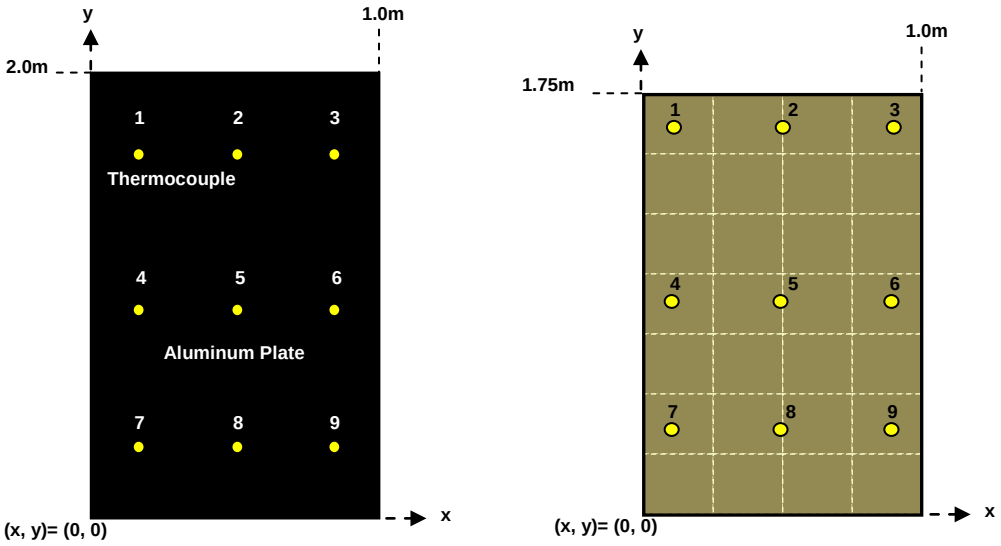

Fig. 2. Thermocouples' location on the plate and santile wall.

2.1. Test conditions and analytical parameters

The test conditions and some of the interested parameter to be investigated in this study are as shown in Table 1. The parameters that vary from one cycle to another of the tests are among solar radiation intensity and suction velocity. Only one design of the transpired plate is involved in this study, which the circular holes are arranged in triangular geometry. Pressure drops across the collector for all the tests are ensured to be at least 10 times greater than the pressure drops in the plenum and so as positive values of pressure coefficient. This step is to avoid outflow air from the plenum. The solar radiation that absorbed by the plate is assumed to be homogenous.

Table 1. Parameters for the experiment tests.

Parameter	Value/ range
Solar radiation intensity (I), Wm^{-2}	300-800
Suction velocity (v_s), ms^{-1}	0.03-0.05
Plenum depth (D), m	0.25
Pressure drop across the collector (ΔP), Pa	12-36
Pitch (Pit), m	0.012
Hole diameter (d), m	0.0012
Height of the collector (H), m	2.0
Width of the collector (L), m	1.0

3. Results

Effects of suction mass flow rate and solar radiation intensity have been studied and results are as discussed in the following sections.

3.1. Effect of suction airflow rate

Fig. 3 shows the temperature rise for different depths of the channel at different suction mass flow rates with a solar radiation intensity of 614Wm-2. The temperature rise of (Tout-Ta) is the overall temperature rise for the system, which is the temperature difference between the outlet air and the ambient air. The temperature rise of (Ti-Ta) is the temperature difference between the heated air after passing through the holes (normal flow) and the ambient air. Whereas the (Tout-Ti) is temperature change of the vertical flow from the bottom to the top of plenum. The values of these temperature rises decrease with the suction mass flow rate. Increasing the suction mass flow rate by about $0.02kgs^{-1}m^{-2}$, Tout-Ta decreases nearly 3K, while (Ti-Ta) and (Tout-Ti) decrease about 1K and 3K respectively. T he shares of temperature rises contributed from normal and vertical flows remain almost the same between 0.04 to $0.06kgs^{-1}m^{-2}$ (Fig. 3). The degrees of temperature decrease for the normal and vertical flows are about the same. Nonetheless, results shows that in term of percentage the vertical flow (Tout-Ti) contributes about 39-49% of the total air temperature rise (Tout-Ta). Thus the air temperature rise along the plenum should not be ignored.

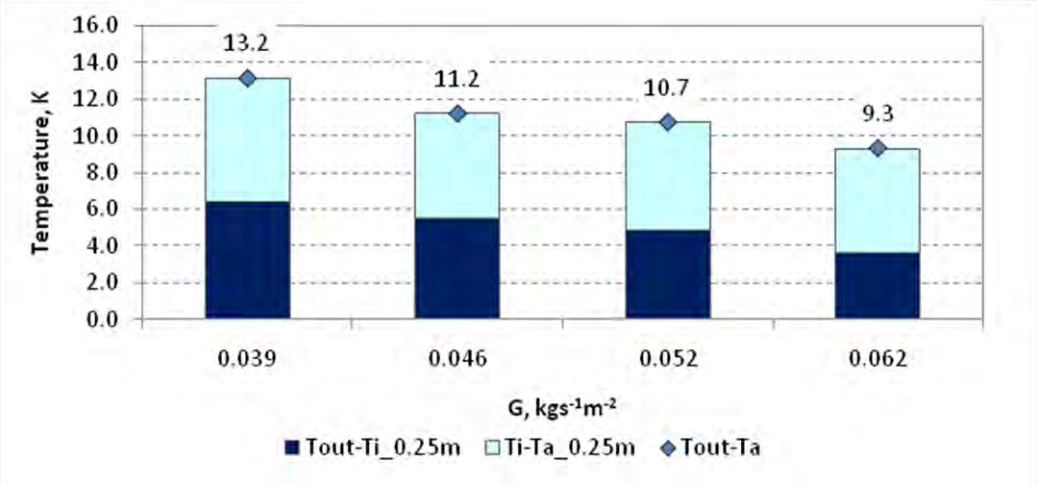

Fig. 3. Values of total, normal and vertical temperature rise at different suction mass flow rates.

3.2. Effect of solar radiation intensity

Fig. 4 shows the temperatures of the ambient, the plate and the air in the plenum for plenum depth of 0.20, 0.25 and 0.30m respectively, at a constant suction mass flow rate. The values of the temperatures increase with the solar radiation intensity and are as shown in Figure 8. The overall rise in temperature (Tout-Ta) from 307 t o 820Wm-2 is about 6 t o 18K, which approximately increases 3K for every increase of 100Wm-2. Thus, the solar radiation intensity plays an important role in the thermal performance of the system. Fig. 5 shows the shares of temperature rises contributed by the normal (Ti-Ta) and vertical (Tout-Ti) flows at constant suction mass flow rate and solar radiation intensity. In terms of percentage, vertical flow contributes 34% of total temperature rise at 307Wm^{-2} and increases to 58% at 820Wm^{-2}. Therefore, this indicates that the temperature rise in the plenum should not be ignored.

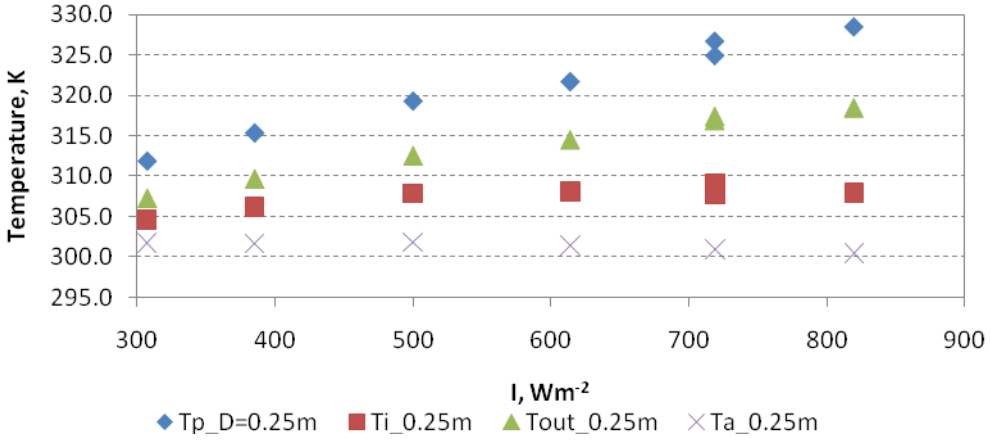

Fig. 4. Temperatures of ambient, at the plate, bottom of plenum and the outlet at a constant suction mass flow rate and different solar radiation intensities.

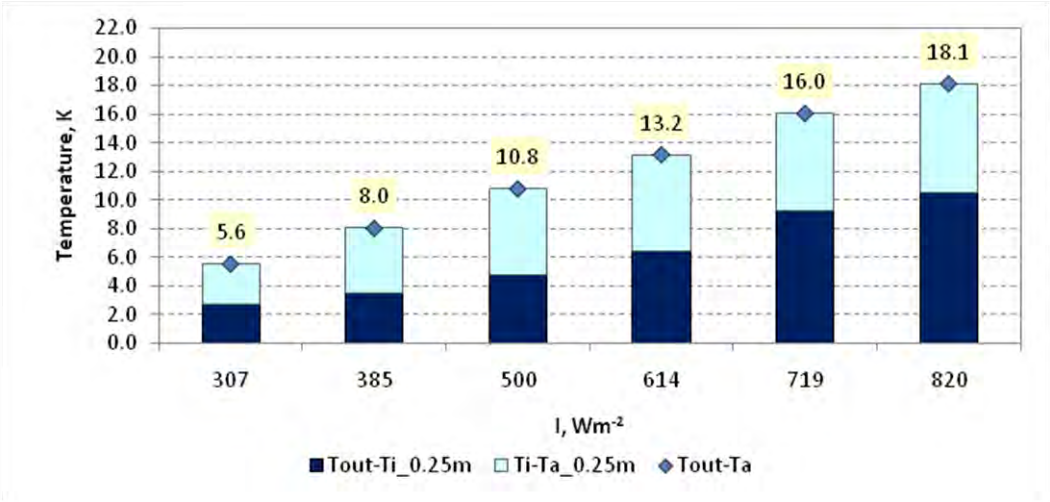

Fig. 5. Values of total, normal and vertical temperature rise at different solar radiation intensities.

4. Discussion and Conclusions

Experimental results show that the vertical flow contributes about 50% of the total air temperature rise. This is contrast with previous studies. As most of the transpired solar collector related studies adopt the same Nu heat transfer correlation [1] and lack of correlation between the plate and the air in the plenum, they accept the same assumption which is neglecting the heat transfer from the back of the plate to the air in the plenum. One of the possibilities for being disagreed with this assumption could be the height of the collector in Kutscher's study [6]. The height for the collector was 0.5m which is quarter of the height of present study. In the study, the author acknowledges that heat transfer from the back of plate might occur for tall vertical collector. Moreover, this could be due to buoyancy-dominated pattern of the vertical flow and causes heat transfer takes place from the back of the plate [5]. Present results show that vertical flow heat transfer is significant for the total air temperature rise. The air temperature rise from the bottom to the top of plenum is between 2 to 10K depends on the operating parameters. However the pattern of the vertical flow is beyond this study. A more precise correlation for vertically tall solar collector need to be developed which include the heat transfer along the plenum whether experimentally or through CFD simulation.

Improving thermal performance of offices in JUST using fixed shading devices

Ahmed A. Y Freewan*

Jordan University of Science and Technology , Irbid, Jordan
**. Tel: +962 796636130, Fax: +962 2 72010381, aafreewan@just.edu.jo (ahmedfreewan@hotmail.com)*

Abstract: Large windows and highly glazed façades have been increasingly used in new buildings, allowing the access to daylight, solar gain and external view. Solar gain through non-shaded windows and glazed facades extremely increases the air temperature in summer especially in hot climates regions, like Jordan. Therefore, it affects thermal comfort, increase the cooling load and become a s ource of glare which harms the visual environment. Generally, shading devices are used to protect inner spaces from direct solar gain through openings, windows and glazed surfaces. The current research examined the effect of using shading devices on thermal environment and air temperature in offices facing south-west façade at Jordan University of Science and Technology (JUST). I n such orientation windows required especial considerations to control solar gain in summer and winter. The research used real experiments to study effects of shading devices on thermal comfort. Three fixed shading devices; vertical fins and diagonal fins and egg crate, were installed in three identical offices. Thereafter, the air temperature was monitored and compared to non-shaded office. The results showed that the temperature in offices with shading devices compared to the office without shading devices was reduced to acceptable level. At the time of measurements diagonal fins perform better compared to other shading devices.

Keywords: *Shading devices, Thermal comfort, Cooling load.*

1. Introduction

1.1. Shading devices

Building around the world required a large amount of energy for cooling, heating and lighting. Well-building design requires integration of many factors, such as orientation shading devices and building form, to compromise energy consumption through a building. In additions windows, glazed façades and openings have an important role in building energy consumption whether for heating, cooling or lighting. Highly glazed façades and large windows have been increasingly used in new buildings, allowing the access to daylight, solar gain and external view. Therefore, their impact on cooling, heating and lighting demand in the building is significantly needed to be considered in building design. Proper shading design can contribute well to indoor illumination from daylight, improve thermal comfort, control solar heat gains and reduce glare at the same time as keep the view out.

Datta [1] studied the effect of using shading devices on thermal performances of buildings in Italy. The study used TRNSYS computer simulation to study many variables related to horizontal shading devices in different cities in Italy. It found that well shading devices could help save energy and improve thermal performance of buildings. Palmero-Marrero and Oliveira [2] studied the effect of using shading devices on thermal performance in many cities, around the world, with different latitude and climatic conditions using TRNSYS. The study showed that shading devices have a great impact on saving energy and improving thermal performance in offices in different climatic conditions. Bessoudo and other [3] and Tzempelikos and other [4, 5] studied how shadings devices effect the thermal comfort in offices with glazed façades in cold climate in Montreal-Canada. They studied interior glazing and shading devices temperature, operative temperature and radiant temperature under different variables such as: Venetian blind, roller shade, and blind rotated angles. The study showed that shading devices could improve the thermal condition in cold and sunny conditions. They also developed a transient building thermal model. However, many

researchers have studied the effect of using of shading devices on thermal comfort, energy consumptions and daylight performance of buildings [6-13].

The literature review has shown the need for studying the effect of shading devices on real building in regions with hot summer and cold winter like Jordan. The current research will investigate the effect of using of shading devices in south-west façade of offices in Jordan University of Science and Technology (JUST) on thermal conditions and air temperature.

1.2. Case Study

Jordan is classified as subtropical area, which is characterized by hot and dry summer and cold winter. Clear sky conditions dominate around the year with medium to overcast sky and moderate rainfall in winter. The average direct sun component is generally about eight hours a day. The major characteristic of Jordan's climate is the contrast between a relatively rainy season from November to April and dry weather for the rest of the year. The country has a long summer with a peak in August while January is the coolest month.

Jordan University of Science and Technology (JUST) is in Irbid (latitude 31.9˚ North, longitude 35.9˚ East) around 80 km to the north of Amman. The campus was designed by the Japanese architect Kenzo Tange. Buildings were constructed using prefab concrete panels and blocks. Office are on second floors, while ground and first floors used for lectures halls and labs respectively. The plan of the office levels, like wing A3 level 3, is double loaded corridor with offices at each side. The number of offices in south-west facade is 11 offices; each office is 3.5m width, 4.25m deep and 2.75m high as seen in figure (1). The façade height comprised three sections; 0.80m sills, 1m windows and 0.5m upper windows figure (2).

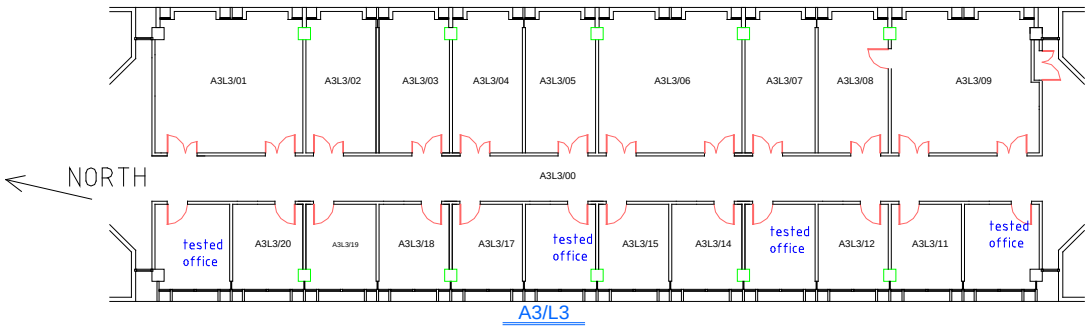

Figure 1 plan of offices level 3 wing A3 at JUST

Buildings oriented toward south-west with large windows area such office spaces in wing A3 at JUST suffer from uncontrolled solar gain throughout the year. In such orientation windows required especial considerations to control solar gain in summer and winter. The offices in wing A3-L3 at JUST expose to direct sunrays from noontime to sunset. The total hours of exposing is more than seven hours in summer raising the air temperature to intolerable level. Sunny area starts increasing gradually inside the offices from noontime to cover most of the office area thereafter as seen in figure (3).

1.3. Current situation

Author noticed that offices oriented to south-west such as offices in wing A3 experiencing high indoor temperature during sunny days at the same time lack of sufficient daylight due to occupants reactions.

Figure 2 office façade (left), single office' windows details (right)

Occupants' reactions to discomfort almost have negative impact from energy view. Users spontaneously used curtains to overcome the problems shaped by large glazing area, especially the increasing sunny area, to block the direct sunrays and to avoid glare figure (3). So, the daylight level inside the offices decreased that needed auxiliary artificial light to keep the light level up to the needed task level. Curtains are 40cm from the window because of architectural design details. Therefore, they could block the direct sunrays, but the heat gain inside the offices will remain with same rate. It will heat up the space between the curtains and the windows which automatically raise the temperature inside the whole office by direct gain, re-radiation and convection currents. F igure out a solution that overcoming such problems needs blocking the direct sunrays from outside before reaching the windows by shading device.

Figure 3 sunny area in the office without shading devices (left) the office with vertical fins (right)

2. Experiment set up

Three fixed temporary shading devices; egg-crate, vertical fins and diagonal fins, were installed in three offices. Thereafter, experimental measurements were conducted in three offices with different common shading devices, in addition to a base case office, an office without shading devices being installed. The offices are identical in all parameters like; area, geometry, orientation, windows design, glazing area and transmittance ratios, function, opening and surfaces material. The exposed façade of the tested offices is oriented to 12 south of the west.
Experimental measurements were taken in offices spaces on fully sunny days. Accordingly, measurements from tested offices fitted with the selected shading devices were compared to the measurement of the base case.

The dimensions and materials of these temporary devices were preliminary designed to keep the original building without major change to ease installing the devices in order to set the requirements of the permanent design. This is a part of long-term program aims at improving

environmental and climatic conditions of JUST buildings to improve thermal conditions, visual environment and reduce energy consumptions. The next step of the research will be to study natural lighting environment and thermal comfort to compromise between thermal comfort, visual environment and energy saving. And so, the current research will be an initial stage for the long-term program to design the permanent shades to compromise between building changes and energy saving. Indoor air temperatures were measured using pre-calibrated thermometer. Data were collected every five minutes using EXTECH thermometer.

Vertical slats of 10cm width were arranged with a small gap of 5cm between the slats to admit some light, provide a view and allow for ventilation. They were not adjustable or designed to be angled. Diagonal fins consist of vertical fins of 30cm width rotated at 45˚ with a gap of 17cm between the slats. Egg crate consists of verticals slats and horizontal louvers of 10cm width. Vertical slats were arranged with a gap of 15cm between the slats and horizontal parts with 7.5cm between the louvers. It could admit light, provide a view to outside and allow for ventilation.

3. Results

Figure 4 (left) shows the results of air temperature in office with vertical fins compared to the base case. Clearly, using vertical fins help reduce the inner temperature compared to non shaded office. It helped reduce air temperature up 17% in the afternoon with an average of 9%. In the morning the air temperature almost closed in both offices, while the difference start to increase gradually as the sunrays start reaching the windows as seen in figure (3). Generally verticals fins reduce the air temperature in the period from 1pm to 4pm by an average of 4C˚ with maximum reduction by 7C˚. On the other hand, diagonal fins as seen in figure 4 (right) reduced the air temperature by up to 21% compare to the base case with an average of 13%. The difference in the morning is neglected while it s tarts to increase dramatically from 12pm to 4pm. The maximum decrease occurred after 3pm by 8.5C˚. Figure 5 (left) shows how the egg–crate shading improves the thermal performance of the office. It reduced the air temperature by an average of 12% in the period from 12pm to 4pm compare to the base case. Between 3pm and 4pm it reduced the air temperature by 8C˚.

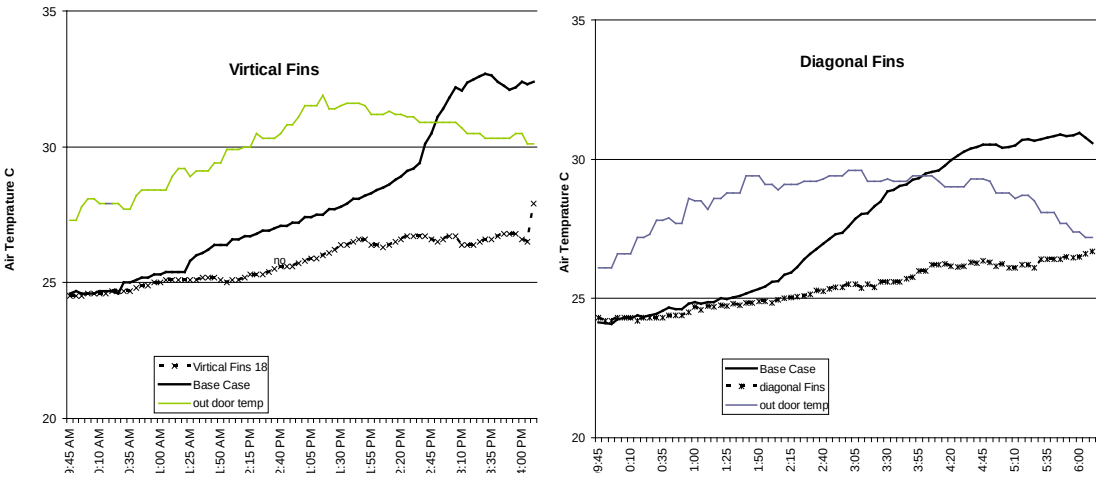

Figure 4 air temperature in office with vertical fins compared to the base case (left) air temperature in office with diagonal fins compared to base case.

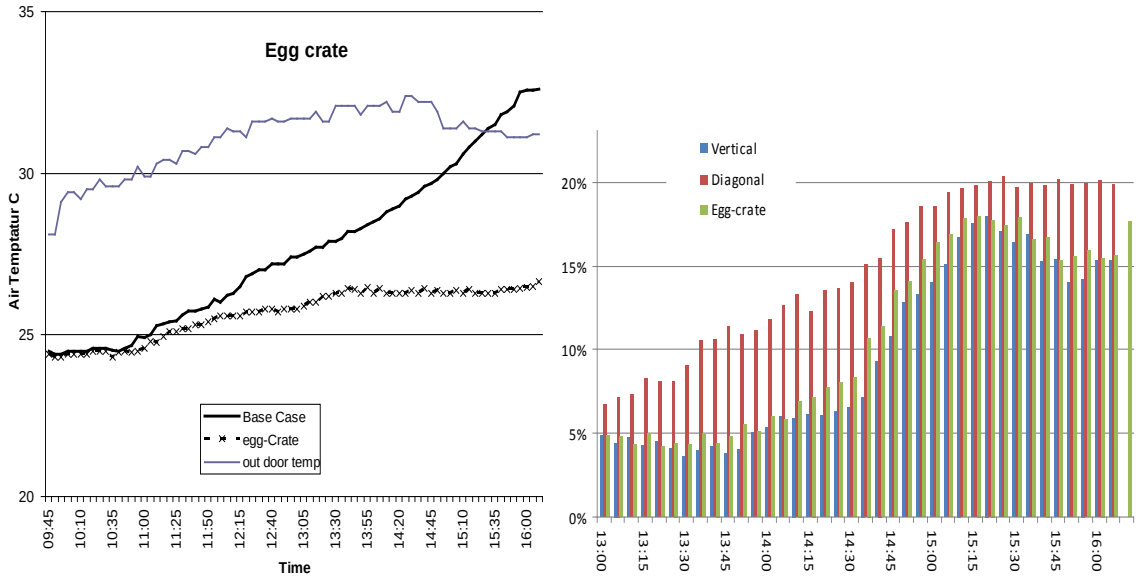

Figure 5 air temperature in office with egg-crate compared to base case and outdoor temperature (left) shows the percentage of reduction in air temperature as a result of using shading (right)

Figure 5 (right) shows the percentage of reduction in air temperature as a result of using shading compared to the base case office. It clearly can be inferred the diagonal fins performed better than verticals and egg-crate in the period from 1pm to 3pm during the period of measurement in September and October.

Graphically analysis of applying shading and shade angles on s undial diagrams show how each type of shading devices perform around the year. Table 1 shows how the shading devices will perform all the time according to solar angles, altitude and azimuth, during the time of the experiments. Diagonal fins will block all sun rays while vertical fins will block the sunrays in the period 12pm-1pm and 2pm to 4pm and allow the sunrays to enter the offices from 1pm to 2pm. Egg-crate shading will allow sunrays to enter the offices between 1:30pm to 3pm and block before and after that.

Studying the performance of shading devices around the year shows that verticals fins partially shade inner spaces in the period from October to February and allow sun to reach inner spaces after 2pm. In contrast, it allows the sunrays to reach the inner spaces in the hot period of the year, March to September, and in the hot time of the day from 1:30pm to 3:30 pm. Diagonal fins fully shade inner spaces in the period October to March and partially in the period April to September. It will block the sunrays only before 1 pm in the period from May to July when the shading are crucially needed. Egg-crate will perform well in hot period and allow for sun rays to enter inner spaces in such orientation in cold period. The analysis of the results show, that well shading design could help improve the thermal performance of the offices oriented to south-west.

Table 1 Installed shading devices and shading angles with sundial diagrams

	Installed shading devices	Shade angles	Sundial Diagrams
			Diagonal Fins			Egg-crate			
4. Discussion and Conclusions

This paper summarizes the experimental results of thermal environment and air temperature in highly glazed offices with shading devices. In general, results indicate a major influence of shading on s olar gains and thermal performance of offices. All shading devices helped improve the thermal environment in the offices in time of the experiments in September and October. It is clear that until 1pm all shading devices reduced the air temperature approximately with same rate. On the contrary, after 1pm the diagonal shading devices performed better as it helped block all the sunrays all the time. On the other side, vertical fins and egg-crate shading devices allowed some part of sun shine to enter the offices in the period 1pm-3pm.

Designing of shading devices requires taking into consideration around the year measurements in both hot and cold periods. Therefore, egg-crate shading devices could perform well around the year if the horizontal part extends to the outside by the half of the

current width. It will block the sunrays in hot period and allow it to enter in cold period. Diagonal fins will completely block the sun rays in the clod period when the sun is crucially required it cloud perform well in intermediate period such as in September. Moreover, diagonal fins block the view to outside while egg-crate will allow for kind of connections to outside. Modified egg-crate could go well with current situation, fewer modifications, as vertical slats of small width can be easily installed on the window sills and horizontal part can be fixed on vertical slats. Further studies are required to study the effect of shading devices on daylight, visual environment and view out.

Abstract: The performances of light shelf systems are evaluated in the context of various interior configurations typical of multistory office buildings by using CBDM (climate-based daylight modeling). A physical scale model of one of the light shelf systems is tested in the first phase under real sky conditions in Raleigh, North Carolina, USA. The data collected from the experiments are used to validate the simulations by a computer-based dynamic daylighting research tool - DAYSIM which is based on the concept of CBDM (Radiance + Perez Sky Luminance Model + Daylight Coefficient). In the second phase, additional simulations utilizing the validated tool are conducted to study the effects of system geometries and interior space characteristics. Specifically, the following parameters are identified and assessed: light shelf length, ceiling height, and interior configurations typical of North American office building settings. The findings have displayed the impact of various system parameters and interior design approaches on daylighting performances. The limitations of the study include possible errors in both computational simulations and the physical testing, and errors caused by the process of generating the sky models from solar radiation data for DAYSIM.

Keywords: *Lightshelf, Ceiling Height, Interior Configuration, CBDM, Simulation*

1. Introduction

Although electric lighting has now assumed the role of being the primary means of illumination for many buildings, people generally express a strong preference for natural light in their work environment. There also has been an interest in daylighting as a means of reducing nonrenewable energy use. In multistory office building, one of the strategies for achieving the comfortable interior environment is to redirect daylight from primary surfaces, such as a light shelf, to secondary room surfaces (ceiling and walls), which in turn will illuminate horizontal work surfaces. A light shelf is a small area of horizontal reflecting surface mounted just below the daylight glazing in the façade. Typically, the designer of the building will have a high degree of control over the placement and optical properties of that reflective surface, which makes it a much better candidate light reflecting source than the ground plane. Furthermore, this reflecting surface can be placed above eyelevel for the building occupants, thereby avoiding the potentially severe glare effects of intense upward light in the eyes of occupants near the window. There are two functions to a light shelf system: To reflect light deeper into the building, thereby providing more light in the interior, and to block excessive light from entering spaces close to the perimeter wall.

There have been a limited number of studies on light shelves. The early studies focused on flat simple light shelves. Simple light shelf is referred to the system with interior shelf length of about 4-6 feet. In a study presented by Selkowitz, et al. [1], it was concluded that "in general, simple light shelf designs provide improvements in light penetration." This study did not assess the effects of changing the length of the shelf. Burt Hill Kosar Tittelmann Associates also presented a study on simple light shelves, showing that light shelves do improve the quality and quantity of light in perimeter zones. In this study, a fixed length exterior light shelf was investigated [2]. Advanced light shelf systems were also developed and tested. Some of these studies focused on ceiling configuration. Fardeheb found that exterior shelves in conjunction with a sloped ceiling were most effective among nine different

light shelf designs that they studied [3]. Another category of advanced light shelf research dealt with the shape and movement of the shelf. Place and Howard developed and assessed two advanced daylighting systems, one involving a static curved-mirror and the other involving a tracking flat-mirror system [4]. Based on the behaviors of the two systems in different seasons under different sun angles, design guidelines were developed. An external curved light deflector was designed and tested by Close as one of the three features of the daylighting system designed for a high-rise building in Hong Kong [5]. The performance of the system was simulated by computer and then verified against physical scale models. Finally, some researchers were interested in the effects of varying the reflectance of light shelf surfaces. Claros and Soler investigated the performances of two light shelves with different types of reflecting materials [6].

This list of studies generally delineates a picture of what has been covered by the efforts of previous researchers. It also introduces the three topics to be explored in this study:

- ***Length of light shelves*** - Throughout the literature there has been little effort to systematically assess the impact of light shelf geometries, especially, of longer light shelves (more than 6 feet).
- ***Ceiling height*** - Ceiling height is a crucial factor in daylighting design. This is also the area where "battles" tend to occur between daylighting designers and other members of the design team, such as the structural and mechanical engineers. It is thus important to quantify the importance of ceiling height for delivering light into a space.
- ***Interior configuration*** - Very few researchers have considered the impacts of interior partition designs (layout & material) on lighting environment. Almost all the experiments were performed in an open space. Modern office buildings take on a variety of interior layouts, which can drastically affect lighting performances.

2. Methodology

The traditional daylighting research approach – the Daylight Factor method, only addresses overcast conditions and leaves out important design factors, such as building orientation. Understanding daylight from a climate-based point of view would therefore be more practical to assess daylighting systems in areas with a highly luminous climate, in which case various types of sky conditions (e.g. clear sky or intermediate sky) are all taken into considerations. However, climate-based experimental testing can be time consuming, since monitoring design options in a full year is normally not feasible for most design projects. As an alternative, a dynamic Radiance-based simulation tool - DAYSIM can be adopted for carrying out Climate-Based Daylight Modeling (CBDM) using meteorological dataset [7, 8, & 9]. By the comparisons with experimental measurements, DAYSIM has been proven to be accurate for performing annual daylight predictions for regular daylit spaces [8]. However, it would be prudent to validate the tool before it is used for assessing any advanced daylighting systems, such as light shelves in conjunction with various interior design approaches in this study.

2.1. Validation of DAYSIM simulations by experimental measurements

A physical scale model (scale: 1:6) is established to represent a 30' x 40' (9.14M x 12.19M) portion of a typical office floor (Figure 1). A daylighting system incorporating a 6-ft (1.83 M) lightshelf and a 3-ft (0.92 M) overhang is integrated on the south elevation (Figure 2). The ceiling height is 11' (3.35M) and the top of view glazing is at 7'-2" (2.18M) above the finish floor. The surface reflectances are: ceiling and walls: 90%; floor: 20%; lightshelf top and bottom surfaces: 90%; overhang top and bottom surfaces: 15%; exterior ground reflectance is assumed at 20%; glazing transmittance: 70%. The interior space is divided into five equal

daylit zones. Annual daylight levels in each zone are predicted by both physical experiments and DAYSIM.

Fig. 1. Physical scale model being tested on a heliodon.

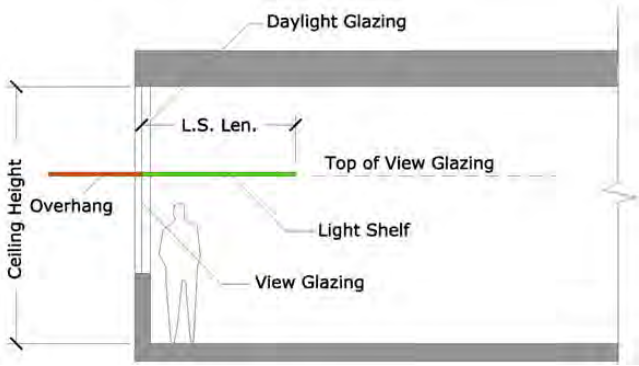

Fig. 2. The daylighting system with a light shelf and an overhang

2.1.1. Physical experiments

To simplify the experimental procedures, the model is only tested under a diffuse sky – a blue sky in this case (clear sky without the sun component), because a diffuse sky is a much more reliable light source than the sun. Sunlight is highly variable depending on seasons, solar angles and weather conditions. A Licor photocell sensor (Model 210L) is installed at the center of each daylit zone (Sensor Ez1 through Ez5). An exterior sensor (Ev) is mounted on a vertical plane facing the same direction as does the window. To simulate a blue sky condition on a clear day, the system designed for facing south is rotated so that it faces only diffuse sky (Figure 3). This approach allows for the system to be tested only under diffuse blue sky by eliminating the sun component. A Coefficient of Utilization can then be developed for each zone to establish the relationship between the sky and interior illuminances. Using Zone 1 as an example, the CU is calculated by the following formulas: CU1 = Ez1 / Ev. Note that a CU relates the interior illuminance to exterior vertical illuminance while a Daylight Factor relates the interior illuminance to exterior horizontal illuminance. Exterior horizontal illuminance only depends on solar altitude, which makes the factor of building orientation out of the question, whereas exterior vertical illuminance depends on both solar altitude and azimuth. Therefore, vertical illuminance is a better indicator of lighting conditions outside especially for assessing sidelighting systems. In addition, the exterior vertical illuminance (Ev), which is taken at the window surface, provides a direct measurement of how much light actually enters the room.

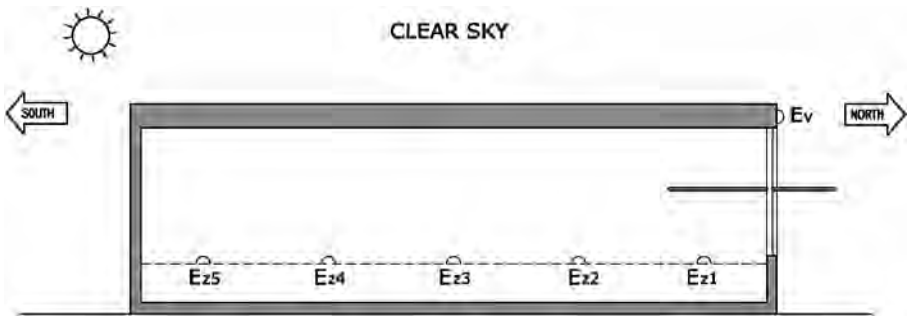

Fig. 3. Model being tested under blue sky. (The lightshelf system is designed for south-facing. However, it is rotated in the experiment to face away from the sun, towards diffuse sky light only)

Hourly daylight levels in Lux in all zones can be developed in a full year by multiplying the CUs by the annual exterior illuminance data (Ev), which were made available by the Daylighting Research Lab at NC State University. The data set, including hourly Ev values in a full year, was collected in a two-year period (1991 & 1992) in Raleigh, North Carolina [10]. Table 1 shows this process for the 1st day (From 7:00am to 5:00pm) of the year.

Table 1: Using CUs to predict hourly illuminances (Lux) for the 1st day of the year by multiplying CUs by the south-facing vertical sky illuminances (Ev in Lux) from the annual sky illuminance data set.

		CU	**0.0938**	**0.06647**	**0.05194**	**0.04342**	**0.04227**
Day	Time	**Ev**	Ez1	Ez2	Ez3	Ez4	Ez5
1	700	**66**	6	4	3	3	3
1	800	**3,074**	288	204	160	134	130
1	900	**7,804**	732	519	405	339	330
1	1000	**13,424**	1,259	892	697	583	567
1	1100	**12,617**	1,183	839	655	548	533
1	1200	**28,730**	2,695	1,910	1,492	1,248	1,214
1	1300	**29,434**	2,761	1,956	1,529	1,278	1,244
1	1400	**64,603**	6,060	4,294	3,355	2,805	2,731
1	1500	**52,715**	4,945	3,504	2,738	2,289	2,228
1	1600	**11,934**	1,119	793	620	518	504
1	1700	**528**	50	35	27	23	22

2.1.2. DAYSIM simulations

A virtual model of the building is built in a CAD tool, which coincided with the physical model. Similarly, five study points are placed along the center line of the daylit zones. The weather file of the site (Raleigh-Durham International Airport) is used as the climate data for the simulation. With a proper ambient parameter setting, the annual illuminance values are calculated by DAYSIM 3.0 and can be presented in the same format as in Table 1.

2.1.3. Comparison

Daylight Autonomy, the numbers of hours in which interior illuminances are above minimum light level for performing the designed tasks (500 Lux in this case), is used as the indicator to assess the two methods (Figure 4).

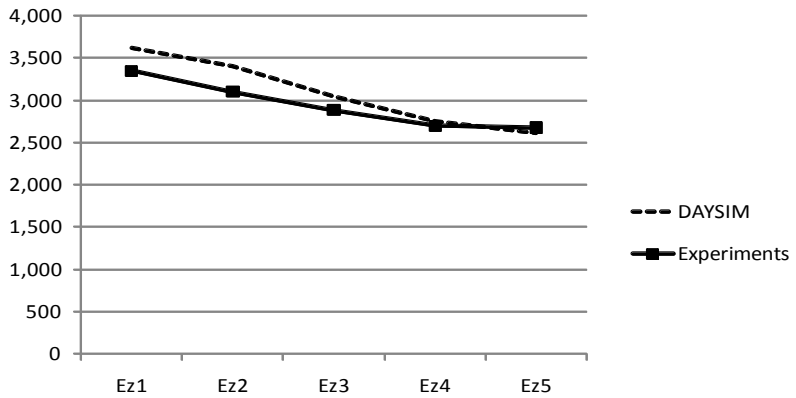

Fig. 4. The numbers of hours in which interior illuminances are above 500Lux predicted by DAYSIM and the experimental methods

To estimate how close the results are between DAYSIM and the experimental methods, the differences in percentage between the two methods are shown in Table 2. DAYSIM generates reasonably close predictions comparing with the experiments. The differences are below 9% in all five zones. For internal zones (Ez3 through Ez5) where daylight levels are lower, the results are even closer (5% and below).

Table 2: Daylight Autonomy values in each daylit zone and percentage of differences when comparing results from the experimental method with those from DAYSIM.

	Ez1	Ez2	Ez3	Ez4	Ez5
DAYSIM	3,615	3,405	3,044	2,747	2,609
Experiment	3,348	3,101	2,885	2,699	2,678
Difference	-7.39%	-8.93%	-5.22%	-1.75%	2.64%

2.2. Assessments of daylighting systems and interior configurations

The validation study reported in section 2.1 demonstrates the effectiveness of the computer-based simulation tool – DAYSIM for predicting climate-based performances of the light shelf system. The tool is then used for the following assessments of the parameters in various daylighting systems and interior configurations.

2.2.1. Length of light shelves

The light shelf lengths of 2', 4', 6', 8' 10', and 12' are simulated in DAYSIM respectively based on the model in Figure 3. Ceiling height, light shelf mounting height, overhang length, and all interior surface reflectances are kept constant. The interior space is open layout.

2.2.2. Ceiling height

Again, based on the model in Figure 3, ceiling heights of 9', 10', 11', and 12' are assessed assuming other systems parameters remain constant (Light shelf length is 6' long in this case).

2.2.3. Interior configuration

Four interior configurations typical of multistory office buildings are identified and compared by using the same method as in the above comparison studies (Figure 5). The same five daylit zones are incorporated in these plans, where there are always two measuring points in the private offices and three in the open area. These configurations are:

Configuration 0: Open office plan where there are no private offices. A section of this design is illustrated in Figure 3.

Configuration 1A: Private offices are located at the perimeter of the floor plate. The partition parallel to the window wall consists of a lower portion (7' high) and an upper portion. The lower portion is an opaque wall; the upper portion is clear glazing (transmittance: 90%). The partitions perpendicular to the window wall are opaque (Figure 5).

Configuration 1B: Same as 1A except that the lower portion of the partition parallel to the window wall is constructed with translucent glazing (transmittance: 50%) (Figure 5).

Configuration 2: Private offices are located at the core area of the floor plate. The lower portion of the partition parallel to the window wall is made of translucent glazing (transmittance: 50%); the upper portion is clear glazing (transmittance: 90%). The partitions perpendicular to the window wall are opaque (Figure 5).

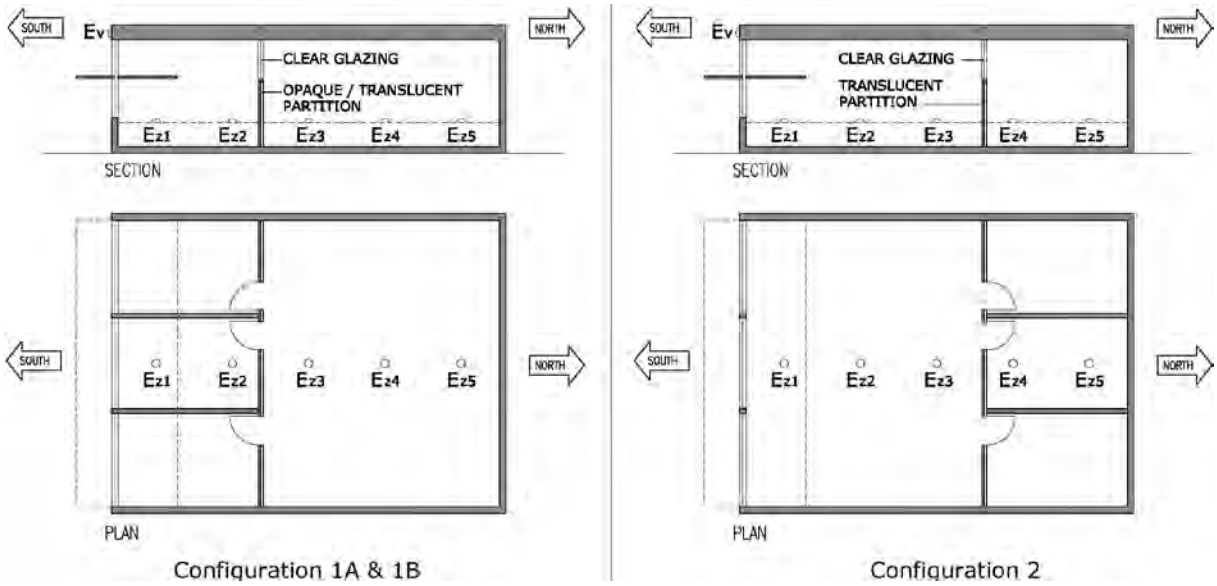

Fig. 5. Interior configuration 1A, 1B and 2.

3. Results & Discussions

Hourly illuminance data in each zone are generated for the above comparison studies. Daylight Autonomy data are then developed based on these values as performance indicators.

3.1. Length of light shelves

The performances of light shelves with various lengths (2' through 12' with 2' increment) are illustrated in Figure 6. For internal zones (Ez3 through Ez5), the 4-ft light shelf performs slightly better than the 6-ft version. However, the longer light shelf outperforms the shorter one for the purpose of blocking the direct sunbeam penetration through the daylight glazing (Figure 7). In general the 6-ft light shelf appears to be the optimal solution among all the lengths tested and will be used for later phases of the study.

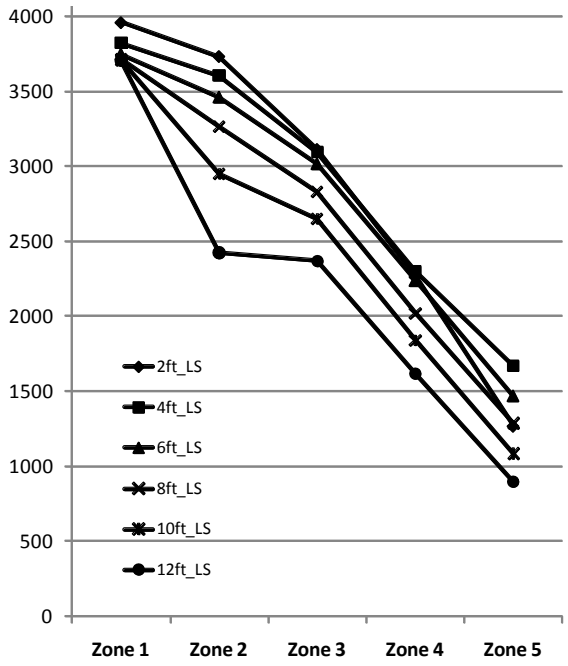

Fig.6. The numbers of hours in which interior illuminances are above 500Lux for light shelves with various lengths

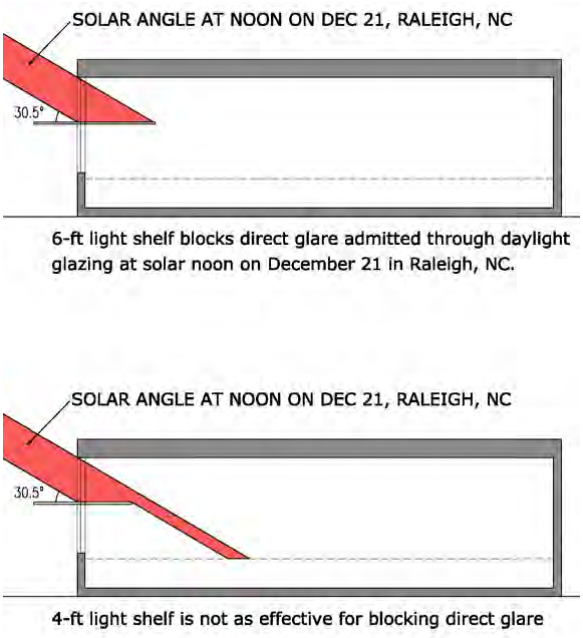

Fig.7. Direct glare admitted through daylight glazing with 4-ft and 6-ft light shelves. 6-ft version performs better for blocking direct glare

3.2. Ceiling height

The impact of ceiling height on light quantity is fairly significant as illustrated in Figure 8. In conjunction with the light shelves, higher ceilings are obviously desirable for the purpose of delivering daylight deeper in the space.

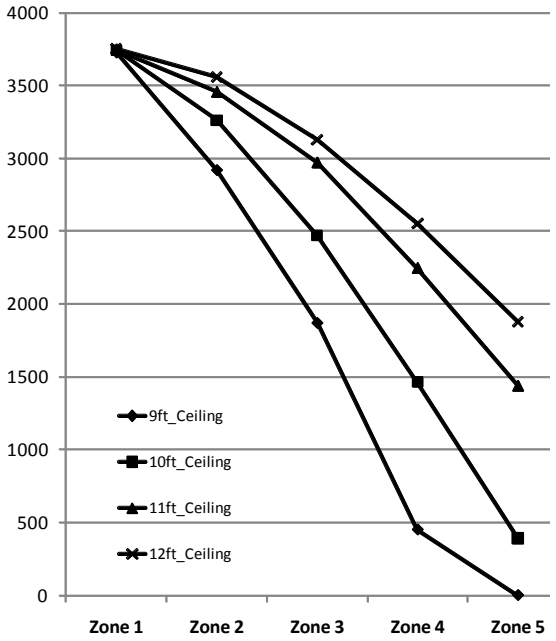

Fig.8. The numbers of hours in which interior illuminances are above 500Lux for interior space with different ceiling heights

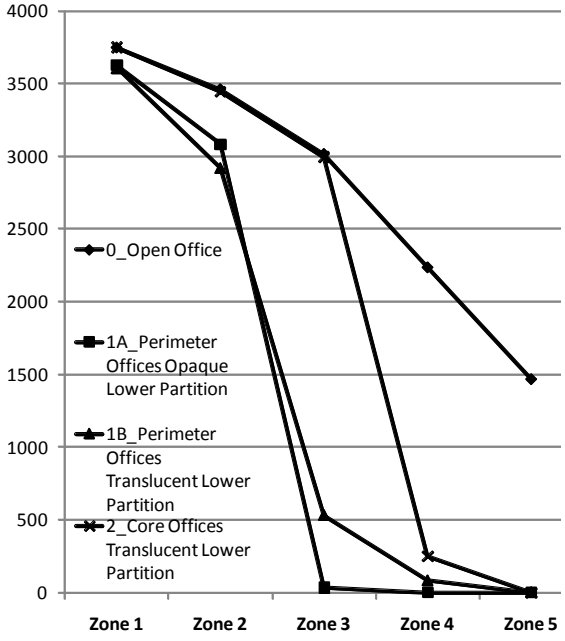

Fig.9. The numbers of hours in which interior illuminances are above 500Lux for different interior configurations

3.3. Interior configuration

As shown in Figure 9, among the four interior configurations proposed in section 2.2.3, open office layout (Configuration 0) certainly gives the best performances in that it maintains higher light levels across the space and produces a fairly uniform distribution without any abrupt change of light levels. Introducing private enclosed offices at the perimeter of the floor plate (Configuration 1A) dramatically lowers the daylight quantity in the inner open office. Switching the material from opaque to translucent for the lower portion of the partition that divides the perimeter offices and the open office improves the condition to some extent (Configuration 1B). However, if private offices have to be provided, relocating them to the core of the space and leaving the open office at the perimeter greatly (Configuration 2) improve the overall lighting conditions, especially at the open area which is occupied by more users. In addition, comparing the results between Configuration 0 and 1A, by adding partitions perpendicular to the window wall to define the private offices in 1A, the light levels in the perimeter zones (Zone 1 and 2) are lowered as well as in the inner open office.

4. Conclusions

Although light shelves generally help project daylight deeper in the space under certain solar angles, it is a misunderstanding that the longer a light shelf is, the better it performs. It is the proportion of the daylighting glazing height and light shelf length that determines the performance of the system. Therefore, the length needs to be optimized based on other geometries of the system, such as ceiling height and daylight glazing height, and the system needs to be evaluated in terms of both light quantity and quality. For the particular daylight system assessed in this study, the 6-ft light shelf is proven to be the optimal solution.

The benefits of raising the ceiling are significant. Even though there are many factors motivating towards lowering the ceiling, including construction cost, fire rating, accommodating structure, duct work, etc., a carefully designed and highly integrated building system needs to be in place to assure adequate ceiling height for daylighting.

Adding partitions that are either parallel or perpendicular to the south-facing window wall to divide open space into small offices creates a fairly big drop in the illuminance deeper inside the space. If private offices have to be incorporated in the floor plate due to programmatic requirements, it is recommended that the small offers be located at the core of the building. Comparing with opaque partitions, translucent partitions give superior illuminance levels deep inside the building and they also produce superior light quality in the form of less extreme luminance ratios in both interior and perimeter spaces. It is highly desirable to use clear glazing above the level required for visual privacy (e.g., from the top of the door up to the ceiling). It is also desirable to minimize the number and width of mullion elements, to allow as much light as possible through the partition.

Abstract: The objective of this paper is to present the computer simulation results that we have obtained with a new window design. This prototype is equipped with the elements necessary to capture and distribute natural daylight in an optimum way. The whole window system is able to be adapted to the weather conditions of most of the Iberian Peninsula. Its design contains elements to let the sunlight into the room, and elements to control it. The initial results of the daylight experimental analysis we have carried out so far, demonstrate the system´s overall efficiency, however, we continue to research about the light shelf´s optimal configuration in order to obtain the maximum and most flexible performance. There is demonstrated in this work that the Modular window with a top hollow of 40 cm, instead of 30 cm of the original one, improves the luminous conditions of the room. Once the preliminary analysis phase is concluded, the window will be installed in one of the two testing houses being constructed at Cáceres (Spain), so that real-scale conclusions can be obtained, and recommendations be set, aimed to improve the quality of the construction process, while maintaining the high standards of sustainability we pursue.

Keywords*: Windows, Daylighting, Solar Protection, Sustainability, Industrialization.*

1. Introduction

This paper summarizes the design process, and the final results, for the development of a Modular window, capable of effectively responding to the climatic conditions of the Iberian Peninsula. It is part of the INVISO research project (Industrialization of Sustainable Housing) under development at the ETSAM (Escuela Técnica Superior de Arquitectura de Madrid). It is being carried out by the Researching Group ABIO (Bioclimatic Architecture in a Sustainable Environment).

The design process started off with the definition of the objectives that the Modular window must achieve, which at the same time, determined it´s basic constitutive elements: a solar shading box, a light shelf for daylight projection into the inner parts of the room, direct light and solar radiation control elements, as well as phase change materials (PCM) for thermal lag profiting. With this basic component list, two 1:10 scale models were built and exposed to real external environmental conditions. Continuous light level measurements [1] were taken with these models, which, along with thermal balance calculations [2] and the simulations presented here, allowed us to correct of the original design until the current Optimized version. This Optimized Modular window consists of three vertically aligned apertures: the top one with a 0.40 m height and light shelf; the central one, with a 1.38 m height and low emissivity glazing; and the lower one with an 0.82 m height and an externally glazed Trombe wall with paraffin as PCM.

Partial prefabrication is intended to make the installation easier, and allow some flexibility in the aspect of the final result.

2. Design objectives

In order to reduce environmental impact associated with buildings envelope, external windows in medium latitude countries, as in the case of Spain, must keep a balance between

daylight entry and it´s implicated heat transfer [3,4]. The window must be industrializable, so its main elements will be pre-assembled in the factory and later brought to the building site. Materials employed will be light, safe, economic and, as far as possible, not aggressive with the environment.

The future objective of the present work is not only the prototype design, but it´s construction and installation in a housing building which will be used as a laboratory. Monitored data from the different thermal and daylighting parameters will be compared to those obtained in an identical building with conventional windows, so that real conditions results and conclusions can be obtained from them. In Cáceres (39º 28' N and 405 m.a.s.l) far from big water masses which would mild the value oscillations, temperature fluctuations per day and per year are very important. In a summer day up to a 15 ºC difference can be measured. Taking into account the annual behavior, external temperature differences can reach 25 ºC between a summer and a winter day. These marked fluctuations require different strategies of environmental conditioning. In summary, it can be said that in Cáceres, like in Madrid, cities of soft and large winters, there´s a need for a mechanical heating system during 73 % of the annual period, furthermore, the short and strong summers require cooling during the 27 % left. The dimensioning stage of the design process, has considered current regulations on daylight and ventilation minimal areas: the Modular Window has an area that accounts for the 22.30 % of the test room´s total floor area, which, by far, surpasses the value stated in the current regulation.

3. Components

The components that make this window an innovative product, Fig. 1, can be grouped in three zones: *Upper zone or clerestory.* It is 0.30 m high, its main function is to light the interior of the room by reflecting daylight on the shelf [5]. The light shelf is 0.9 m deep and it is covered on its upper side by a 90% reflectance mirror. The light shelf is partly inside the module (1/3 of its depth). The *Central zone, or window view.* It is 1.48 m high. Its main function is to allow observation and contact with the outside environment. It is also able to open and allow ventilation. And finally, the *Bottom zone,* 0.82 m high, and designed to integrate phase change materials in order to maximize thermal benefits. Besides, the Central zone and the Lower zone are surrounded by a frame which overhangs 0.6 m in order to reduce the direct sun radiation and also the diffuse sun radiation.

4. Experimental analysis of the Modular Window´s daylighting performance

In the previously undertaken experimental study, two 1:10 scale models were used. These were situated on an obstacle-free (no overshadowing) terrace in Madrid. One of the models was equipped with a simplified Modular window, consisting of its three basic parts: top light shelf, central shaded opening, and lower completely opaque box. The second model was equipped with a conventional window, without the light shelf, nor any shading device. This was used as the reference model. Continuous measurements were taken, for global horizontal illuminance using five photometric sensors Li-Cor 210SA, two scenarios were tested: the first one, allowing light only through the top opening (*clerestory* only), and the second one, allowing illumination through both the top, and central openings (*clerestory* and *view*). Los the results are summarized in the following statements:

- With the top section opened (clerestory), and the rest of the window shut (opaque), the sensor located furthermost from the window, registered higher illuminance values for the Modular window, during 75% of the time. Reaching a maximum difference value of 1.87 times in a Modular – Conventional comparison. Therefore, the light shelf on

the Modular window significantly contributed to a better illumination of the inner room area farther from the window.

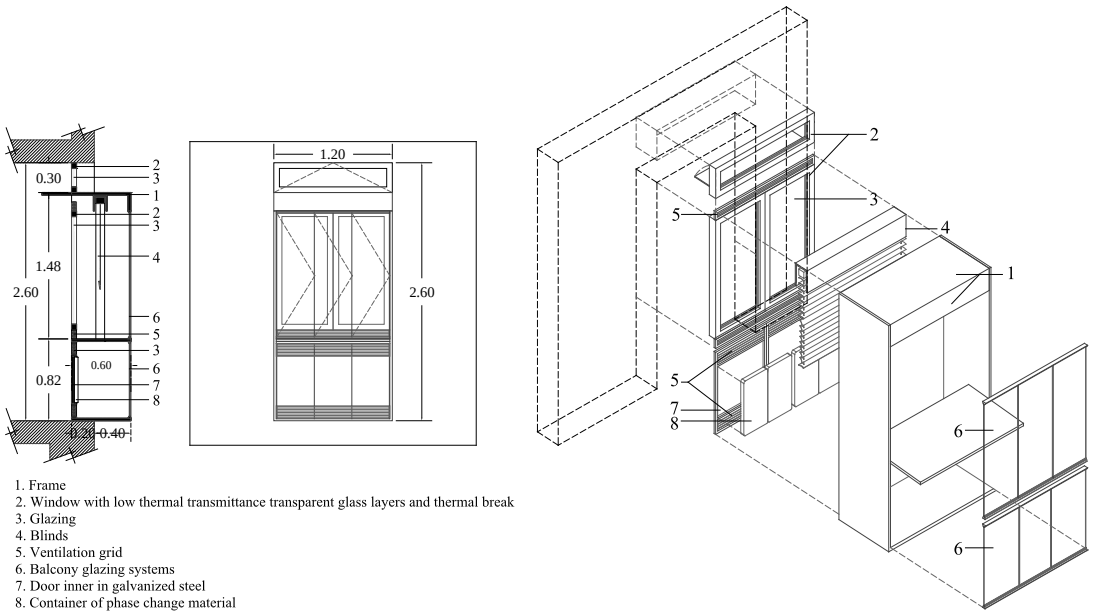

Fig. 1. The components of the original Modular Window

- When the two upper sections of the window (clerestory and view) were open on both models, the inner sensor (furthermost from window), registered higher illuminance levels for the Modular window during 21% of the time. The difference with the result mentioned on the previous statement is due to the effect of the solar shading box on the Modular window.
- The Modular Window improved the lighting conditions in the area closest to the window because the solar shading reduced the high illuminance values of that particular zone (especially during summer´s high solar angle period).
- The differences in illuminance levels obtained with the sensors located near and far from the window, were smaller in the Modular window equipped model. This demonstrates a more uniform daylight distribution in the room´s interior, and thus a significant glare reduction.

5. Clerestory modifications for the optimization of the Modular window

The study described so far, corresponds to the basic design of the Modular window, which had a 30 cm high top opening (clerestory). In order to improve the previously obtained results, we have carried out a brief comparative analysis with a variable clerestory dimension, ranging from 30, 35, 40, and 45 cm, Fig. 2. This range is derived from the limits established as acceptable: for starters a vertical dimension less than 30 cm is not constructively or functionally possible; on the other hand, the light shelf´s vertical position must correspond to a certain height that does not cast any direct reflexion at the occupant's eye level. Accordingly, with a 45 cm clerestory, the light shelf sits at a top height of 215 cm from the floor, which is enough to avoid any light reflexion related disturbances. This analysis has been developed with the use of the simulation tools Autodesk Ecotect, and LBNL Radiance[6]. In the first place, the annual periods with different thermal requirements have been defined, and consequently, their relationship with the window design. Based on the climatic records from the Spanish Weather for Energy Calculations (SWEC) [7] for the city of Madrid (very similar conditions to the ones found at Cáceres) and with the use of the Adaptive Comfort

Chart, developed by J. Neila, and his research group at ETSAM [8], we have defined a basic human comfort temperature range that goes from 18 ºC up to 26 ºC.

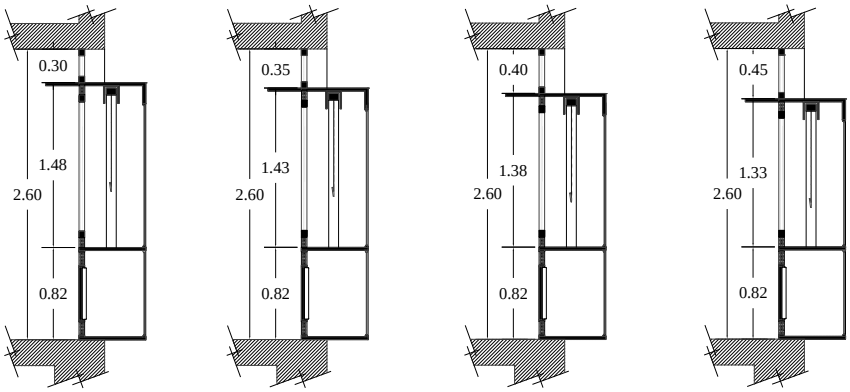

Fig. 2. Detail sections of the four dimensioning options analyzed for the clerestory(dimensions in m).

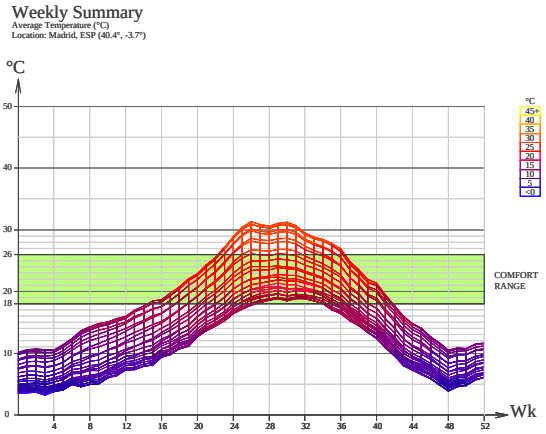

Fig. 3. Average temperature trend and human comfort range for the city of Madrid.

From here, the annual period with average temperature values under 18 ºC, has been established as “Heating Requiring Period”, and inversely, the period with average temperature values over 26 ºC, has been defined as ”Cooling Requiring Period”. Fig. 3 shows the average temperature trend throughout the year, along with the previously mentioned comfort range. Fig. 4 shows the monthly heating/cooling requirements as well as the solar radiation available so as to clearly observe each period and its thermal requirements. With the start-end dates established for each period, the clerestory´s dimension was analyzed so that it would allow the maximum collect of direct solar radiation during the underheated period, but at the same time, it would offer the maximum protection from possible heat gains during the overheated period.

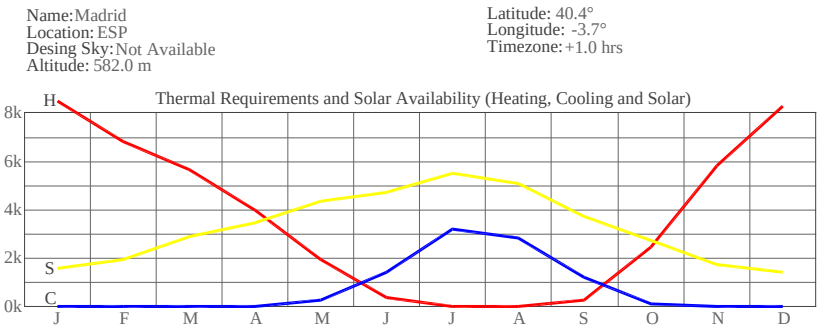

Fig. 4. Thermal requirement curves (heating: red ; cooling: blue) and solar availability (yellow) for the city of Madrid.

5.1. Shading coefficient analysis

In order to optimize the clerestory dimensions and ensure the light shelf´s máximum efficiency, the following premise has been set: a very small opening, offers a good protection (shading) during the overheated period, but limits the thermal contribution of solar direct radiation during the underheated period; in an opposite way, a very big opening maximizes thermal benefits during this cold period, but also contributes to interior space overheating during the warm period. To be able to objectively compare this factor, we have analyzed the Shading Coefficient value, which has been defined by the australian research group SquareOne[9] as: "*…an hourly averaged value that represents the shaded area of a vertical opening in relationship to the opening´s total area* ". The values of each dimensioning option have been studied considering a minimum inset of 18 cm (typical value of an unshaded window built with a conventional system). Fig.5 shows the respective performance in terms of the capture/protection balance described above. Amongst the multiple interpretations that can be made, the one we are more interested in is the one related to each of the openings behavior during the warm and cold periods. For instance, it is clear that all of the openings offer 100% shading during May, June, and July, however, the 45 cm opening considerably loses effectiveness during August and September, at a monthly ratio slightly superior to 15 %. In a similar way, the original 30 cm opening minimizes the heat gain profits during the cold period, with a minimal shading coefficient of 30 % year-round. For these particular reasons we have focused on the 35 cm and 40 cm openings, of which a very similar performance can be apreciated. Nonetheless, the 40 cm hole has an average shading coefficient 3% smaller than the 35cm hole one during the underheated period of the year (months with heating requirements). This results in a slightly better solar-thermal energy penetration and minor savings in heating-energy. Hence, the 40 cm hole has been selected to undertake the daylighting performance simulation analysis.

5.2 The use of Ecotect/Radiance for daylight simulation.

Having selected the optimized dimensions for the clerestory (40 cm), and keeping the original design dimensions (30 cm) as a reference, we carried out computational daylight simulations of interior luminous distribution. Furthermore, in order to visually determine the advantages of the proposed design, we have compared both Modular windows (original and optimized) with a conventional window. The simulation has been done using a software combination of Autodesk Ecotect + LBNL Radiance, and therefore all of the results obtained are subject to the accuracy and acknowledgement of these programs. All of the analysis have been undertaken in an hourly sequence, the luminous internal penetration and distribution results are presented for 13h (legal time), and accordingly there are three images for each date.

Fig. 6 shows the illuminance range for a date representative of the underheated period: December 21st (winter solstice). There are no remarkable differences between the three models (Conventional, Modular, and Optimized Modular), mainly due to the low angular rise of solar rays (23º at noon).

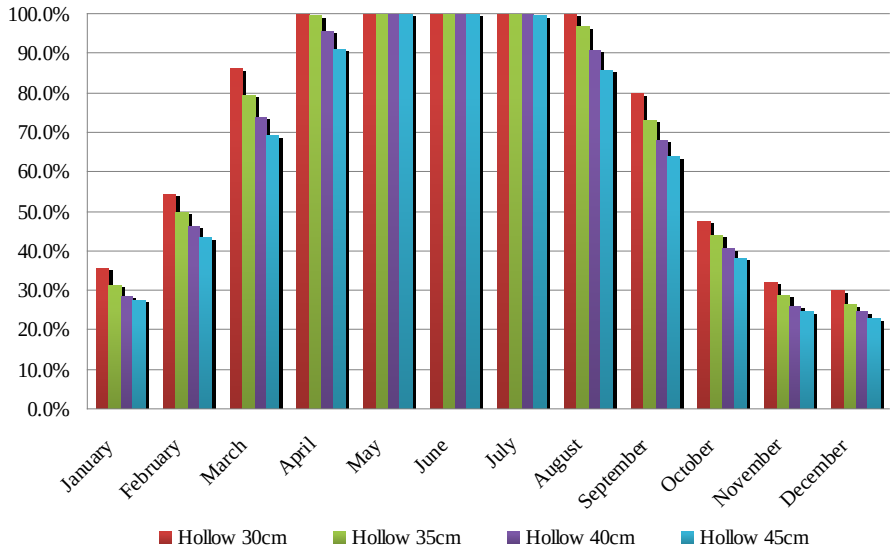

Fig. 5. Monthly shading coefficients comparison for the four dimensioning options.

The conventional window (on the left) shows the highest illuminance levels both during morning and evening hours, plus, it performs similarly to the Modular (center) and Optimized Modular (right) models during midday. In spite of this, a slightly better performance (more depth) can be observed for the Optimized Modular against the original design.

Fig. 7, shows the same analysis done for a date representative of the overheated period: June 22 (summer solstice). For this second series of analysis, a better performance on behalf of the Optimized Modular Window becomes quite evident: a deeper luminous penetration, along with a more uniform light distribution, and mainly a better shading protection against direct solar radiation during all day.

Finally, the last analysis series correspond to a “thermal neutrality” date: September 21 (fall equinox), Fig. 8. Clearly demonstrates the functioning of the three window models in a moderate solar height scenario. On top of a better overall illumination, the Optimized Modular Window offers the best shading against direct solar radiation and thus, it avoids as much as possible the potential glare effect.

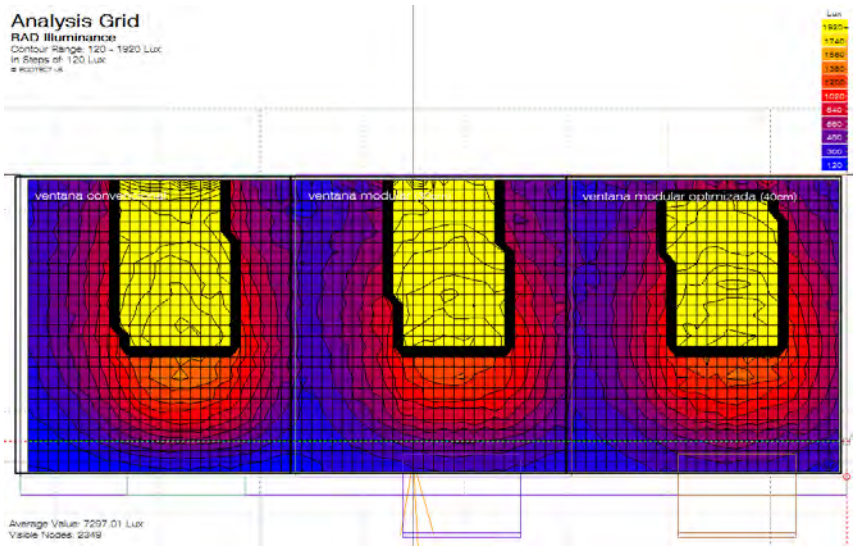

Fig. 6. Internal illuminance distribution (plan view of the room) for the three window: Conventional (left), Modular original (center), Modular optimized (right), during December 21st at 13 h.

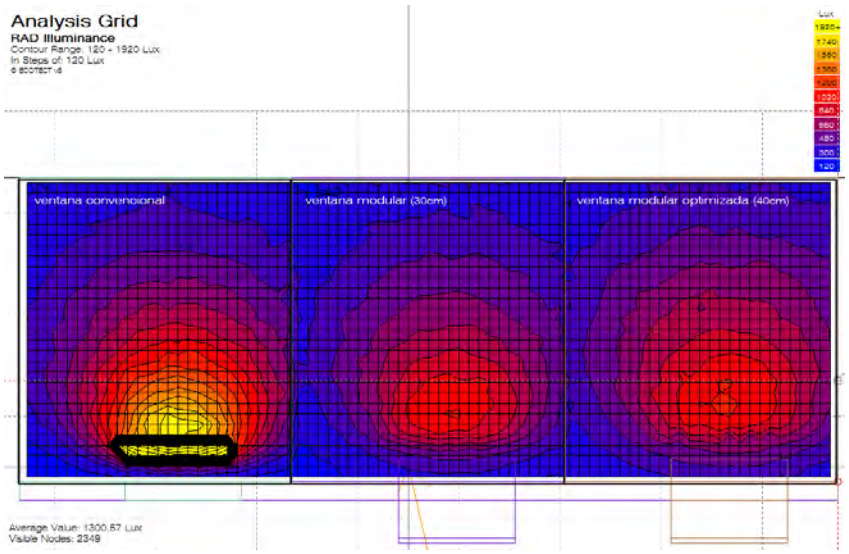

Fig. 7. Internal illuminance distribution (plan view of the room) for the three windows: Conventional (left), Modular original (center), Modular optimized (right), during June 22nd, at 13 h.

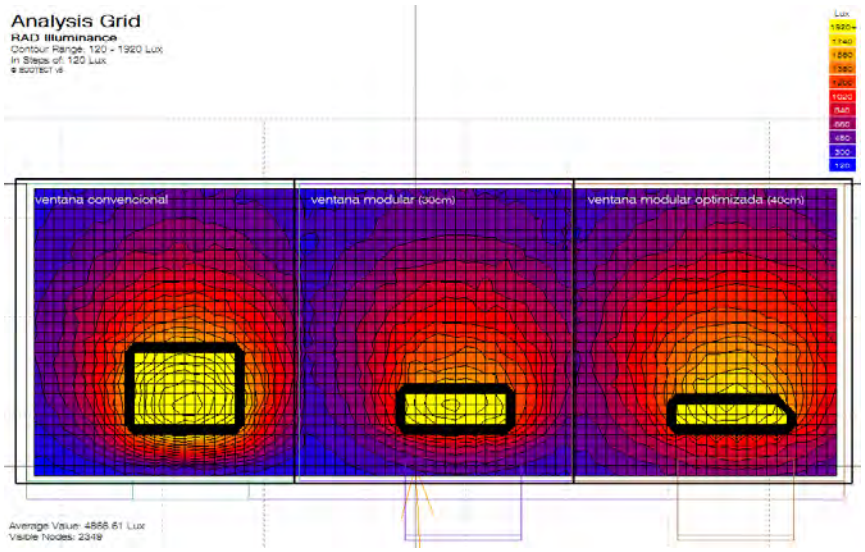

Fig. 8. Internal illuminance distribution (plan view of the room) for the three windows: Conventional (left), Modular original (center), Modular optimized (right), during September 21st at 13 h.

6. Conclusions

The Modular window consists of three parts: i) the top section, which is a 30 cm high opening equipped with a light shelf to improve the illumination of the inner room area, farthest from the window: ii) the central section, with a 148 cm high opening that not only pursues natural illumination and visual contact with the exterior surroundings, but also counts with the protective shading elements required by our climatic conditions; and iii) the lower section is an opaque, 82cm high element, that includes a trombe wall formed out of paraffin, which is an innovative building material that changes its physical state (solid-liquid) at specific predetermined temperatures, thus reducing and retarding the heat exchange through itself. In order to be able to test its luminous performance, a previous study was made with the use of scale models, for which the Modular window design was compared against a conventional unequipped window; this study demonstrated that the Modular window improved daylighting intensity in the inner part of the room, located farther from the window. However, since the

experimental study advanced very slowly, and was too dependent to the highly variable environmental conditions (i.e. cloud cover), we set to study the modification of the upper opening and its light shelf, with the use of photometric simulation tools: specifically the combination of analysis programs Autodesk Ecotect + LBNL Radiance. Four dimensioning possibilities for the upper opening were tested: the original 30 cm height, plus another three: 35, 40, and 45 cm. The four options provided a protection of 100% from solar direct radiation during the first three months of the overheated period (May, June, July), however the 45 cm opening considerably lost its protective effectiveness during the months of August and September, at a monthly rate slightly superior to 15 %. In a similar way, but during the underheated period, the 30 cm opening was too limiting on the required solar heat reception, as its shading coefficient didn't go under the 30 % value during any month of the year. A very similar behavior was appreciated with the 35 and 40 cm openings. Nonetheless, and although it was only by a small difference, the 40 cm opening performed 3 % better to the thermal requirements of the cold period. Taking into account the balance between solar heat profiting, and excess direct radiation shading, during the two annual periods with heating and cooling requirements, the analysis results are that the 40 cm opening performed better, hence, it has been proposed as the new dimension to use with the Optimized Modular window design. It has been demonstrated that the Optimized Modular window produces the best overall daylight conditions in the interior of the room, because it improves the illuminance levels on the deeper area (far from the window), contributes to a more uniform light distribution, and at the same time protects from overheating and potential glare effect.

Abstract: The relationship between architectural shape and daylight is very well known. The geometry of the building and its context influence quantitatively and qualitatively indoor natural illumination. But this architectural feature highly determines also the thermal environment and sometimes these two requirements are contradictory.

The results presented in the paper are part of a wider research that intends to evaluate the influence of the transitional spaces (indoors – outdoors) on the interior spaces environment. In order to do that, measurements of temperature and humidity have been carried out in housing buildings in some urban areas in Habana City, and at the same time, daylight conditions in those buildings and spaces have been simulated. The results of this computer simulation and its discussion are presented in the paper, focused on the performance of the geometry of these transitional spaces.

A representative sample of apartment buildings typologies that are being studying in different urban areas was selected in order to simulate daylight performance indoors, using the professional software "DIALux". The better daylight conditions are got in spaces related to wide streets. On the contrary, small yards are not enough, depending on its proportions.

Keywords: *Daylight, Simulation, Architectural design, Apartment buildings.*

1. Introduction

Taking advantage of the urban land is an essential condition to a sustainable built environment. That's why many developed countries are intending to increase density in cities. On the other hand, conservation of traditional urban centers is another important requirement in order to pass to the future generations the historical legacy of each society.

Related to that, the National Institute of Physical Planning in Cuba is promoting the integral rehabilitation of traditional cities, and a departing point for what should be the insertion of new housing buildings in the available plots. But how should these new housing building be? What architectonic references should be taken?.

During the 60's and the 70's, mostly new urbanizations were developed out of the traditional urban grid, using block type building by repetitive projects in open urban areas. When no repetitive projects were built in the consolidated urban zones during the 80's in Havana, the mistakes committed [1] showed the lack of knowledge about the traditional repertory of apartment buildings preexisting in these urban contexts. Finally, the last two decades has been characterized by disperse low density urbanizations that generate a disproportioned and unsustainable urban growing.

Then, projecting and constructing new apartment buildings in traditional urban centers is unavoidable as part of their integral rehabilitation process and for that, it is necessary to know the wide precedent repertory of buildings integrated to the context and conforming the city, to take them as references of the good practices to be recovered and the mistakes to be avoided.

Several researches have been carried out in the Faculty of Architecture of Havana during the last ten years, driven to characterize the repertory of existing apartment buildings in the traditional urban centers and to evaluate their performance according to the quality of the thermal and luminous indoor environment, taking into account besides, the inhabitant's perception.

The results of the evaluation of the volumetric and spatial solution of apartment buildings existing in three different urban contexts of Havana City according to their influence on indoor daylight are specifically presented in this paper.

2. Methodology

In order to evaluate the influence of the building volumetric - spatial design on the indoor daylight levels, real spaces were selected from the study sample composed by 279 apartment buildings located in three different context in Havana City (Centro Habana, El Vedado y Miramar) [2], to simulate interior daylight. The selected spaces are related to outdoors in different ways, according to the volumetric – spatial solution of the building and the urban context.

Indoor daylight depends on several variables. The geometry of the transitional space between indoors and outdoors is the one to be evaluated in this work, which determines the exposition angle to the sky and to direct daylight (e_0), and also to the light reflected by the exterior elements in the context (e_e).

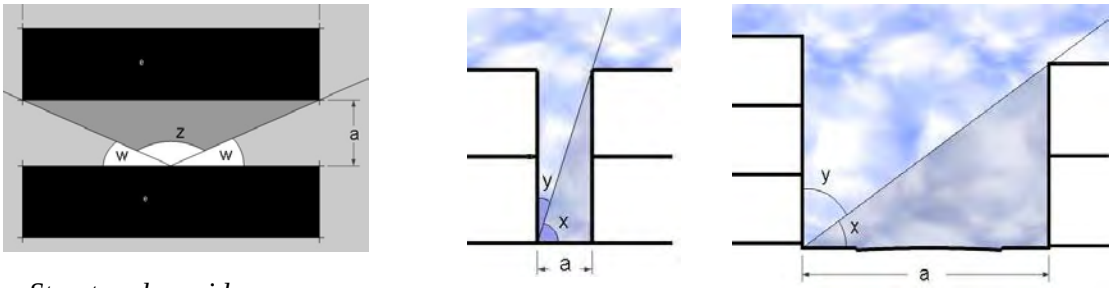
The interior daylight level is also influenced by the reflection coefficient of the surfaces (indoor or outdoor ones), the window area, its location, proportions and type of enclosure (the windows itself) and color, that determine the reduction coefficient for daylight incoming. In order to isolate the studied variable (the transitional space geometry), the rest of the variables were cancelled, assuming the same values or features in all the simulated cases.

The volumetric – spatial design solution was characterized by angles (horizontal and vertical) that determine the exterior geometry respect to the exposed façade of the indoor space to be evaluated. Each way of indoor – outdoor relationship was identified by the angles, the surface that they determine (closed or open) and one dimension, since having only one dimension and the proportions (angles), it is possible to get the characterization of the whole geometry
Indoor – outdoor relationship ways were classified in precedent researches [3]:

- To the streets: main streets (15m) and secondary ones (6m), considering longer dimensions as exceptional.
- To corridors, parallel or perpendicular to the street, belonging to the building itself, it means, inside its volume, as part of the architectural solution.
- To lateral, back and surrounding corridors: open spaces (without roof) annexed to the building as port of the urban context.
- To internal yard: open spaces (without roof) located to the interior of the plot, with width between 1.7m and 4.0m, and length between 4.0m and 26.0 m.
- To lateral yard: open spaces (without roof) located to the interior of the plot, but laterally, where one of the dimensions is considerably larger than the other, with width between 1.0m and 6.0m and length between 9.0m and 25.0m.
- To small yards ("patinejos" or wind boxes): open spaces (without roof), but closed in their four vertical surfaces, located to the interior of the plot, with smaller dimensions than the yards (width between 0.5m and 1.7m, and length between 1.2m and 4.0m).

- To "grecas": open space (without roof) similar to small yards, but also open by one of the vertical surfaces.

Departing from this detailed classification, only three general types of transitional spaces have been identified for the simulation, according to the geometric characterization: corridor (Figure 1), yard and "greca" (Figure 2).



Street and corridor *Corridor section* *Street section*

Fig. 1. Corridor type spaces: closed in the front and open laterally (corridors and streets).

Fig. 2. Yard and Greca type spaces

Where X: frontal obstruction angle in section; Y: angle of opening to the sky in section (x +y =90^o); Z: frontal obstruction angle in plan; W: lateral opening angle in plan (z +2w =180^o); r: lateral obstruction angle in section; t: frontal opening angle in plan; p: lateral obstruction angle in plan (t +2p =180^o); **a:** distance from the angle origin to the frontal obstruction surface.

2.1. Study cases

Taking into account this geometric characterization of the transitional in – out spaces, 44 spaces were selected from the repertory of apartment buildings studied in precedent researches, representatives of each of the three urban context considered (Centro Habana, El Vedado and Miramar), and of each transitional type, including diverse orientations.

Despite orientation was taken into account to select the study cases (because of its influence in the thermal environment studied in other parallel research), this variable was not considered in the simulation of daylight performance, since the used software departs from a uniform sky to determine the daylight factor.

The spaces selected in Centro Habana are related to outdoors by streets and yards, streets with different sections (proportions) and orientation, and yards with extreme proportions. In El Vedado and Miramar, the spaces selected are related to yards, corridors and "grecas". (Table 1)

Table 1. Study Cases, according to type of transitional space and urban context.

Urban Context	Corridor	Yard	Greca	Total
Centro Habana	6	8	-	14
El Vedado	8	8	1	17
Miramar	4	4	5	13
Total	18	20	6	44

2.2. Software

Four software were evaluated to simulate indoor daylight performance: DIALux 4.6 (2007), Ecotect (2007), Relux (2007), Adeline (1998), by comparing the results achieved with each of them to real values measured by De la Peña in 1986 [3] in a living room rectangular in plant (5.2m x3.6m) with unilateral daylight through a balcony, locating the luxometer in the center of the space. The daylight factor achieved in the measurement was 0.56.

In order to simulate daylight using Dialux 4.6 a transference coefficient for windows was considered as 0.90 (glass windows), reflection coefficients for ceiling, walls and floor as 0.70, 0.50 and 0.20 respectively, and the sky type was assumed as uniform, according to the model defined to Havana. The daylight factor (e) was simulated on a surface located 0.75m over the floor, and the point located in the middle of the space was used to compare to the real measurements. The coincidence between the values simulated and measured (e=0.56) confirms the possibility of using Dialux 4.6 for interior daylight simulation. Dialux 4.6, besides, allows making the model of the space easily, quickly and with high precision, and offers numerical and graphic results with high quality renders.

2.3. Simulation

The study cases were considered in extreme conditions, that's why the spaces were located on the ground floor, and the time assumed was December at 4.00 pm, the more critical for indoor daylight.

Dialux 4.6 considers an overcast sky that corresponds to the uniform sky as a theoretical model, with the same luminance in all directions. The model is appropriate to Havana's sky, defined as partially cloudy, with tendency to be overcast and not permeable to the solar rays, intermittent light and constant luminosity, as an isotropic model with the alternative presence of the sun [4]. Fort the latitude of Havana, in December at 4.00 pm Dialux 4.6 assume diffuse daylight values on an outdoor horizontal plane, equivalent to 10 163 lux.

In order to simulate indoor daylight in the selected study cases, a standard space (3.60m by 3.60m in area and 2.80m in height) was taken, with a louver wooden windows (1.40m wide by 1.20m height), white colored and located to the center of the wall, as traditionally used. The reflection coefficients considered to surfaces were: 0.2 to the floor, 0.5 to the ceiling and 0.7 to the walls, as well as 0.5 to the exterior ones, coincident to the values recommended by the software; the windows transmittance was assumed as 36% and reflectance as 79% (light color). The values of indoor daylight were considered on a gridded plane located at 0.75m height from the floor level.

The simulation process started with a space directly exposed to outdoors in an open context, which result was compared to the simulation of spaces related to outdoors by different types of transitional spaces with their particular geometry, in order to evaluate the influence of the volumetric – spatial solution on the indoor daylight.

3. Results

The results got in the simulation process were summarized in relation to the geometry of the transitional space and the percentage of reduction in comparison to a similar space connected to outdoors without obstruction, where "a" is infinite and "x" equivalent to 0^0.

The simulated spaces didn't compliment the required daylight level (daylight factor value=1.5 for kitchens), and only in one case, the minimum uniformity (0.3) is achieved. The higher daylight levels are got in spaces related to corridors (width streets and the more favorable urban context is Miramar, with lower land occupation. (Table 2)

Table 2. Daylight Factor and Uniformity indoors according to transitional space and context

Urban Context	Corridor		Yard		Greca	
	e_0	U	e_0	U	e_0	U
Centro Habana	0.32	0.09	0.03	0.18	-	-
	0.09	0.03	0.01	0.02	-	-
	0.46	0.15	0.02	1.00	-	-
	0.17	0.06	0.01	1.00	-	-
	0.20	0.09	0.00	0.00	-	-
	0.32	0.11	-	-	-	-
El Vedado	0.01	0.07	0.05	0.07	0.02	0.05
	0.01	0.07	0.05	0.07	-	-
	0.03	0.04	0.05	0.07	-	-
	0.03	0.04	0.05	0.07	-	-
	0.15	0.05	0.01	0.25	-	-
	0.02	0.05	0.05	1.00	-	-
	0.02	0.05	0.00	0.00	-	-
	0.02	0.05	0.00	0.00	-	-
Miramar	0.16	0.04	0.04	0.26	0.08	0.05
	0.14	0.05	0.04	0.26	0.06	0.31
	0.33	0.09	0.04	0.26	0.19	0.08
	0.14	0.04	0.04	0.26	0.19	0.08
	-	-	-	-	0.12	0.08

However, the influence of the geometry of the transitional space on the indoor daylight can be evaluated taking into account the reduction of daylight level (in %) respect to the reference space directly related to an open outdoors.

4. Discussion and Conclusions

There is a direct relationship between the type of transitional space and the reduction of indoor daylight. The corridors constitute spaces only closed on the front, but open to the top and laterals. Those spaces, as well as the "greca" type, opened by one of their vertical surfaces

(frontal or lateral ones) besides the top, are more favorable than yards from the daylight point of view. (Figure 3)

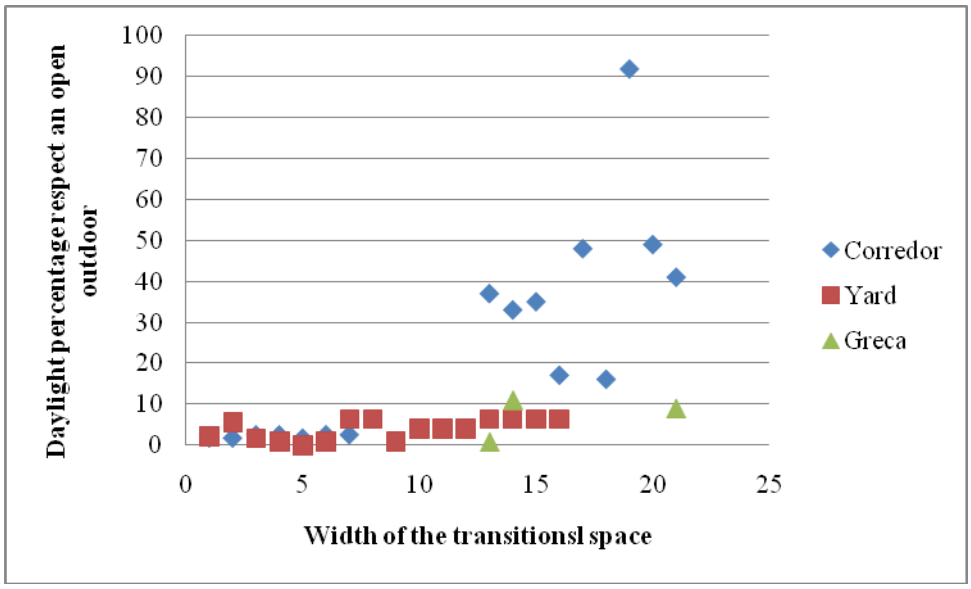

Fig.3. Percentage of daylight in spaces related to each transitional space, respect to a direct relationship to an open outdoors.

Of course, the dimensions and proportions of the transitional spaces also influence indoor daylight that decreases with the reduction of the separation between volumes, it means, with the dimension of the transitional space. In that sense, spaces with width minor than 10m reduce daylight levels in more than 50%. Something similar happen related to the building height that determines the vertical angle (x). With angles over 60^0, also indoor daylight decreases to less to the half of the value achieved in relation to an open context (x=0.0).
For the same height of building volume and distances between them, open corridors are better than closed yards respect to daylight.

These results reinforce some conclusions formerly achieved respect to the convenience of reducing land occupation in current compact urban areas and to avoid using small yards to provide daylight and natural ventilation in housing buildings. Next steps in the research requires an evaluation of this transitional spaces also from the thermal point of view, according to the Cuban climate, to get a balance about what could be really more appropriate form an integral point of view.

Abstract: The daylight factor model given by Charted Institute of Building Services Engineers (CIBSE) was modified in this paper to incorporate time variations with respect to zenith angle (θz) and vertical height (h) of working surface above ground surface which was normalized with central height (H) of skylight dome. The modified model contains constant exponents which are determined using linear regression analysis based on hourly experimental data of inside and outside illuminance for each month of the year 2007–2008. The prediction of modified model is found in good agreement with experimental observed inside illuminance data on the basis of values of root mean square percentage error (e) and correlation coefficient (r). The annual average daylight factor values for big and small dome skylight rooms are determined as 2.3% and 4.4% respectively. The energy saving potential of skylight rooms for selected climatic locations in India is also presented in this paper. This paper also investigates embodied energy of an existing eco-friendly and low embodied energy adobe house with dome shape roof located at Solar Energy Park inside IIT Delhi campus in New Delhi (India). Based on embodied energy analysis, the energy payback time for the adobe house was determined as 18 years. The embodied energy per unit floor area of reinforced cement concrete (R.C.C.) building (3702.3 MJ/m^2) is quiet higher as compared to adobe house embodied energy (2298.8 MJ/m^2).

1. Introduction

Daylighting is an important issue in modern architecture affecting the functional arrangement of spaces, occupant comfort (visual and thermal), structure and energy use in building [1]. Daylight is considered as the best source of light for good color rendering and its quality is the one light source that most closely matches with human visual response. It gives a sense of cheeriness and brightness that can have a significant positive impact on the people. The amount of daylight penetrating a building is mainly through window openings which provide the dual function not only of admitting light for indoor environment with a more attractive

and pleasing atmosphere, but also allowing people to maintain visual contact with the outside world. People desire good natural lighting in their living environments [2,3].

The energy consumption of lighting in buildings is a major contributor to carbon emissions, often estimated as 20–40% of the total building energy consumption as reported by Building Research Establishment (BRE) energy consumption guide [4] and Chartered Institute of Building Services Engineers (CIBSE) [5]. Furthermore, the heat gains produced from artificial and natural lighting have an important influence upon he ating and cooling loads reported by Peacock et al. [6]. Using controls for demonstrating the optimized configuration for daylight supplemented electrical lights is well-documented by Greenup et al. [7], Reinhart [8] and Li and Lam [9], with particular interest on the effect of thermal loads reported by Franzetti et al. [10]. However, the more advanced and material-based solutions were reported by Lee et al. [11], Tong et al. [12] and Smith [13] for optimizing daylight. They provide innovative solutions for reducing lighting-energy consumptions.

With the project considering a large number of buildings, it is important that the approach should be as efficient as possible with regards to the available time as reported by Reinhart and Fitz [14]. While building-simulation packages and time-series techniques can be used for detailed predictions of lighting use [15]; they can be both time consuming and unnecessary for obtaining first-order estimate. The annual variation in daylight availability in UK can be represented using data reported by CIBSE [16] and Hunt [17,18]. The domestic lighting demand was determined using simple model developed by Stokes et al. [19]. The economics of lighting retrofits for emission reduction was reported by Mahlia et al. [20]. Daylighting is one of the basic components of passive solar building design and its estimation is essential. Laouadi et al. [21] had reported that the daylight factor of building depends upon position of light source with respect to the room orientation, the room geometry, the optical characteristics of the room indoor surfaces, any outdoor obstructions and the optical behaviour (transmission, reflection and light scattering) of the fenestration system through which light is admitted into the room space. Daylight coefficient is independent of sky luminance distribution as reported by Tregenza and Waters [22]. Recently, calculating indoor natural illuminance in overcast sky conditions was reported by Rosa et al. [23]. In India and many parts of the world, the availability of measured outside illuminance values are very few. The Indian climate is generally clear with overcast conditions prevailing through the months of June–September, which provides good potential to daylighting in buildings as reported by Joshi et al. [24]. This paper investigates a mathematical model for existing skylight integrated dome shaped mud-house to estimate daylight factor based on the modifications in the model developed by CIBSE [25]. The daylight factor model developed by CIBSE [25] was validated for ground surface illuminance by Chel et al. [2] using experimental data of the existing building. The model developed by CIBSE [25] does not include time variation in a day and vertical height (h) of the work plane above ground surface. Hence, there is need for the modification in the model developed by CIBSE [25] to incorporate vertical height (h) normalized with respect to central height (H) of the skylight room and time variations in terms of zenith angle (hz). This concept of modeling for skylight is rarely reported in the literature for New Delhi composite climate. The constant exponents in the modified model were determined on the basis of linear regression analysis which is explained in depth in this paper. The values of exponent were determined based on hourly inside and outside illuminance data for typical clear day in each month.

Using the modified model, the daylight factor is determined for three different work planes at different vertical heights (h) from ground surface, i.e. at h = 0 (or ground surface), 0.75 m and

1.5 m above ground surface. The study of work plane at ground level implicates to the students seating on floor and reading and writing in rural village schools in India. The vertical height of 0.75 m implicates to reading on work plane (or table) in modern schools and colleges in India while the 1.5 m vertical height implicates to standing posture of a working person like engineer in the factory (or teacher in school/conference room). The daylight factor values using modified model and experimental data were tabulated and presented in this paper. The energy saving potential of the skylight big and small domes for different selected climatic conditions is reported in this paper.

The annual average artificial lighting energy saving potential and corresponding CO2 emission mitigation were evaluated for the existing building by Chel et al. [2]. The research pertaining to energy savings due to existing experimental setup of mud-house integrated with an earth to air heat exchanger and embodied energy analysis of building were respectively reported by Chel and Tiwari [26,27]. The existing dome shape building is found to be a promising example of sustainable and low carbon building (or green building) integrated with stand-alone photovoltaic reported by Chel and Tiwari [28].

2. Pyramid shape skylight over dome shape roof of Mudhouse

Laouadi and Atif [29] and Chel et al. [2] had reported other different skylight shapes for daylighting in buildings. The existing mud-house has vault (or dome shape) roof structure integrated with pyramid shape skylight as shown by the pictorial view in Fig.1. The inside view of skylight circular aperture is also shown in Fig.1.

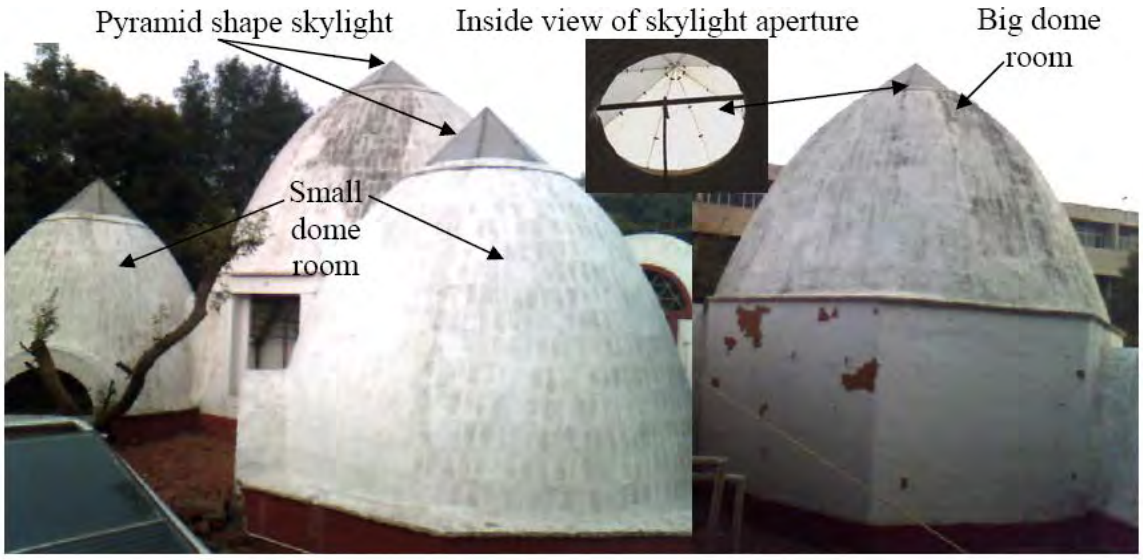

Fig. 1 Pyramid shape skylight over the dome shaped roof of Mudhouse

3. Percentage daylight factor, DF (%) for the naturally illuminated work plane

The percentage daylight factor, DF (%) is the percentage ratio of inside illuminance, Li (lux) on the horizontal work plane and outside diffuse illuminance, Lo (lux) on horizontal surface. The daylight factor for skylight integrated dome shape building at ground level is given by Eq.(1) developed by Chartered Institute of Building Services Engineers (CIBSE) [25] and validated by Chel et al. [2] as follows:

$$DF = \left[\frac{L_i}{L_o}\right] \times 100 = \left[\frac{\tau \times C \times A_g \times \theta \times O_F}{A_t \times (1 - R^2)}\right] \quad (1)$$

The various parameters in Eq. (1) are tabulated with their values considered in Table 1. The variation of daylight factor (%) with the time of the day and vertical height (h) above ground surface is developed by Chel et al.[30] and expressed in the Eq. (2) as follows:

$$DF = \left[\frac{L_i}{L_o}\right] \times 100 = \left[\frac{\tau \times C \times A_g \times \theta \times O_F}{A_t \times (1 - R^2)}\right] \times \left(1 + \frac{h}{H}\right)^m \left(\cos\theta_z\right)^n \quad (2)$$

Line equation can be easily written as follows:

$$Y' = M'\left[X'\right] + C' \quad (3)$$

This Eq.(3) of line is represented for following Eq.(3) as follows:

$$\ln\left[\frac{L_i}{L_o} \times 100\right] = \left[n \times \ln\left(\cos\theta_z\right)\right] + \left\{m \times \ln\left(1 + \frac{h}{H}\right) + \ln\left[\frac{\tau \times C \times A_g \times \theta \times O_F}{A_t \times (1 - R^2)}\right]\right\} \quad (4)$$

$$Y' = \ln\left[\frac{L_i}{L_o} \times 100\right] \text{ and } X' = \left[\ln\left(\cos\theta_z\right)\right] \quad (5)$$

$$m = \frac{\left\{C' - \ln\left[\frac{\tau \times C \times A_g \times \theta \times O_F}{A_t \times (1 - R^2)}\right]\right\}}{\ln\left(1 + \frac{h}{H}\right)} \quad (6)$$

Where, $n = M' =$ slope of line and $C' =$ intercept of line on Y'axis

The total power of lighting, P (W) can be determined by considering the artificial light source luminous efficacy, ε (lm/W) and efficiency of ballast, B_F (or ballast factor). The total power of artificial electrical lighting required for the measured amount of total luminous flux, Ø (lumen) from the existing skylight in building can be determined mathematically by Eq.(7) using Jenkins and Newborough [31] as follows:

$$P = \left[\frac{Ø}{B_F \times \varepsilon}\right] \quad (7)$$

$$Ø = \left[L_i \times A_s\right] \quad (8)$$

Where, L_i is measured illuminance level (lux or lumen/m^2) inside the skylight building on the horizontal working surface area, As (m^2).

The total lighting-energy consumption, E (W h/day) can be determined by multiplying total power of lighting, P (W) and required number of hours of operation per day, N (h/day). The total lighting-energy consumption can be expressed mathematically using Eq.(9) as follows:

$$E = \left[P \times N\right] \quad (9)$$

Table 1. Values of parameters considered for daylight factor estimation

No.	Parameter	Value	Parameter	Value
1	Total area of room surfaces in big dome (A_t, m^2)	80	Total area of room surfaces in small dome (A_t, m^2)	25
2	Floor area of big dome (A_f, m^2)	26	Floor area of small dome (A_f, m^2)	5
3	Transmittance of glazing (τ)	0.8	Vertical angle of visible sky from horizon (θ, degrees)	90
4	Correction factor for glazing due to poor maintenance/dust ($0.5 \leq C \leq 0.9$)	0.6	Vertical height of work plane above floor surface (h, m) [0, 0.75 m, 1.5 m]	0, 0.75, 1.5
5	Orientation factor for glazing ($0.97 \leq O_F \leq 1.55$)	1	Average reflectance of all room-surfaces ($0 \leq R \leq 1$)	0.3
6	Total area of glazing (A_g, m^2) for big dome	2.6	Total area of glazing (A_g, m^2) for small dome	1.5
7	Ballast factor (B_F)	0.9	Artificial light luminous efficacy (ε, lm/W) (CFL lamp)	40

4. Results and discussion:

Based on e xperimental data of inside and outside diffuse illuminance, the daily average experimental value of percentage daylight factor is determined and compared with daily average predicted value of daylight factor using modified model Eq.(2) for each month in Table 2 (DF- Daylight Factor (%), B- Big Dome, S-Small Dome with h= 0 cm, 75 cm, 150 cm).

Table 2. Experimental comparison of daylight factor with developed skylight model

The linear regression analysis was carried out as explained in section 3 and the results were potted for big dome for h= 0.75 m as follows in Fig.2.

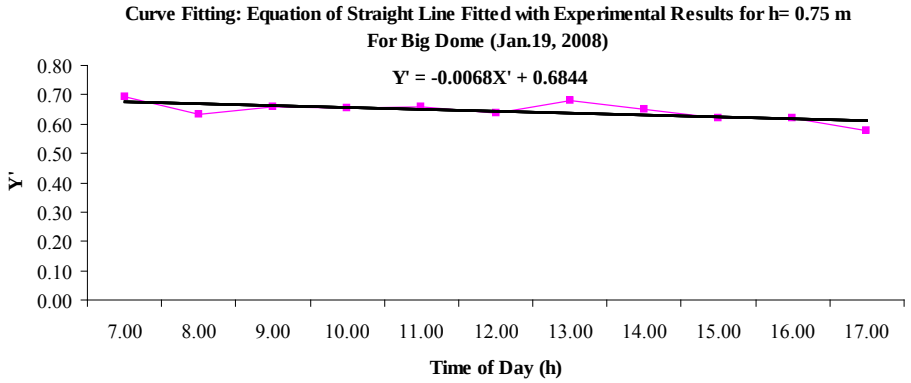

Fig.2. Linear regression of experimental results for big dome at h=0.75 m

The validation of daylight factor (DF) using experimental data of daylight factor for big and small domes at three different heights above floor surface were carried out for January and June based on the prediction of developed skylight model Eq.(2) and plotted as shown in Fig.3 (for January). The annual average energy saving potential for three heights for big and small domes were determined for selected locations in India and plotted as shown in Fig.4.

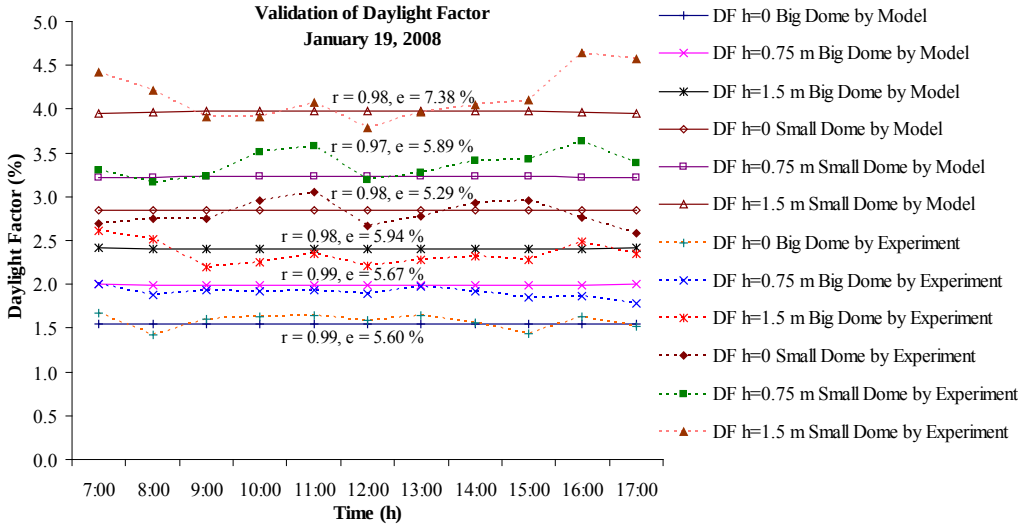

Fig.3. Validation of daylight factor model for big and small dome in January

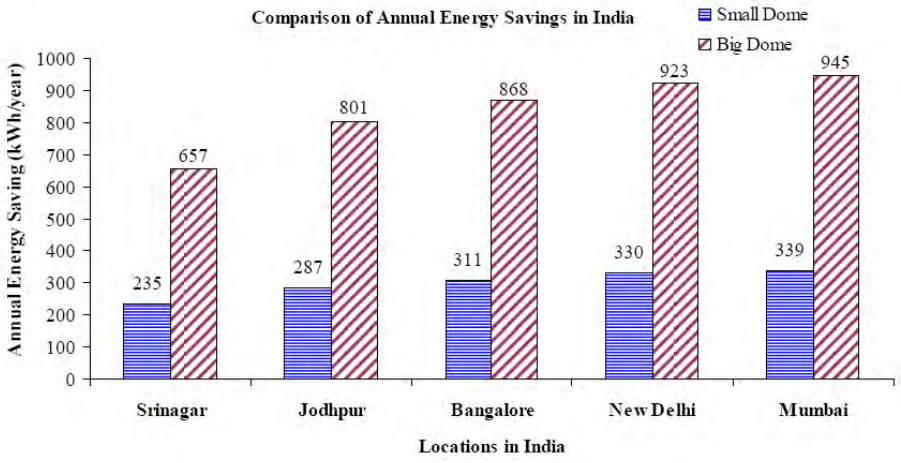

Fig.4. Annual energy saving potential of skylight for big dome room in India

5. Conclusions

The following key conclusions can be drawn from the study as follows:

1. It is found that the root mean square percentage error is small and varies in the range of 5–8% for the developed model Eq.(2). Hence, the proposed daylight factor model represented by Eq.(2) can be used to estimate the daylight factor (%) and corresponding inside illuminance at different vertical heights in skylight integrated dome shape roof mud-house which can be seen from Figs.5.
2. The illuminance level inside the mud-house was found sufficient for office work inside the room from 9 am to 5 pm. The small dome room has maximum illuminance value (for h = 0–1.5 m) in the range of 450–650 lux (in winter) and 800–1800 lux (in summer) while big dome room with maximum illuminance value (for h = 0–1.5 m) 250–400 (in winter) and 400–900 lux (in summer) in New Delhi (India).
3. The illuminance level was found 100 lux (minimum) inside both small dome and big dome rooms from 9 am to 4 pm in all months of the year in New Delhi composite climatic conditions.
4. The experimental daylight factor over the year for big dome room (for h = 0–1.5 m) are found in the range of 1.5–2.5% (January) and 1.5–3.5% (June) while for small dome rooms (for h = 0–1.5 m) it varies in the range of 2.5–4.5% (January) and 3–7.5 (June) based on skylight performance in both winter and summer. The annual average value of percentage daylight factor (for h = 0–1.5 m) is determined as 2.3% and 4.4% for big and small dome skylight rooms respectively. Hence, the skylight rooms are suitable for office building, e.g. state government offices in rural and urban areas of India, temple, church, mosque, etc.
5. The vertical height (h) of work plane above floor surface for the skylight room gets significantly different amount of illuminance. This effect shows that distance of work plane from skylight is directly proportional to amount of illuminance received on that work plane surface. This can be observed from different values of daylight factor (%) at different vertical height (h) above floor for working surfaces inside big and small dome rooms.

Abstract: The aim of this paper is to assess the use of an intelligent glass envelope in the refurbishment of existing buildings in Italy in order to fit their energetic performance considering Mediterranean climate inputs. With the new European and Italian regulations on energy efficiency of buildings, envelopes are not only forced to respect heat transmission limits (e.g. U value) and to improve their thermal insulation, but also to use and receive benefits from environmental input such as passive solar gains. Comparing to the North European solutions, a glass envelope seems not to be the most suitable solution for a Mediterranean climate, mainly due to the great incidence of solar gains and the risks of overheating during summer season. Examples presented in this paper indicates how double skin glass façades, that are commonly used in new constructions where the concept starts from a low environmental impact, can be also employed in the refurbishment of existing buildings, which is the main challenge for the global reduction of CO_2. An overview on the main technical of intervention can indicate to architects and planners the weakness/strength points to take in consideration in the use of a double layer glass façade in a Mediterranean climate in order to reduce the overall energy balance.

Keywords: *Building envelope, Sustainable technologies, Energy retrofit, Double skin glass façades.*

1. Introduction

This paper purpose to remark the importance of the use of sustainable technologies, such as a double layer glass envelopes, in the renewal of existing buildings in order to fit their energetic performance to different climatic inputs. This solution is mainly used in public buildings (offices and productive buildings) where the potential of a new high-tech image may easily justify high costs of realization. Moreover, the use of double layer glass envelopes is heavily conditioned by the climatic factor. The main purpose of the double glass envelope is to balance the desire for daylight and outdoor view with the concerns for heat gain and loss. The air cavity can be heated by the sun to create a warm buffer zone that protects rooms in winter and can be configured to function as a thermal chimney in summer utilizing the stack effect to remove excess heat. Case studies presented in this paper indicates how double glass envelopes, that are commonly used in new constructions, can be also employed in the refurbishment of existing buildings, which is the main challenge for the global reduction of CO_2. An overview on the main technical of intervention can indicate to architects and planners the potentiality for the improvement of the existing buildings, in order to reduce the overall energy balance. The energy failure in existing building stock is mainly due to the poor insulating efficiency of the façades. Making use of hi-tech envelopes, not only the energetic balance, but also the architectural value of a building can be improved. A set of rules concerning energy efficiency in buildings has been acknowledged in Italy by enacting the Decree 311/2006, that states new standards for the energetic performance including also the existing building stock, except for cultural heritage. The experiences gained till now in other Countries suggest wide chances of interventions on building stock by promoting the use of "intelligent envelopes": dynamic and active bounding surfaces automatically able to gear their performance to the changes of the environmental conditions, as they integrates a great deal of working functional devices. Following these experiences it is possible, therefore, not only to introduce basic standard improvements but even proper architectural lifting on the building

façades, mainly considering post war building stock that is one of the most cause of energy consumption due to the poor building techniques and the heavy state of decay.
A sustainable upgrade should mainly provide active or passive energy from renewable sources in order to achieve the highest indoor comfort by restricting the use of HVAC (Heating Ventilation Air Cooling) units and artificial lights. The most efficient technical solutions that can be used to refurbish buildings are based on fundamental principles of the sustainable architecture such as: heat gaining by collecting and storing solar energy in winter, use of passive cooling and natural ventilation in summer, maximum natural day lighting, reduction of heat loss through the walls, use of systems with low environmental impact such as dry technologies.

1.1. Methodology

This study examines three case studies in Italy where the refurbishment of existing building envelopes was done using a double layer glass façade. The aim of this study is to assess which technical solution can improve the energy efficiency and the global quality of the building by considering some variables:
- The climatic conditions: in Italy climate is very different from Northern Europe, where the double layer glass envelopes are largely used. The main problem is the risk of overheating in spring/summer season as, in Mediterranean climate, the energy efficiency is based not only on the performance of thermal insulation such in Northern countries, but also on the necessity to reduce big solar gains and improve ventilation in summer;
- The composition of the technical solution: in the most cases of refurbishment the original inner façade is conserved and improved by insulation, so the "double layer glass" systems turns in "hybrid" system where opaque parts of parapets are present;
- The applicability of different solutions (full height façades, cell façades, natural or forced ventilation) to the existing façade by considering operations and costs/benefits.

The evaluation was done on the basis of the following steps:
- Energetic diagnosis of the building before the intervention (mainly considering energy consumptions in operational phase);
- Examination of the project/design/technical details;
- Visit in building site during the construction;
- Monitoring of the building for one year, by considering the grade of satisfaction/comfort of the occupants and energy consumption recording.

2. Double layer glass façades: the technical solution

A typical double glass envelope system includes a single glass layer and a double-glazing low emissive layer separated by an air space. An operable shading device is installed in the cavity to minimize the solar heat gain in summer. In addition to the energy savings, the double envelope system has other potential benefits such as: acoustic control, water penetration resistance and an enhanced office atmosphere because of the external view and the utilization of daylight. Double glass façades in the refurbishment are generally hybrid systems, formed by the existing wall and a new glass envelope. The external envelope is a glass façade: during the winter season it supports the solar gain that, by heating the air cavity, consequently improves the thermal capacity of the whole system. The use of high – performing glasses is fundamental to obtain solar reflection and to prevent overheating. If the refurbishment is oriented to the complete substitution of the existing envelope, also the internal wall is a glass façade, forming the conventional double-layer skin. In the most cases, it's more convenient to conserve the existing wall and, after the changeover of the windows, to add up insulating panels on the structure and on the parapets.

In winter, during the warmest hours, the heating of the air cavity is the fundamental factor that reduces the thermal losses and the air permeability through the wall. During the night, the air vents are closed, preventing the entrance of cold air. In summer, through the solar shadings, good levels of internal comfort can be obtained. Throughout the day, the cavity is closed to avoid the entrance of warm air, while during the night the natural air flue cools down the walls and the rooms.

The thermal performance of double façade systems depends on many factors, such as:
- The composition and performance of the layers (glass/glass or glass/wall, kind of glass used);
- The (height) extent of the air cavity (which can be continuous or divided in floor-height cells, in this case the ventilation is related to each cell);
- The thickness of the air cavity (which can range between 20 cm to 90, if it encloses maintenance routes);
- The type of ventilation in the cavity (natural or forced) that is strictly related to the height of the façade and to the climatic conditions;
- The relationships between air cavity and HVAC systems (possibility to utilize warmed air from the cavity and expel internal air. This is rare occurrence in the refurbishment).

2.1. Typologies of construction

Double layer glass façades can be realized in three main typologies of construction:
Full height: in this case the air cavity is continuous and comprehends the whole façade surface. The external glass layer is fixed on the existent envelope in a limited number of points (generally in correspondence of concrete border beams). Air cavity thickness ranges between 40 to 90 cm. Pipes: the external façade is fixed to the internal by means of a common frame or punctual anchorages. The cavity is sectioned in vertical or in horizontal: this means that the surface is divided in several ventilations chimney, instead of an unique air cavity area. Air cavity thickness ranges between 40 to 90 cm. Cells: The façade is formed by the aggregation of modular cells, independent each other, one floor height and generally not more than 30 cm thick. Each cell has his inlet airs. Table 1 analyzes the suitability of the typologies of construction in the refurbishment of existing buildings.

Table 1. Main typologies of construction and applicability in the refurbishment

Typology of façade	Scheme	Description	Applicability
Full Height		Air cavity is continuous. Anchorages are punctual Thickness ranges from 40 to 90 cm	high
Pipes		Air cavity is vertically sectioned. The thickness ranges from 20 to 50 cm	medium
Cells		The façade is formed by the aggregation of modular cells, independent each other. Each cell has his inlet airs. The thickness is 20 - 40 cm	medium

2.2. Air cavity ventilation

The cavity in double glass façades is either naturally or mechanically ventilated. In case of natural ventilation, the air in the cavity flows naturally: if properly designed, wind flowing over the façade can create pressure differences between the inlet and outlet inducing air movement. Air vents at the bottom and at the top of the façade allows the natural flowing in the cavity by the so called "chimney effect" of the warmest air that naturally rises up. In this configuration the internal layer is the layer with thermal performance (insulation on parapets, low-e glass windows) while the external layer is single glass. The temperature in the air cavity is closer to the external temperature. Internal windows can be opened or not. If internal windows can be opened, this allows the natural ventilation of the rooms, even it's necessary to carefully evaluate the right period of opening (winter day- summer night), otherwise the positive effect of the natural air could be neutralized. Natural ventilation is not without risk. It may create a door-opening problem due to pressurization. Besides, if the air path is not appropriately designed, the solar heat gain within the façade cavity will not be removed efficiently and will increase the cavity temperature. If windows can not be opened this helps in the air cavity control, but decreases the user requirements (necessity of fresh air). In the case of forced ventilation air is compressed into the cavity by mechanical devices. The mechanically assisted ventilation systems usually use an under floor or overhead ventilation system to supply or exhaust the cavity air to ensure good distribution of the fresh air. This air rises and removes heat from the cavity and continues upwards to be expelled or re-circulated. Because air is not pumped in directly from the outdoors, there is potentially less risk of condensation and pollution in the cavity. The internal façade is generally closed and single glass made while the external layer is the insulated and performing layer. The temperature in the air cavity is more similar to the air temperature in the rooms. In areas with severe weather conditions or poor air quality, the mechanically assisted ventilation system can keep conditions in the buffer zone nearly constant to reduce the influence of the outdoor air to the indoor environment. The relationship between type of ventilation and applicability in the refurbishment is synthesized in table 2.

Table 2. Main typologies of ventilation and applicability in the refurbishment

Typology of façade	Scheme	Description	Applicability
Natural ventilation		The air in the cavity flows naturally by chimney effect Internal layer= performing glass External layer= single glass	high
Forced ventilation		The air in the cavity flows by means of mechanical devices. air is utilized by HVAC systems. External layer= performing glass Internal layer=single glass	low

2.3. Case studies

2.3.1. Torno International Headquarter in Milan

Originally built in 1950, the building had many problems mainly related to: lack of thermal and noise insulation, overheating in summer season, lack of natural light into the offices. Big consumption was registered due to the necessity of heating in winter but most of all for the big air conditioning use in summer. An average consumption date was estimated in about 250

Kwh/m^2 per year. The strategy of intervention was to coat opaque parts of façade (e.g. concrete skeleton, ground floor) with a dry coat finished with gypsum panes. The south façade, made by single layer windows and thin brick wall parapets, was replaced with full height double low-e glass windows. Starting from the first floor, a full height glass facade was overlapped. The air cavity is 55 cm wide, air flows naturally: at the bottom the cavity is always open thanks to a metallic grid (also helpful for maintenance routes), at the top moveable glass louvers can control the air flow in the different climatic conditions (maximum ventilation in summer, minimum in winter). Solar shadings are in the air cavity: aluminum venetian blinds in front of the internal windows. Internal wall can not be opened, this helps in the control of the natural phenomenon of the chimney effect in the cavity. Main benefits with this intervention were obtained. For first, the reduction of thermal losses due to the air cavity that acts like a warm buffer zone in winter and improves solar gain: this caused the reduction of HVAC of about 35% in winter and 40% in summer. Moreover, the improvement of noise insulation (a reduction of 6 Db was registered). The cost of the intervention is about 1100 Euro/m^2.

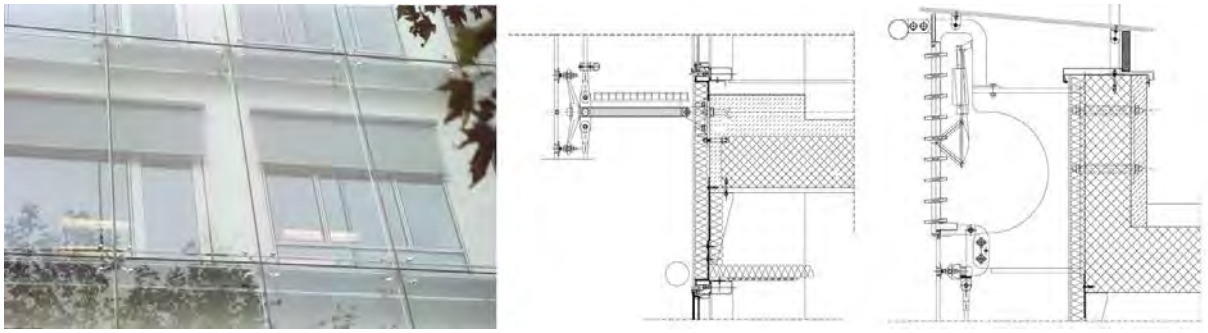

Fig. 1. Image and technical details (bottom – top) of the new façade

2.3.2. Johnson Wax Headquarter in Milan

The building, 20 m tall, was originally built in 1977 with a curtain wall façade. Main requirements that was asked to the designers were:
- to allow the natural ventilation that could be independently managed by the users of each office;
- to achieve high thresholds of natural light, even for environments located in the central part of the buildings, while avoiding the phenomena of glare and overheating of indoor air;
- to ensure adequate levels of sound insulation from noise coming from the adjoining highway;
- to carry out the remediation of asbestos cladding;
- to improve the quality of architecture.

The facade of the building was replaced with a double skin façade made by aluminum windows (internal layer) and 8 mm safety glass layer supported by a system of spiderglass and rotules (external layer). A full height natural ventilated façade was designed to meet users and owners' s requirements. In the cavity, 90 cm thick, air flows naturally but mechanical fan at the top of the façade were installed to provide to forced ventilation in case of low-pressure. The façade works as a dynamic filter for the regulation of energy exchange between inside and outside. In winter time the cavity acts as a "thermal buffer" by reducing heat loss and heat gain by allowing the greenhouse effect. Internal wall can be opened: three doors per side allows natural air exchange and the access to the corridors for maintenance routes. Aluminum blinds in the cavity allows to avoid summer overheating, moreover also 90 cm grilled corridors contributes to shield the solar radiation. Concerning the indoor comfort, an average temperature of the rooms was calculated, ranging between 18 ° and 20 ° C for opaque

surfaces, and between 16 ° and 17 ° C for glass panes. Indoor relative humidity is about 50/60%: this means that the temperature inside of the cavity can exclude any risk of condensation. Main technical data after the refurbishment are: the reduction of thermal losses of 30%, reduction of HVAC of 30% in winter and 40% in summer, noise insulation damping: 7 Db, The cost is about 1300 Euro/m^2 .

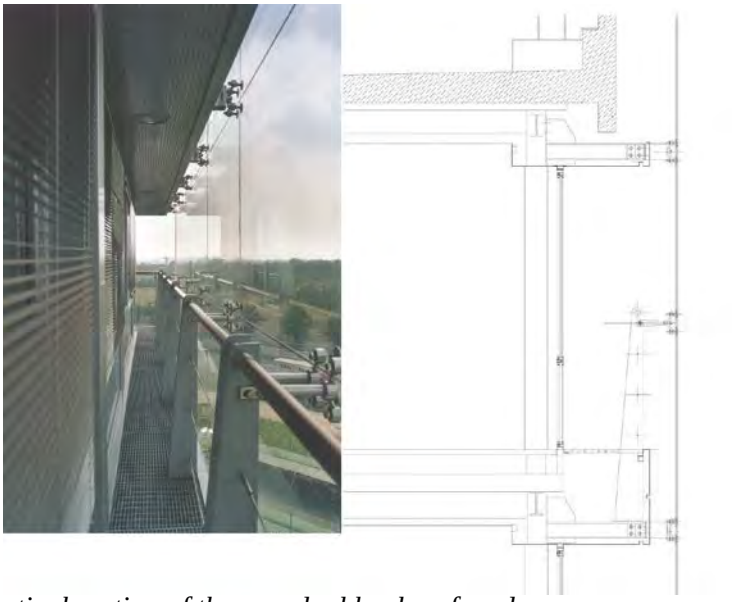

Fig. 2. Image and vertical section of the new double glass façade

2.3.3. Hines Headquarter in Milan

The building is a part of a commercial area, consisting of 4 buildings of the '60s. The project was organized around some architectural choices towards environmental design and energy conservation. Main design guidelines were: a new double skin glass façade on the main building, the partial covering of the internal courtyard, the creation of an indoor garden, the careful control of the natural day light. In particular, for the building towards via Bergognone, characterized by significant thermo-acoustic lacks (single-glazed windows and wooden panels as parapets without insulation) the energy retrofit was done by the removal of the existing façade that was replaced by a double skin façade on the south-west front. The air cavity is 75 cm thick, full height and natural ventilated. The inner envelope, made by low-e double glass, acts as thermal and acoustic insulation and solar control factor, while the external front (a system suspended by metal cables to fixed glass components), due to a special surface treatment with oxides of iron, is able to harness the positive effects of solar radiation in winter and to control the flow during the summer (solar factor g of 65%). Natural ventilation is ensured by the openings at the base and the top of the façade. Moreover joints between the glass panes are open: a distance of 10 cm, allows ventilation in the cavity during the summer to avoid overheating. For this reason, it was chosen not to govern the dynamic condition by systems of opening/closing of the inlet and outlet air vents. Main results after the refurbishment are: the reduction of reduction of HVAC of 35% in winter and 40% in summer.

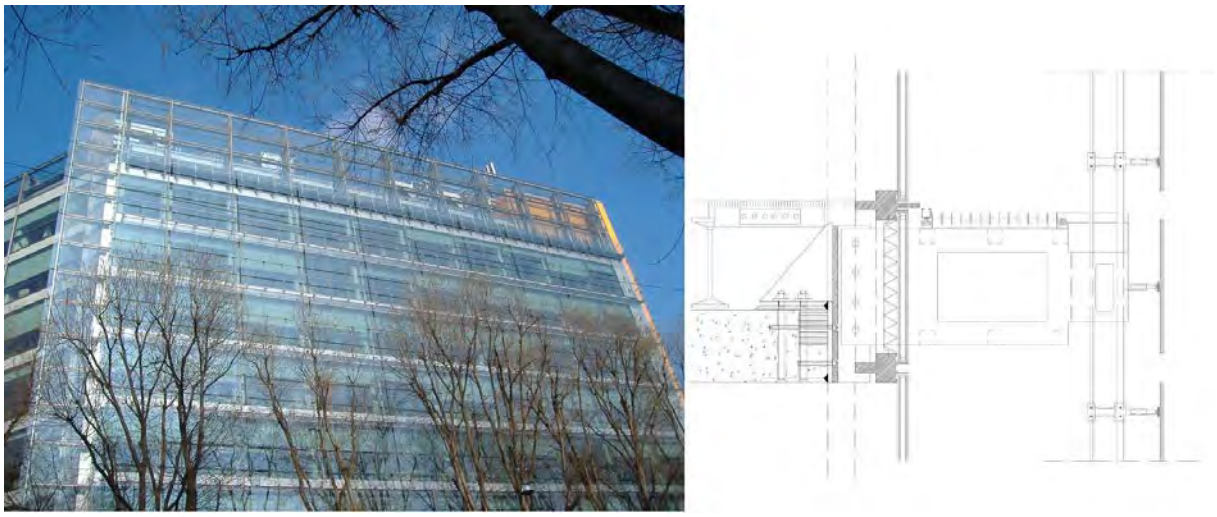

Fig. 3. Front of the building and vertical section of the new double glass façade

2.4. Results

By considering the case studies examined some conclusions can be made. The most useful typology in the refurbishment is the full height façade: generally the overlapping of a new glass layer doesn't greatly alter the whole system: in these cases, the original windows are replaced with double-glass windows and an insulating coating is applied on the opaque parts. The natural ventilation of the cavity doesn't involve big plant variations, this is the reason why the solution is the most suitable in case of refurbishment. The careful design of the air cavity (thickness, position and dimensions of air vents) is fundamental, so that the phenomenon of the natural draught can properly occur. The use of cells façade is the most convenient when the building is so high that the natural flow of air is impossible, even if it's not suitable for in each case. The operational route of the double skin façade in Mediterranean countries such as Italy remains unknown today. The climate conditions, warmer and wetter than in the North-European Countries, make very difficult to exploit a system of natural ventilation of the facade able to make use of its full potential performance. For this reason, the design strategies undertaken by the Italian projects have used the double-skin "buffering" system, that can reduce the heat load and meet the sound insulation and sealing requirements, rather than operate on the heat and energy recovery through installations. Because of the typical Mediterranean conditions, the natural ventilation of the rooms through the cavity was generally avoided in the most examined projects, keeping the skin closed and obtaining internal comfort through air conditioning systems. The decision to equip the inner shell with opening windows has a helpful effect on the psychological health of the people, but must be assessed in relation to the climatic conditions of the site. In the Italian context, the choice may not be appropriate since it does not provide guarantees on the benefits offered by the air present in the cavity. This choice also involves the reduction of the noise level of the system.
For the project of renovation of the Hines company in Milan, for example, the strategy of refurbishment has prioritized the issue relating to the control of the thermal load and the daylight through the use of high-performance glass rather than the use of natural ventilation in the offices. In the renovation of the Johnson Wax building, the possibility of opening the inner façade exist: this helps the comfort of users, who can enjoy natural ventilation in the workplace, even if, in the reality, the optimal conditions for opening the windows occur only during the summer night-time and the achievement of the comfort is largely delegated to the air conditioning. For the Torno International headquarters the internal façade can not be opened and an external skin made by laminated security glass was realized. The lower air vent is full open, the upper is electronically adjustable by made of moveable louvers. In tall

buildings, when the cavity is over 20 meters, an area of low pressure can occur: this can block the chimney effect and consequently, the need to move this critical area as high as possible. One solution should be to design the outlet air vent (at the top), according to a generalized average of 2 to 1 respect to the inlet air vent (at the bottom).

3. Conclusions

Double skin glass façades are in the most cases used in the refurbishment of office and public buildings where high investment costs can be justified with the architectural renovation of the building. In the summer season in Italy, the maximum performance obtainable from a naturally ventilated double skin glass façade is mainly to act as a "buffer space" to reduce overheating. This implies that the main result that could be obtained is the reduction of operating costs for cooling, due to the increased thermal performance of the envelope.
All of these case studies demonstrated that a reduction of energy consumption both in summer that in winter season is possible: the average consumption of the buildings before the interventions was about 250-270 Kwh/m^2 , that was reduced of about 30-40% thanks to the realization of the new envelope. The most suitable solution might be an integrated plant that regularly provide for a mechanical ventilation of the cavity and it should be operative when the outside conditions are extreme. An interesting way that might really enhance the management of the energy balance, should also include to support the system with integrated photovoltaic panels or solar collectors, combining the benefits offered by the double skin structure (in terms of ventilation, noise protection and control of the pressure exerted by the wind), with the possibility of an active exploitation of the solar energy.
The payback for incremental investment in energy efficiency using a double glass envelope has been estimated at 20-25 years. Investment costs could have a fast payback if the glass envelope integrates active solar energy devices (e.g. photovoltaic systems).

Abstract: Daylight has been regarded as a significant environmental advantage of atrium buildings because the natural light can illuminate potentially dark core areas and decrease energy consumption. This study has investigated the average daylight factors (overcast sky conditions) and annual lighting energy load (real weather conditions of Sheffield, UK) in adjoining spaces to assess the fundamental daylight performance and energy performance in an atrium model. Radiance and Daysim (based on Radiance algorithm) were the tools to simulate the daylighting and lighting energy use. A comparison of the measurement and simulation showed the validation of the basic Radiance simulation in the model. In terms of the well façades (decided by the ratio of window area to solid wall area) and well surface reflectance, the variations of daylight level and annual electrical lighting use in the adjoining rooms have been analysed and some design strategies for supporting preliminary design decisions are presented. Only the square atrium model and relatively simple climate conditions have been considered in the investigation.

1. Introduction

Daylight use in an atrium is particularly beneficial as the atrium well can allow natural light to reach potentially dark core areas in adjoin rooms, decrease energy use by artificial lighting and improve the indoor environment on psychological and ergonomic grounds. In general, the daylight levels in the adjoining rooms are directly influenced by the vertical daylight levels on the well facade and the room properties (size and surface reflectances) [1, 2]. A linear relationship between the vertical daylight factor at the facade and the average daylight factor in the room with a specific dimension and reflectance can be given by a theoretical expression [3]. It has been found that well geometries and surface reflectances have a direct effect on the decay of vertical daylight levels across the well wall in atria [4]. Well geometry can be quantified in terms of the well index (WI) [1], equation (1) which is a function of well length (l), width (w) and height (h) (Fig. 1):

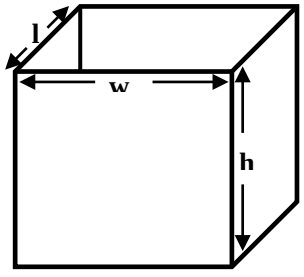

Fig. 1. Atrium geometry and WI definition [1].

$$WI = \frac{h(w+l)}{2wl} \qquad (1).$$

Two measurements using scale models [5, 6] pointed out that changing the proportion of glazing or opening areas between well and adjacent spaces could be a practical solution to the imbalance of light flux received at the top and bottom of the atrium walls and adjoining spaces. A common rule was suggested: small glazing areas on the top floor and the fully gazing areas on t he ground floor. Nevertheless, a recent study [7] based on Radiance simulation indicated that increasing well surface reflectances had little impact on the daylight level of full glazed rooms at ground floor because of the lack of solid reflecting surfaces. This demontrates the complexities of refleted light in atria. It is still essential to carry out more investigations on daylighting performance of rooms in atria with various facade systems. Moreover, the lighting enegy saving under the conditions of daylight use in atria is another significant toipc to be studied. A field measurement [8] in two large atria showed that daylighting illumination can displace 46% and around 15% of annual lighting consumptions through introducing two different lighting control systems respectively. By providing sufficient daylighting illumination, the daylight use in atria displaces the artificial lighting load in the adjacent spaces, which is regarded as one of the most important and hardest-to-achieve objectives of atrium environmental design [2].

This study investigated the daylight performance and energy performance (annual lighting use) of adjoining rooms in a five-story atrium model with various façade systems and well reflectances. Radiance and DaySim (Radiance-based package) were used in the calculations of daylight factor and annual lighting load respectively. Firstly, a comparison between model measurements and Radiance simulations was undertaken to validate the basic Radiance outputs. Next, more Radiance simulations were carried out to display the impact of façade configurations and well reflectances on t he average daylight factors in rooms. Thirdly, the lighting energy consumption of rooms in the atrium model was considered. Finally, some design strategies have also been suggested.

2. Comparisons of simulation and measurement

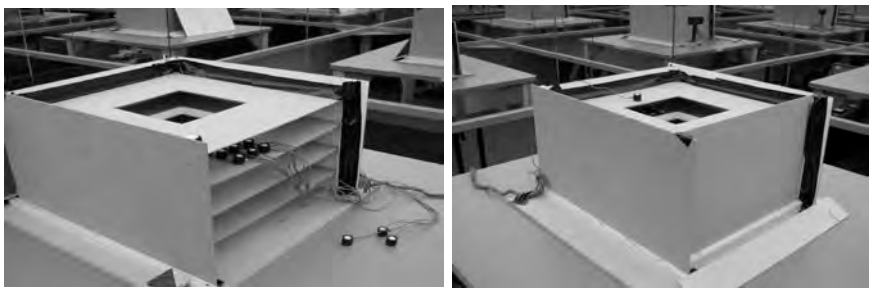

Fig. 2. Physical atrium model in a mirror box artificial sky.

A physical atrium building model was tested in a mirror box artificial sky that reproduced a CIE standard overcast sky (Fig.2). The measured data were compared with simulated data from Radiance. The scale building model had an atrium well and adjoining spaces. In the centre of the building, the well had a square plan of 200mm × 200mm whilst the whole building had a square plan of 500mm × 500mm. With a height of 350mm the atrium well had a WI value of 1.75, which represents a medium atrium. Four-storey adjoining spaces were set around the well and the height and the depth of each side room at each floor were 70mm and 150mm respectively. There were two different façade types: rooms with unobstructed windows and rooms with balconies on t he border of the well (balcony height = 1/3 room height). The well floor had been given three different surface reflectances: low (black), medium (grey) and high (white).

For models with balconies, the comparisons of measured and simulated average daylight factors (ADF) in rooms are indicated in Fig.3. It can be seen that, generally, the simulations are close to the measurements at the ground, 1st and 2nd floors. However, the measured data are underestimated by the simulations at the top floor, which is dominated by direct sky light. Taking the measurements as reference, the percentage differences of simulations are 18.5% (maximum), 0.06% (minimum) and 9.5% (average) respectively.

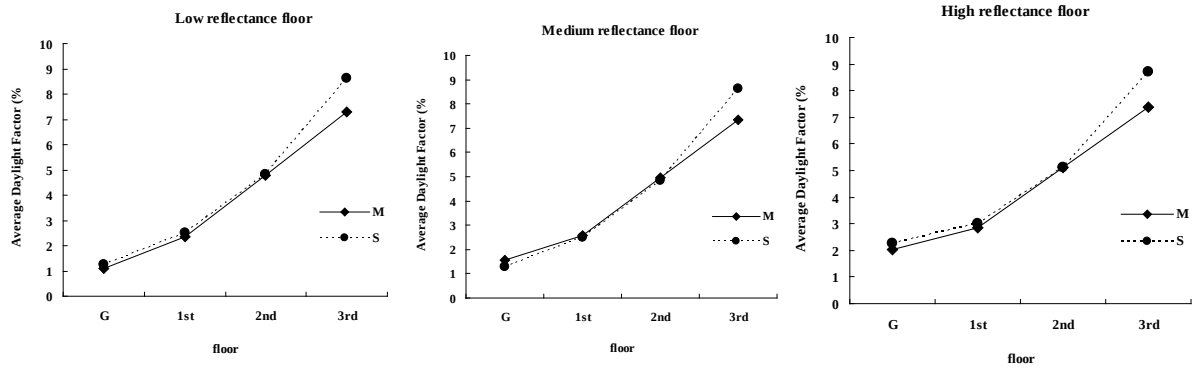

Fig. 3. Comparison of measured (M) and simulated (S) average daylight factors at each floor in a four-story atrium model with balconies.

For models with open facades, Fig.4 shows the comparisons of measured and simulated ADF in the adjoining rooms. The models without balconies have a very similar form of variation of average daylight level to the models with balconies: the top floor has a divergence between the two values; other floors have achieved a good agreement. Likewise, the three percentage divergence values are: 17.8% (maximum), 0.43% (minimum) and 8.6% (average).

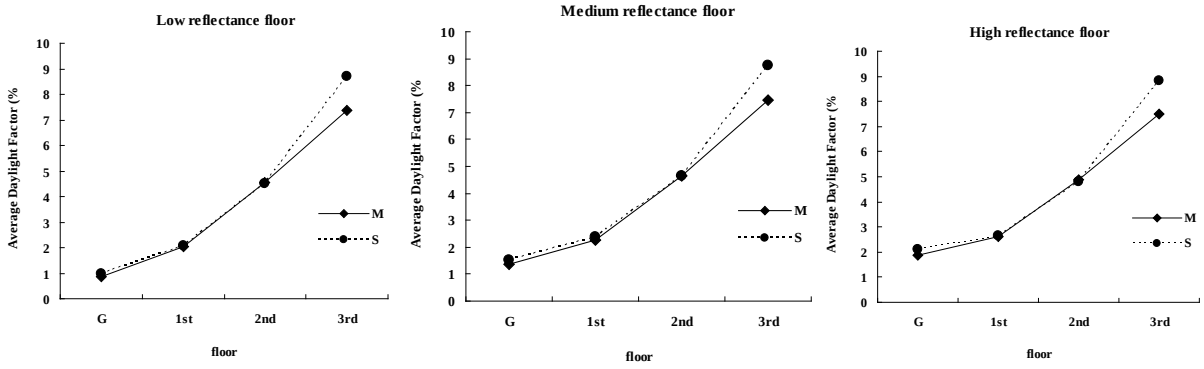

Fig. 4. Comparison of measured (M) and simulated (S) average daylight factors at each floor in a four-story atrium model without balconies.

Overall, the varying trends of the simulated data are similar to those of the measured data in the atrium models with various facades and well floor reflectances. The trends express an exponential form from the atrium base to the top. For all the models studied, the average percentage difference between simulation and measurement was less than 10% even though a few positions see a relatively larger divergence. The bigger disagreements between the measurement and simulation can be explained by the geometric and photometric deviations between the physical model and the Radiance model, which have been analysed in two earlier papers [9, 10]. In addition, the nature of some Radiance algorithms also contributed to the divergence brought by the reflected light from the lighter surfaces. In general, the Radiance simulations have been validated by the measurements in this study.

3. Daylighting performance in an atrium

Radiance was used in this section to calculate the average daylight factor in adjoining rooms of an atrium model. The ADF was used as an indicator of fundamental daylight performance in rooms of atria under CIE overcast sky conditions.

3.1. Atrium model

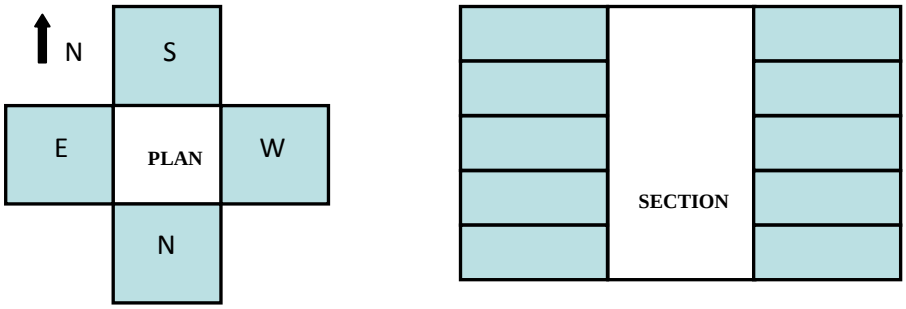

Fig. 5. Plan and section of a five-story atrium model (dark part: rooms; white part: well).

The atrium model studied consisted of a five-story building with a centre square well and four-sided rooms with the same size (Fig. 5), where N, E, S and W indicate the direction the well opening is facing. The WI value of the atrium model was 1.55, which means a medium atrium. The solid part of the well (including well floor and balcony) had reflectance values of 0, 0.2, 0.4, 0.6 and 0.8. The rooms had a fixed ceiling reflectance (0.8), wall reflectance (0.5) and floor reflectance (0.25). In addition, the models were divided into three groups in terms of the façade/balcony type - see Fig. 6 where (a) = window with no balcony (opening façade); (b) = 1/4 room height balcony; (c) =1/2 room height balcony.

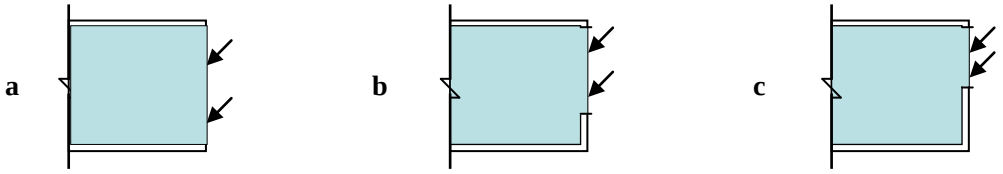

Fig. 6. Three different types of façade.

3.2. Average daylight factors in rooms

The rooms at the top floor (4th floor), middle floor (2nd floor) and ground floor were studied. Fig. 7 shows the variations of ADF in rooms at the three different heights in the atrium with various well reflectances and façade systems. Apparently, the higher balcony reduces the incident light for the rooms, giving a lower ADF. The 1/2 balcony room had the least daylight. At different floors, the daylight levels in the 1/4 balcony room are close to those in the room with no balcony, which are much larger than those of 1/2 balcony room. Interestingly, when the positions of room become lower, the differences between curves of the 1/2 balcony and the curves of the open window tended to be smaller. This implies that the impact of the balcony on ADF is decreasing near the base. On the top floor, the ADF values of rooms are not significantly influenced by the increasing well solid surface reflectances. The middle floor and ground floor, nevertheless, see that an increasing well surface increases the ADF in rooms. The lower are the floors then the slopes of the curves (reflectance as a function) are steeper. This means increased magnitudes of ADF by increasing reflectance tend to be larger at lower floors than those at upper floors, especially for the model with 1/2 balcony. For instance, the relative differences between refl0 and refl0.8 of the open window and 1/2 balcony on the top floor are 2% and 12% respectively, whilst the two values have greatly increased to 73% and

188% on the ground floor. This might be due to the fact that the main components of ADF consist of reflected light. For all models, the rooms on the top floor have the largest daylight level which decays in an exponential form toward the atrium ground (see the sub-figure at the right of the below part in Fig.7). This responds with the results of scale model measurement in section 2.

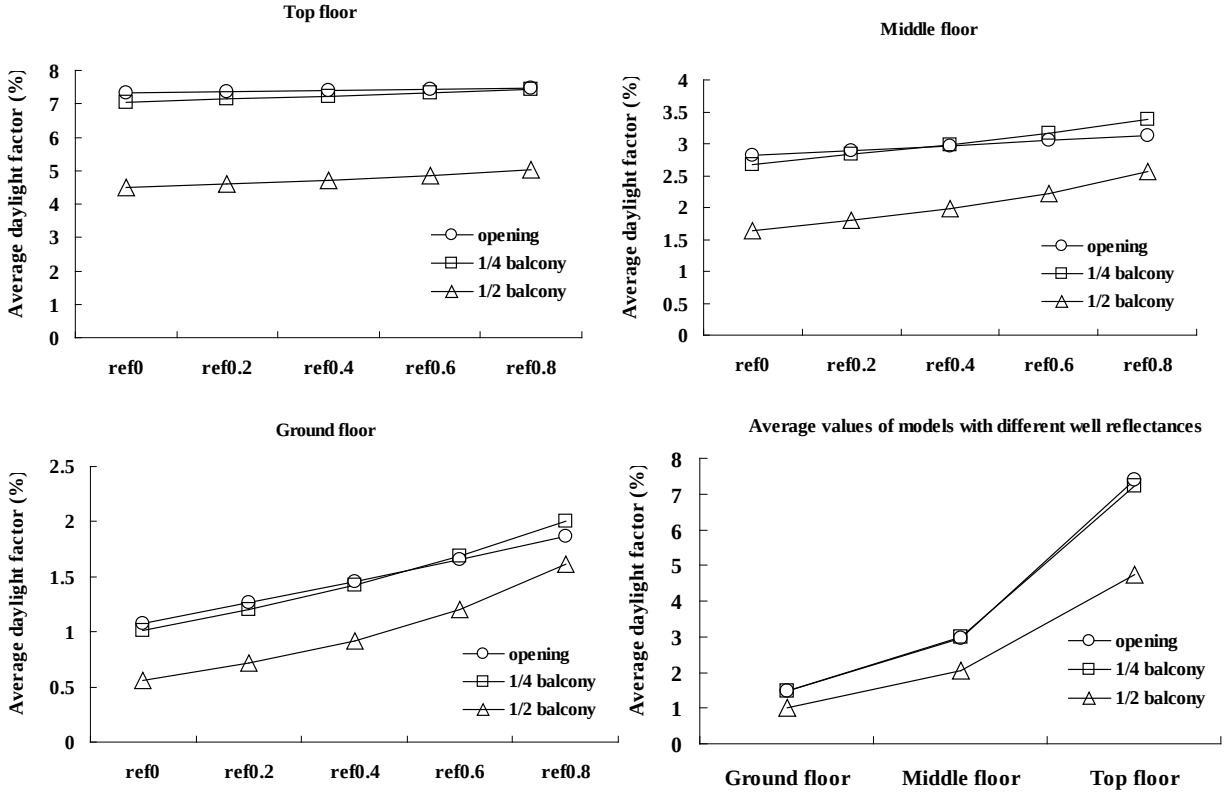

Fig. 7. Variations of ADF in rooms of different floors in an atrium with various façades and well surface reflectance.

4. Energy performance in an atrium

DaySim (using basic Radiance algorithm) [11, 12] was utilized here to predict the annual electrical lighting energy usage in adjoining rooms of the atrium model. The annual lighting consumption per unit area was used for the assessment of fundamental lighting energy performance in the daylit adjoining rooms. Based on the weather datasets, Daysim can derive the sky conditions include a large range of sky models like overcast sky, intermediate sky and clear sky [11].

4.1. Simulation preparations

The atrium model studied for energy analysis was the same as the model in section 3.1. The location of the atrium was in Sheffield, UK (Lat: 53.50′N; Lon: 1.00′E). According to Fig.5, the rooms at different sides can be named as: east-facing room (e), west-facing room (w), south-facing room (s) and north-facing room (n). The reflectances of room components were still kept the same while only a medium value 0.4 was adopted as the well solid surface reflectance. The facades followed the three types shown in Fig.6.

For lighting energy calculation, several fundamental aspects [12] were quoted as follows:
(1) Daylight savings time is from April 1st to October 31st; (2) The atrium is in an office building. All adjoining spaces are used as the working zone, which is occupied Monday through Friday from 8:00 AM to 17:00 PM; (3) A minimum illuminance level of 500 lux is

needed to support the working task of occupants; (4) The electric lighting system has been installed in the adjoining spaces with a typical lighting power density of 14.00 W/m^2; (5) The adjoining rooms do not use any dynamic shading device system and the lighting system is manually controlled with an on/off switch.

4.2. Lighting energy usage in rooms

Fig. 8 shows the annual electrical lighting energy consumptions (unit area) of rooms at the three different heights and four different sides in the atrium with various façade systems. It is obvious that generally the rooms on the higher floors have the lowest electricity load for the task illuminations in a whole year because the positions can receive the most incident daylight from the sky. The ground floor rooms are the ones which consume the most electrical lighting energy. Surprisingly, the lighting energy usage in rooms in the middle floor is just a little lower than the rooms on the ground floor while it is much larger than the top floor. Taking the east-facing side room as an example, the average annual lighting load at three different floors are 24.23 kWh/m^2 (top), 30.87 kWh/m^2 (middle) and 31.30 kWh/m^2 (ground) respectively. Considering the energy algorithm in Daysim [11], the orientations of the rooms also have some impact on the lighting energy usage. The rooms facing south or east apparently consume the less energy (28.76 kWh/m^2 or 28.8 kWh/m^2) whilst the rooms facing west and north need more electricity for task lighting (29.14 and 29.23 kWh/m^2). Interestingly, the differences between rooms with 'good' orientation and rooms with 'bad' orientation are not very large. This might be explained by a fact that the building location (Sheffield, UK) is dominated by overcast sky conditions, which has a radial symmetric sky luminance distribution [12].

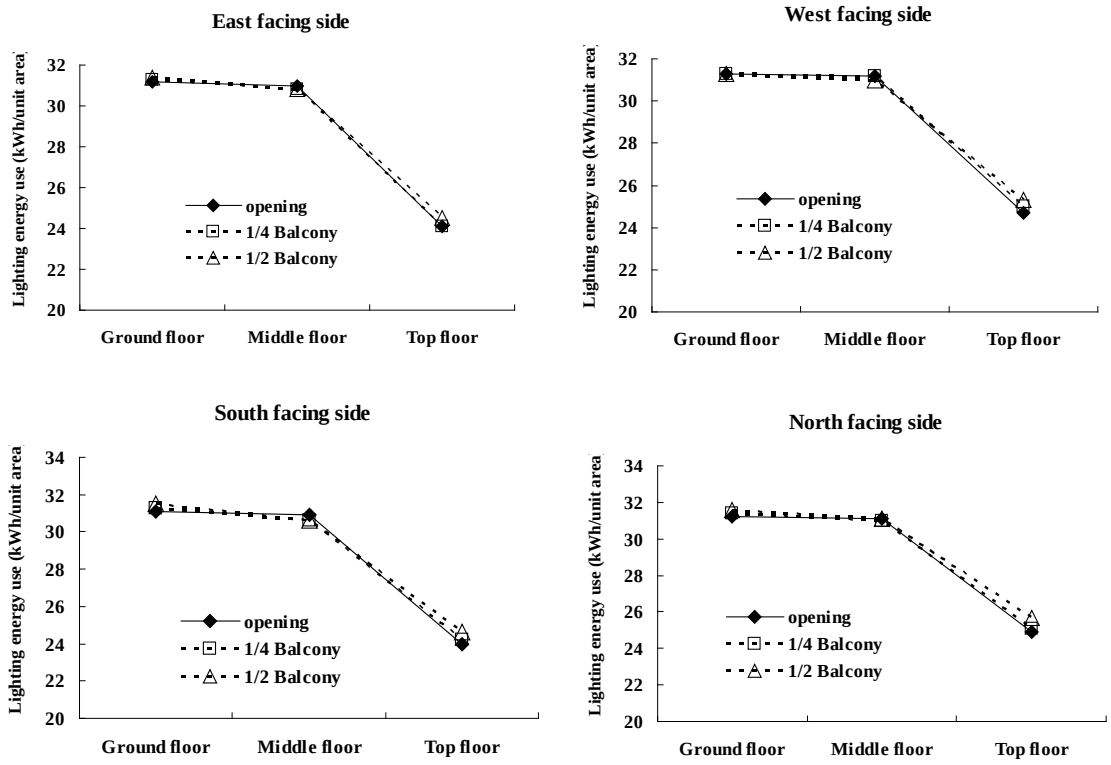

Fig. 8.Annual lighting energy consumptions (kWh/m^2) of adjoining rooms at different floors and different sides in an atrium.

Table.1 expresses the effect of façade systems on the annual lighting energy consumption in adjoining rooms. For the top floor and the ground floor, the higher is the balcony then the more is the lighting energy usage. This actually coincided with the basic daylight performance

(worst scenario: overcast sky) of rooms in section 3.2. However, the middle floor sees a different trend: the rooms with two different balconies have the same energy consumption which is less than the value of rooms with an open façade system. The trend displays a little difference from the variation of basic daylight performance (overcast sky) on this floor. It should be noted that the daylighting calculation used in the Daysim energy analysis is based on real weather dataset and the sunlight has also been included. Also, the daylight levels in the room of middle floor would be significantly influenced by the well wall, which can bring more reflected light into the rooms than other floors [3, 4]. But, the average lighting consumption in all rooms with opening façade is 28.88 kWh/m^2, while the values in all rooms with 1/4 balcony and 1/2 balcony are 28.94 and 29.12 kWh/m^2 respectively. So, increasing the balcony height generally increases energy consumption if all the rooms of in the atrium are considered.

Table 1. Annual lighting energy consumptions (kWh/m^2) and atria with various facade systems.

Floor	Side	Annual lighting consumption (kWh/m^2)		
		opening	1/4 balcony	1/2 balcony
Ground floor	E	31.2	31.3	31.4
	W	31.3	31.3	31.3
	S	31.1	31.3	31.5
	N	31.2	31.4	31.6
	4 sides average	31.2	31.3	31.5
Middle floor	E	31	30.8	30.8
	W	31.2	31.2	31
	S	30.9	30.6	30.6
	N	31.1	31	31.1
	4 sides average	31.0	30.9	30.9
Top floor	E	24.1	24.1	24.5
	W	24.7	25	25.3
	S	24	24.2	24.6
	N	24.9	25.1	25.7
	4 sides average	24.4	24.6	25.0

5. Conclusions

This study has given an assessment of daylight performance and artificial lighting consumption in adjoining spaces in an atrium model. Some findings can be drawn from the results and discussions above:

(1) There is an agreement between scale model measurements and Radiance simulations on average daylight levels of rooms in a medium height atrium. This enhances again the validation of basic Radiance algorithm in calculating atrium daylight levels.

(2) Under overcast sky conditions, the varying trend of average daylight levels in rooms expresses an exponential form along the vertical direction from the top to the base.

(3) Under overcast sky conditions, only the highest balcony can have a detrimental effect on the average daylight levels in rooms.

(4) The rooms on the top floor mainly receive direct sky light and are clearly not influenced by the variation of well reflectances; the rooms on the middle floor get both the direct

daylight and reflected daylight; the rooms at ground floor level are substantially dependent on reflected daylight.
(5) In an atrium with four-sided adjoining rooms, the rooms on the top floor need the least energy for electrical lighting; the lighting energy performances are similar for the rooms at the middle floor and ground floor, both of which are much worse than the top floor.
(6) In an atrium with four-sided adjoining rooms located in the northern hemisphere, the rooms facing east and south perform better than the rooms facing north and south in terms of the lighting energy saving through daylight usage.
(7) In a four-sided atrium with adjoining rooms, the well facade consisting of the higher balconies and open windows would generally have a more negative impact on lighting energy saving in rooms than the open facades or facades with lower balconies (façade types in fig. 6).
The limitations of the study are: (i) only the model with a square plan was analyzed, whose four sides were the same length; (ii) the façade configurations were relatively simple and no glazing has been considered in the models; (iii) the energy calculations are just focused on a site with a simple cloudy sky condition with little sunlight involved. Future work will focus on models with a broader range of geometries, more complicated well facades and a variety of sky luminance conditions at typical climate zones around the world.

Abstract: In this paper the authors present the results of a numerical analysis concerning the study of daylight transmission and thermal comfort in underground areas and basements of a building without any direct openings toward the external environment. The study was carried out on a two-level building, illuminated by the "Double Light Pipe" (DLP), an innovative technological device developed in the Laboratory of Technical Physics, Faculty of Architecture, Pescara, Italy.

The DLP consists of two concentric pipes of different diameter, able to illuminate both the final room and the intermediate one and to allow the entry and the extraction of the air inside the environments of life.

In this first phase, the authors carried out a numerical analysis by the soft-wares RADIANCE and ECOTECT with the aim to define the illuminance distribution in the intermediate room illuminated by the DLP in standard conditions of sky; in addition the CFD code FLUENT/AIRPACK is employed with the aim to define the thermal comfort level considering external wind condition, air temperature and solar radiation. The indoor air temperature and velocity, mean age of air and the indexes PMV and PPD have been evaluated so verifying the indoor air quality.

Keywords: *Light pipe, Lighting, Daylight, Indoor air quality, Numerical analysis*

1. Introduction

Buildings use almost 40% of the world's energy [1] and artificial light is responsible of a significant part of the whole energy consumption of a building. A considerable reduction of energy consumption is achieved when natural light inlet is optimized and this can be achieved both by traditional sources, as windows or skylights, or by technological devices, as light pipes [2, 3]. The latter are particularly suitable in underground areas of buildings, in large commercial or industrial buildings, with windows placed on perimetral walls away from the centre of the room, or in exhibition rooms, museums or similar, where a particularly diffuse light with not too high illuminances on the work plane and a uniform luminance distribution of walls are preferred in order to guarantee a correct perception of the work of arts, particularly paintings on display. Moreover underground areas or rooms without any direct interface outwards need mechanical ventilation systems to make the necessary change of air in order to realize comfortable conditions for the occupants. In this paper the authors address the problem and propose a solution which is the Double Light Pipe (DLP), an innovative technological device recently developed in the laboratory of Technical Physics of Pescara [4, 5]. The DLP is an evolution of a traditional light pipe. The latter transport daylight from the collection point, commonly on the roof top of the building, trough the ceiling to the final rooms where it is distributed by a diffuser [6, 7]. When an intermediate area has to be crossed by the system, its encumbrance makes it a problem to position the device in the centre of the passage room. The idea is to give the system an illuminating function both for the destination room and the passage area. In this case it becomes acceptable indeed desirable, particularly in wide plant area rooms such as museums or exhibition areas, in which a high quality light, characterized by low illuminances on the work plane and quite a uniform distribution of luminances of the walls, is requested. In this paper the authors present the double light pipe modified in its geometric configuration in order to allow an efficacy circulation of air in the

passage room able to effect the necessary change of air requested for the comfort of the occupants. This is a ventilated double light pipe, whose performances have been analyzed in the Laboratory of Technical Physics of Pescara through a numerical analysis, by which the thermal and visual comfort level are realized in a large area room without any direct interface to outwards, by the ventilated double light pipe.

2. Methodology

A numerical analysis was carried out by the authors: the soft-wares RADIANCE and ECOTECT were used with the aim to calculate the illuminance distribution in the intermediate and final room illuminated by the DLP in various standard conditions of sky. The CFD code FLUENT/ AIRPAK [8] is employed to determine the values of the parameters by which the thermal comfort level for the occupants can be defined, depending on external wind condition, air temperature and solar radiation. In particular, by means of the numerical tool, the indoor air temperature, air velocity, mean age of air and the indexes PMV and PPD have been evaluated in order to verify the indoor air quality. [9]

2.1. Description of the test room

The test room modeled by the sw is a two levels square modular form. Each level consists of a 12x12 m plant area room, 4 m high, in which four ventilated double light pipes are installed, able to introduce daylight both in the passage and the final level, while natural ventilation is achieved in the passage room thanks to openings properly applied on the top and the bottom of the pipes. In Fig. 1 a three-dimensional representation and a cross section of the device are shown. The DLP described in [4, 5] is modified in order to allow the air circulation in the room. The inner pipe is narrow at the top and the outside is narrow at the bottom, so the air cavity between the two concentric pipes has a convergent section at the bottom for the introduction of air and the inner pipe has a convergent section at the top for the extraction of air. In the test-room four DLP are installed, two for the extraction and two for the introduction of air. At the top and the bottom of each DLP openings are properly realized in order to allow air introduction and extraction from the environment.

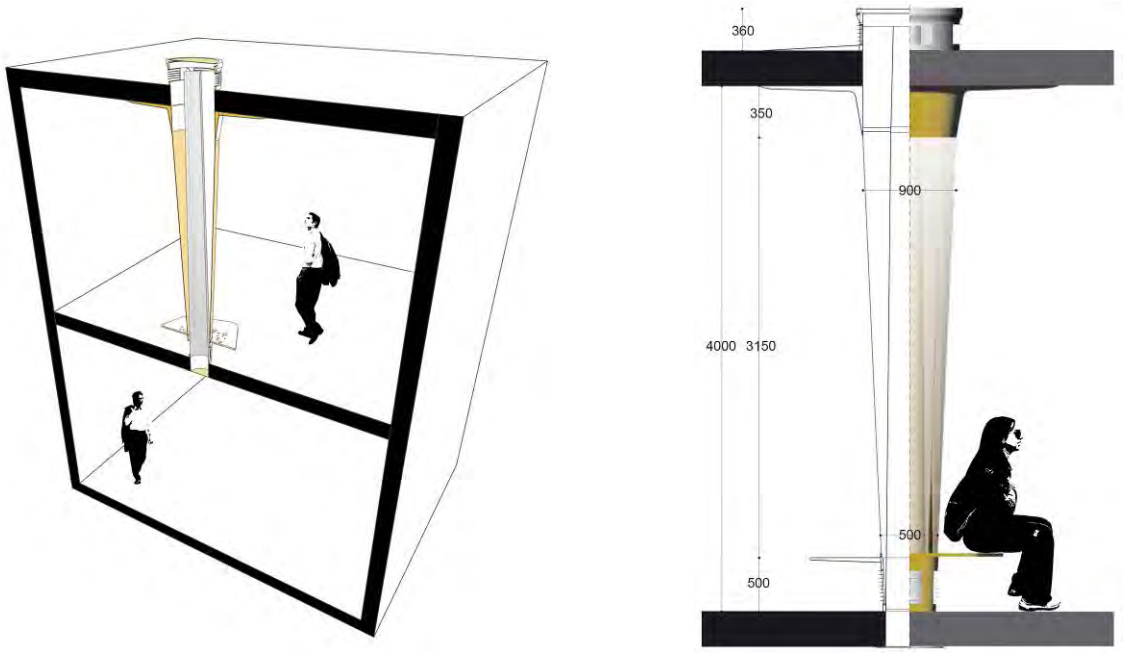

Fig. 1. A three-dimensional representation and a quoted section of the Double Light Pipe

3. Daylight results

In Fig. 2 the daylighting levels distribution on a 0,8 m high horizontal work plane by the sw Ecotect is illustrated on December the 21st under CIE Overcast sky (a) and on June the 21st under CIE Clear sky (b) .

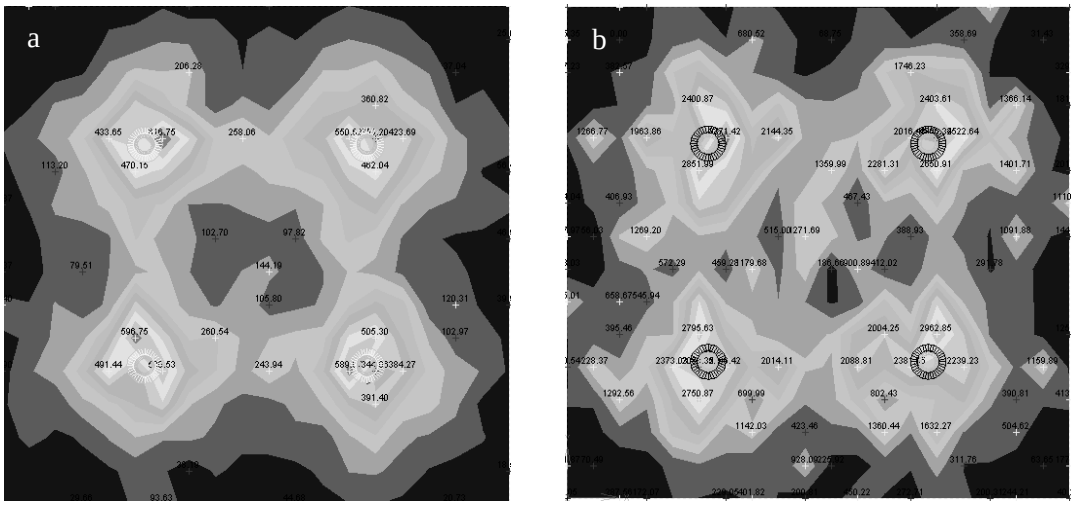

Fig. 2. Daylight Illuminance (lux) by Ecotect in Winter (a) and Summer (b) conditions

In Figg. 3 and 4 the luminance and illuminance data by Radiance are shown, respectively in winter and summer conditions. In the first case, the simulation is effected under Overcast sky on December the 21st , while, in the second, under Clear sky on June the 21st.

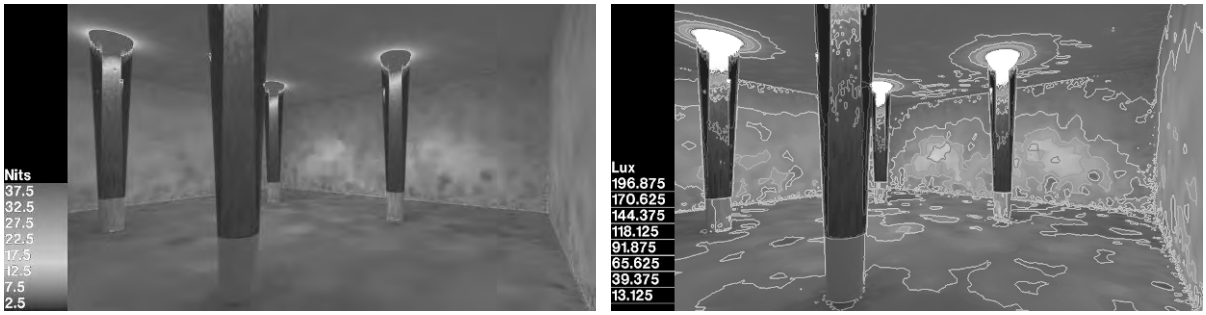

Fig. 3. Daylighting simulation by Radiance in Winter condition

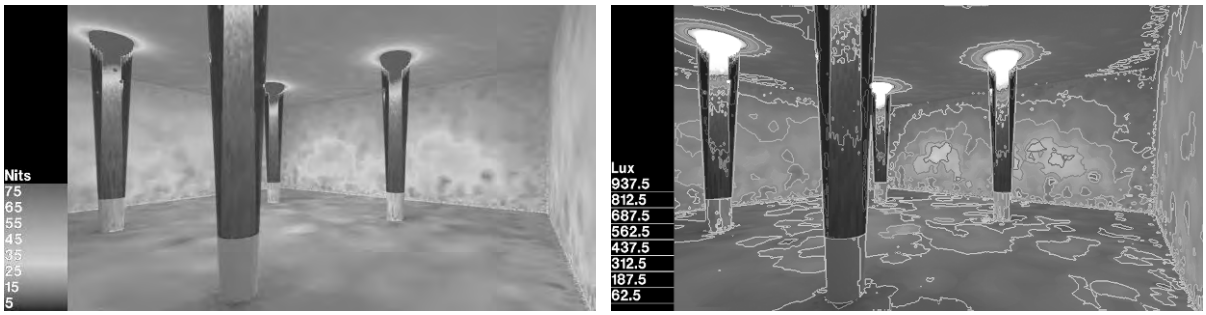

Fig. 4. Daylighting simulation by Radiance in Summer condition

4. Thermal comfort results

The numerical analysis was carried out by Fluent/Airpak in steady state summer and winter conditions. The following results regard the test on September the 16th at 13 a.m. with the following boundary conditions:

External air temperature: t_{ext} = 27°C;
Mean radiant temperature t_{mr} = 27°C;
Mean internal surface temperatures of floor, t_f = 25°C
Mean internal surface temperatures of walls t_w = 26°C
Mean internal surface temperatures of ceiling t_c = 26,5°C
Inlet air velocity close to the vent 1 and 2: v_{in} = 3 m/s;
Surface temperature on the polycarbonate collector: t_g = 36°C.
The external air temperature was experimentally measured at the same time, while a higher temperature of the collector was imposed to take into account the solar radiation heating.
In Fig. 5 a qualitative trend of air introduction and extraction by the device is shown. Each DLP can function as an extraction or introduction system. In the extraction pipe the inner tube is open at the top and the bottom, and the air cavity is closed, while in the introduction pipe the air cavity is open and the inner pipe is closed.

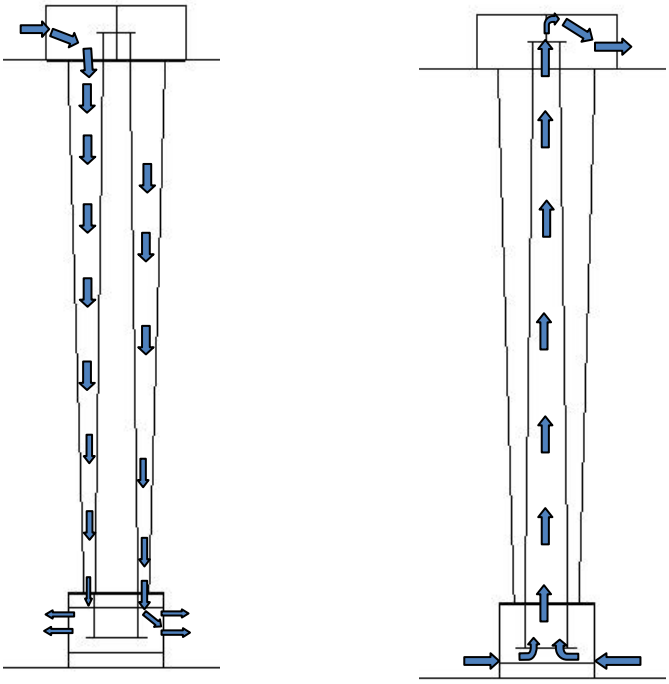

Fig 5. Qualitative Air circulation through the two DLP in the room

In Fig. 6 (a) the air speed distribution on a horizontal plane 1,6 m high on the floor is shown: a good uniformity is verified in the room. In Fig. 6 (b) the air speed distribution is calculated on a vertical cross section 1 m distant from to the extraction DLP. This last image underlines higher values of speed in correspondence to the openings used for the air circulation. However the air speed is comfortable in the whole environment, with very low values everywhere in the room as confirmed by Fig. 7 (a). The Fig. 7 (b) shows the air temperature on a vertical plane vs the height on the floor. It is evident that a low vertical gradient of temperature is obtained. Fig. 8 confirm this trend.

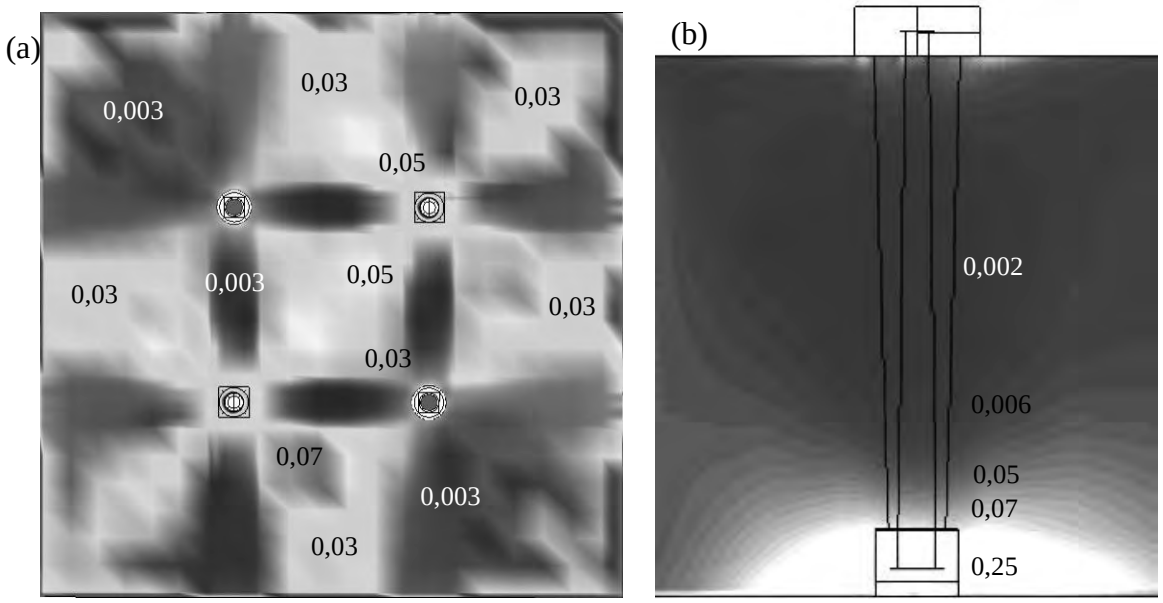

Fig 6. Air speed distribution (m/s) on a horizontal plane 1,6 m high on the floor (a) and on a vertical plane 1 m distant from the DLP (b)

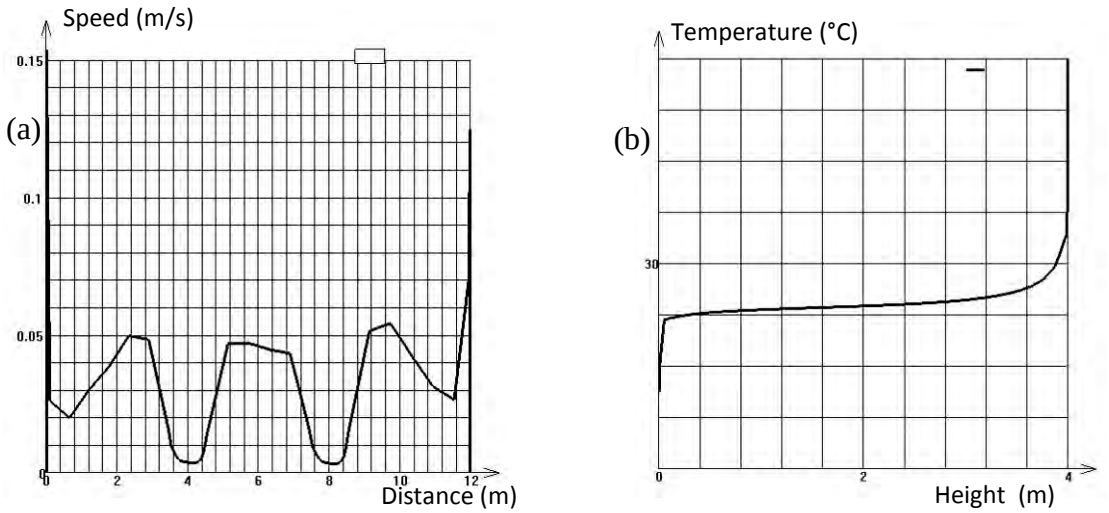

Fig 7. Air speed vs distance from wall to wall at the centre of the room on a horizontal plane 1,6 m high on the floor (a); air temperature vs height exactly at the centre of the room (b).

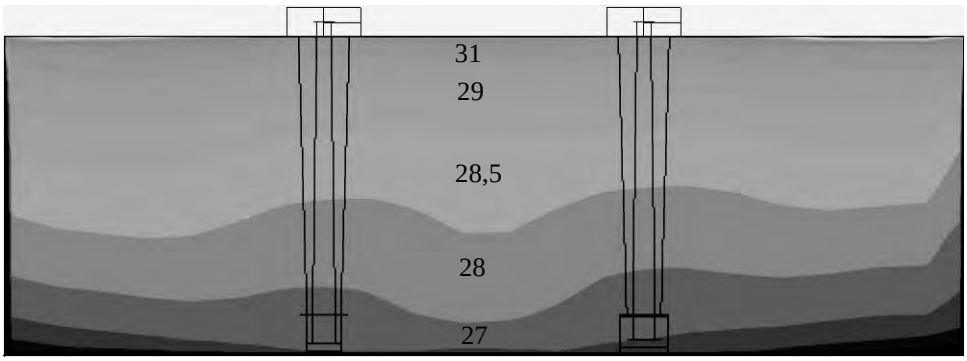

Fig. 8. Air temperature field (°C) on a vertical cross section at the centre of the room

The predicted mean vote (PMV) is commonly used as a measure of the average response about thermal comfort from a large group of people voting on a range included between -3 and +3. In this work the PMV has been calculated on a reference horizontal plan in the room and the results are shown in Fig. 9. A satisfactory condition is obtained considering that the PMV is very uniform and close to the optimum value 0. This is confirmed by the predicted proportion dissatisfied (PPD) index which provides a measure of the percentage of people who will complain of thermal discomfort in relation to the PMV. In this case it is about 13-14 % as shown in Fig. 10. The PMV and PPD are evaluated considering a metabolic rate level of 1,6 met and a clothing level of 0,9 clo.

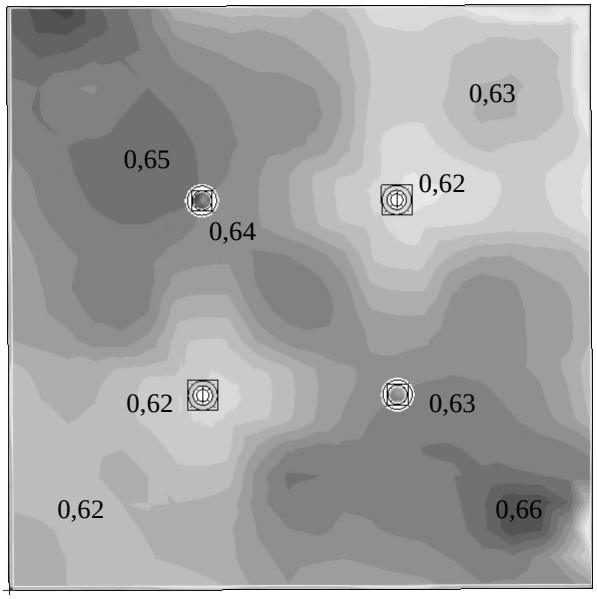

Fig. 9. PMV index distribution on a horizontal plane 1,6 m high on the floor

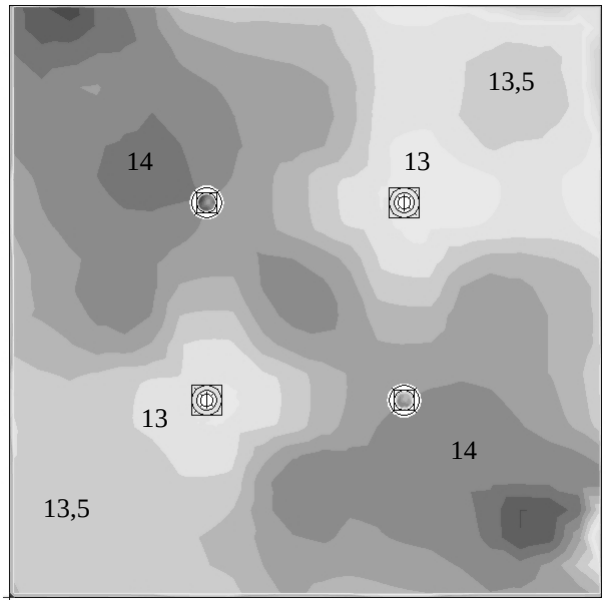

Fig. 10. PPD index distribution (%) on a horizontal plane 1,6 m high on the floor

In Fig. 11 the mean age of air distribution calculated by the numerical tool on a horizontal plane 1,6 m high on the floor is shown. It is obviously higher in the corners of the room and very low in correspondence of the DLP where the change of air is very efficacy, but in the whole environment the air change seems to be very comfortable.

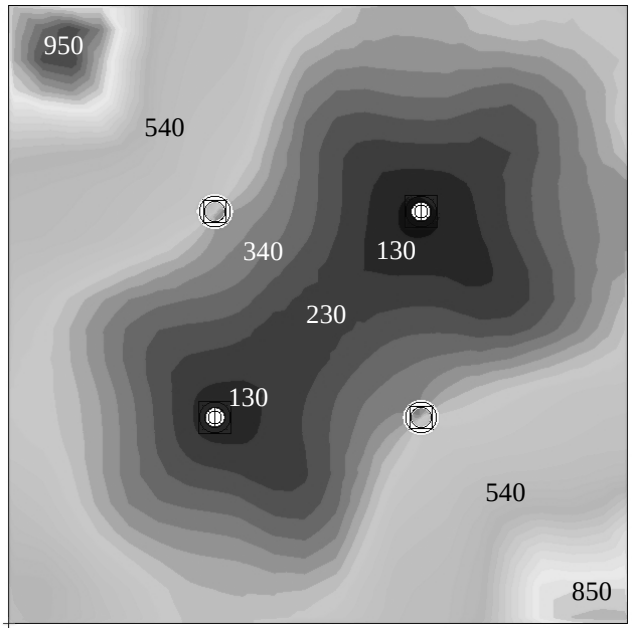

Fig 11. Mean age of air distribution (s) on a horizontal plane 1,6 m high on the floor

The results obtained in winter conditions are similar to the summer ones about the indoor air speed field, but with higher values. On the contrary the indoor temperatures are obviously very different, as shown in Fig. 12. In winter condition the thermal comfort is not assured due to the absence of a thermal plant.

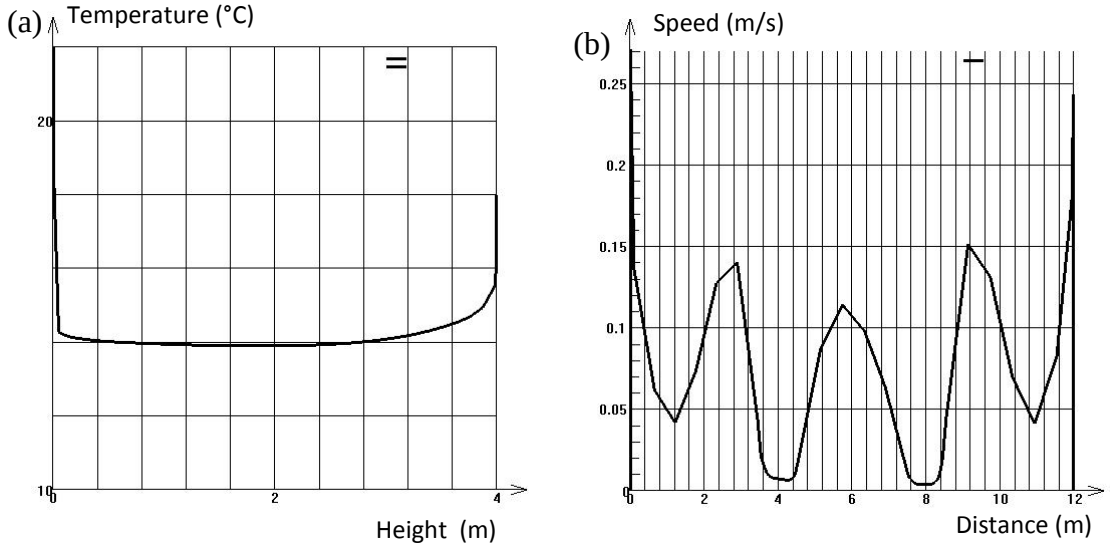

Fig 12. *Air temperature vs height exactly at the centre of the room (a); air speed vs distance from wall to wall at the centre of the room on a horizontal plane 1,6 m high on the floor (b) in winter conditions.*

5. Conclusions

The DLP previously developed by the authors with the aim to distribute daylight in a two/level underground building has been modified in order to allow the air circulation in the upper level necessary to ensure the thermal and hygienic comfort for the occupants. The first numerical results show how the Ventilated Double Light Pipe can be successfully used both to introduce daylight and to allow natural ventilation in the room. It is suitable for large area

exhibition rooms or museums due to its encumbrance and the features of daylight distribution in the environment. Quite uniform illuminace data with low luminances of the boundary walls of the room is realized, except for the higher portion of the system which is characterized by high luminances with the risk of glare. The authors are developing a solution for this problem, using a diffusing film applied on the upper portion of the system, but this work is chiefly devoted to demonstrate the capacity of the system to be employed as a tool for the air change of the room. The first results encourage the authors to carry on the work. Transient numerical analysis has to be carried out in order to simulate the behavior of the system with various external conditions of wind velocity and test its capacity of making an efficacy change of air of the room.

Abstract: In this paper the authors present the first experimental results about the natural ventilation obtained by a device called Ventilated Illuminating Wall (VIW), which carries out the function to introduce natural light in underground areas or that don't have facing outwards, contemporarily operating in the same areas a natural ventilation effective action necessary to guarantee thermal comfort and healthy conditions to the occupants.
The VIW is represented by a 1:1 prototype scale model, constituted by a precast removable manufactured product set to a window of a room. Such device is able both to transport the natural light, captured by the coverage, in underground areas and to introduce outside air for the required ventilation through the vents positioned both inside the room and in the retaining structure of the coverage.

Our study's objective is to verify experimentally, through air speed measurements in different points, if in every condition the indoor air quality is guaranteed.

The results about daylight performances of the system are satisfactory; besides they show that the VIW is able to assure a significant natural air ventilation, but the thermal analysis can be improved measuring the air mass flow rate and the comfort parameters for the occupants.

1. Introduction

Buildings are often equipped by underground areas in which the absence of natural light and ventilation create uncomfortable conditions for human activities. In many cases mechanical ventilation and artificial light are used to ensure comfortable conditions for the occupants. It is known that buildings use almost 40% of the world energy [1] and, obviously, a meaningful part of the whole energy consumption of an edifice is due to artificial light and mechanical ventilation of underground rooms.

Moreover, the case can be considered of buildings utilized as museums, exposition rooms or similar. These spaces need a particularly soft luminance distribution, avoiding direct solar radiations from windows or skylights or very intense reflections from shiny surfaces that may be present in the environment, which can generate the risk of glare. Besides, the paintings on display can be sensitive to light and deteriorate in the presence of high values of illuminance. Usually in museums or exhibition rooms low illuminances are preferred over the illuminated surfaces because, in this case, a favorable balance of luminances is more easily obtained between the visual task and its background.

For these reasons, in these cases any direct interface to outdoor environment through traditional windows or skylights is often avoided and artificial light is adopted all the time. The absence of windows and skylights makes it impossible natural lighting and ventilation. On the other hand it is known that the enjoyment of works of art is better in the presence of natural light than in the absence of it, and a significant energy saving can be achieved by using natural light instead of artificial light. Taking into account that every effort must be made in order to reduce energy consumption of buildings, many technological systems have been applied in architecture with the aim to ensure comfortable conditions for the occupants, concurrently providing a significant energy saving. In recent years many technical devices,

such as light pipes and similar, have been proposed with the aim to introduce natural light in areas without direct interface with outwards and many papers have been published in order to explain the way to design tubular light pipes or similar technological devices [2, 3, 4, 5] .

In some cases light pipes are equipped with technological systems able to ensure air extraction from the room in which they are installed [6]. In this work the authors present an innovative device able to capture daylight from a transparent horizontal surface on the top of the device and redirect it into the room, and simultaneously allow the introduction and extraction of air. This device, called Ventilated Illuminating Wall (VIW), was built in real scale and experimentally tested in order to verify its lighting and air circulation performances, in order to reduce the use of electric light and mechanical ventilation and so diminishing the energy request of the building.

2. Description of the V. I. W.

An innovative technological system was developed by the authors named "Ventilated Illuminating Wall (VIW)". Moving from the idea of building an apparatus able to introduce daylight in underground areas or rooms without direct interface to outdoor, simultaneously ensuring the necessary air circulation, the authors developed a multilayer boundary wall, equipped with a glass plate cover on the top able to capture daylight and a vertical interspace internally covered by a highly reflective film (3M Radiant Mirror Film) by which light is redirected to a transparent surface, like a window, and introduced into the room.

Thanks to a second exterior vertical air cavity, which allows the greenhouse effect in presence of thermal solar radiations in the case of not underground buildings, and fifteen openings with wire mesh properly practiced on the walls, air is allowed to circulate for extraction and introduction in the room so creating an effective air change able to ensure internal comfortable conditions for the occupants. The Ventilated Illuminating Wall is particularly suitable in large exposition areas, which don't have facing outwards and need diffuse light, avoiding glare phenomena which occur when intense direct light from windows comes towards the illuminated surfaces.

3. Methodology

An experimental analysis was carried out on a 1:1 prototype scale model of the V.I.W. The tests were carried out by measuring internal and external illuminance, wind velocity and direction, and internal air velocity in various positions of the room: near the air inlet and outlet vents and in the centre of the room.

3.1. Experimental apparatus

The test room is a 5x3 m plant area room, 2,7 m high. The V.I.W. is constituted by a precast removable manufactured product placed against the window in the north-west wall perimeter of the room. In Fig. 1 some pictures of the system are shown taken during successive stages of its construction: an iron frame was applied against the window on the perimeter wall of the laboratory (a, b); an air space was created between the window and the first opaque layer, which consists of a 4 cm black painted polystyrene panel which gives the necessary thermal insulation and improves the greenhouse effect in the second vertical hole. This last is a 10 cm air space between the polystyrene panel and the external 1 cm transparent polycarbonate panel applied on a second iron frame (c). On the top of the system a glass plate cover is applied which allows daylight entering the room (d).

Fifteen openings with wire mesh allow the natural air circulation necessary to ensure favorable hygienic conditions in the room. The internal ones are shown in Fig. 1 (e) and the external in Fig. 1 (f), where the final configuration of the apparatus is shown.

Fig. 1. Realization steps of the VIW.

The experimental line used to carry out the analysis consists of four CIE Lux-meters sensors, range 0-25 klux, accuracy 3% of the reading value, for the internal illuminance, a CIE sensor range 0-100 klux, tolerance 1.5 %, for the external illuminance, a data-logger with 20 inputs, by which data are registered and elaborated; three internal hot wire anemometers, range 0-20 m/s, accuracy 0,01 m/s, 1%; one tacho-gonioanemometer with direct output.
In Fig. 2 a section of the device with a description of the principal components of the V.I.W. and a quoted section of the system are shown.

3.2. Description of the experimental test conditions

The experimental tests were carried out positioning the sensors in the room as represented in Fig. 3, in which a plant and a section of the room are shown with the position of each sensor.
The tests were carried out in summer and autumn conditions. Air temperature was measured in positions 1, in the center of the room, and in positions 2 and 3, close to the wire mesh applied on the inferior and superior openings. In the same positions air velocity was measured, while illuminance was measured in positions 4, 5, 6 and 7 (Fig. 3).
On the roof top of the building, close to the transparent glass covering plate by which light is collected from the sky, the external lux-meter and the tacho-gonioanemometer dedicated to measure wind velocity and direction were positioned.

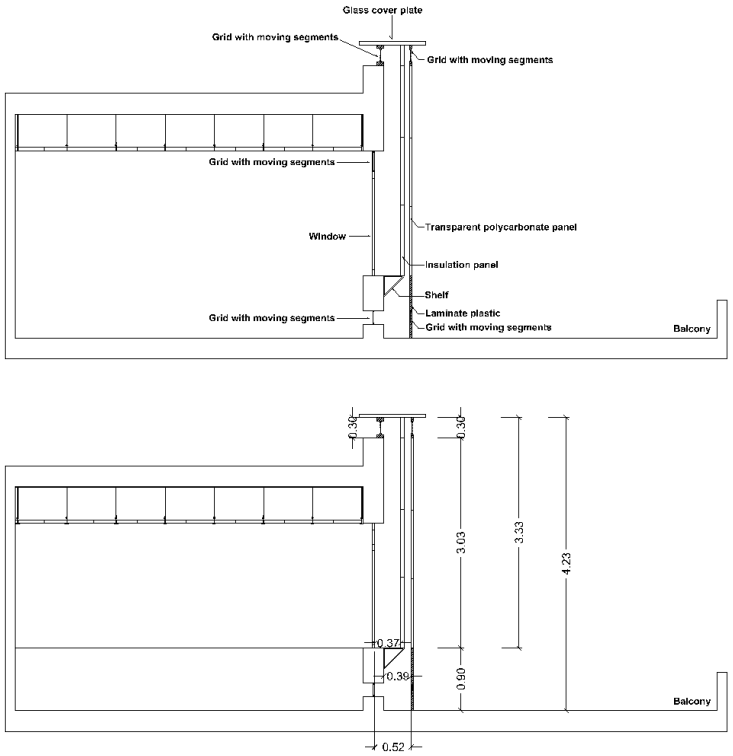

Fig. 2. Sections of the VIW.

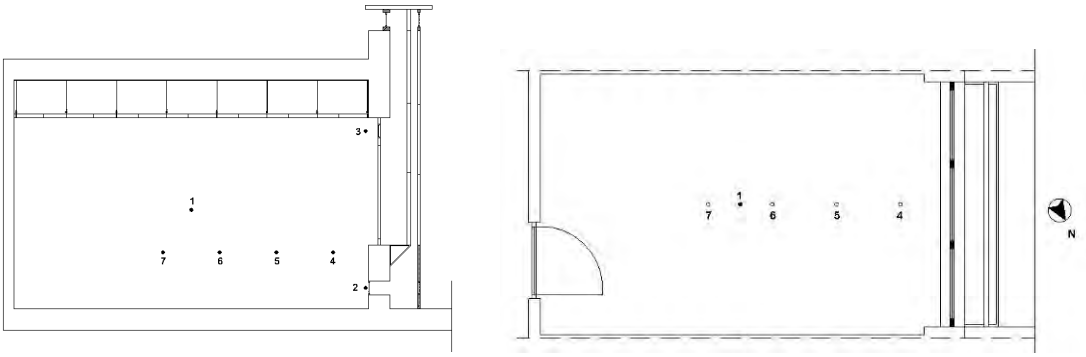

Fig. 3. Section and plant of the test room with the measure positions

4. Results

In Fig. 4 illuminance data measured on September the 16th are shown. External illuminance is referred to the right axis while the ratios between internal and external illuminance in the measure positions are referred to the left one. In this case, with a very regular trend of external illuminance, the influence of the V.I.W. on internal distribution of illuminance is significant up to quite 2 m from the system for a large range of daytime, but in the morning some very high pick values are verified in positions 4 and 5 close to the V.I.W and the influence of V.I.W. is meaningful also in positions 6, quite 3 m distant from the VIW, as shown in table 1, thanks to reflections directly coming from the Radiant Mirror Film.

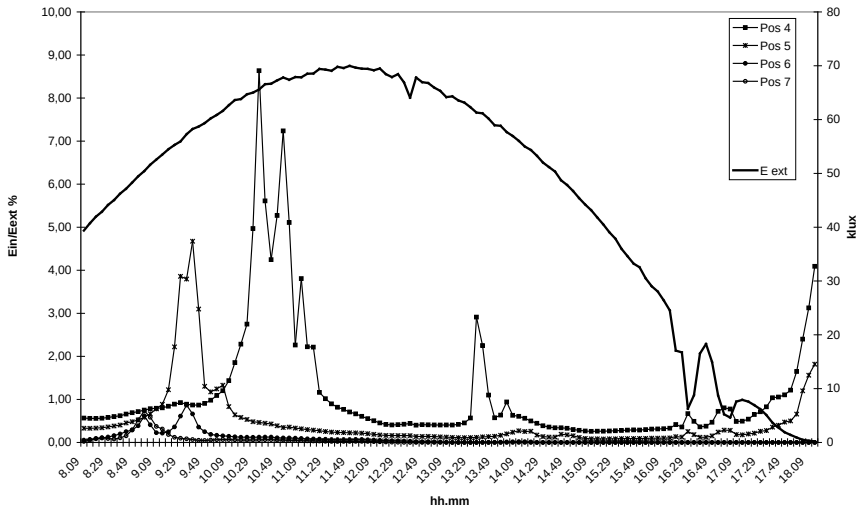

Fig. 4. Illuminance data in positions 4-7 on September the 16th

Table 1. Minimum, Medium and Maximum illuminance data in positions 4-7, on September the 16th

	Pos. 4	Pos. 5	Pos. 6	Pos. 7
Minimum (lux)	9	4	0	0
Medium (lux)	572	222	46	24
Maximum (lux)	5664	2722	497	372
Distance from V.I.W. (m)	0,5	1,3	2,1	2,9

In autumnal conditions, with lower and less regular external illuminance, in the measure positions a similar situation is verified, but pick values of illuminance in the morning are absent and the influence of the system to internal illuminance is significant up to 2 m from it, as shown in Fig. 5.

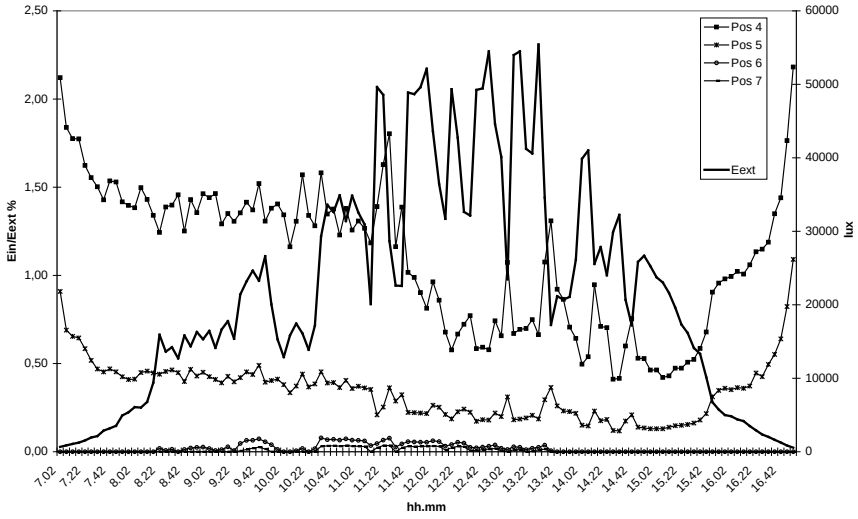

Fig. 5. Illuminance data in positions 4-7 on November the 5th

The natural ventilation allowed by the V.I.W. permits the necessary change of air in the room and different ways are traced in summer (night and day) and winter conditions. In the design phase the authors provided for the behavior of the system as shown in Fig. 6 in which a representation of expected natural ventilation in summer and winter is shown, obtained by

different configurations (close/open) of the openings. In particular, the Fig. 6 (a) shows the expected natural ventilation in daily summer condition, while Fig. 6 (b) the expected natural ventilation in night summer and in winter (night and day) conditions.

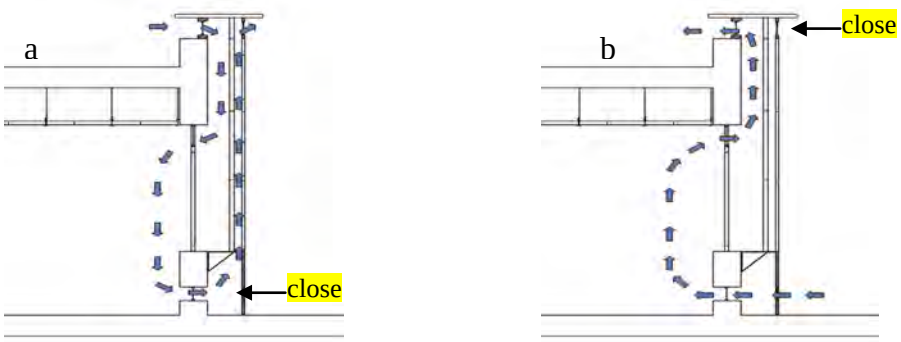

Fig. 6. Natural ventilation in daily summer conditions (a), night summer and winter conditions (b) .

In Fig. 7 data of wind direction and velocity on September the 17th are shown. Higher speeds are verified from 9 am to 5 pm with a medium wind direction angle from North of about 97°, while a medium value of about 158° is verified in night conditions, just favourable for a good air circulation. All the summer tests carried out confirm this trend, that can be considered representative of summer conditions.

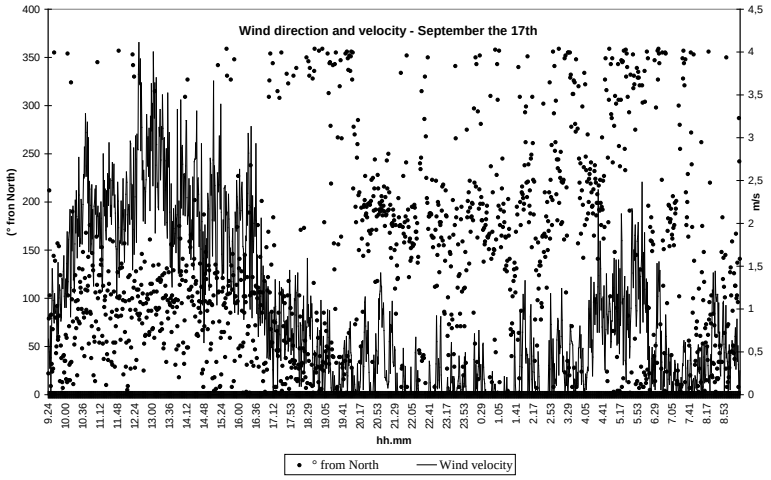

Fig.7. Wind direction and velocity on September the 17th

In Fig. 8 air speed is shown on September the 17th, measured in positions 2 and 3 close to the air inlet and outlet vents. Table 2 shows minimum, medium and maximum data. During the day the vent 2 is the outlet opening and the 3 is the inlet one, while at night the reverse situation occurs. In the centre of the room (position 1) air velocity is less than 0,03 m/s all the day with a mean value of about 0,005 m/s, while in night conditions the maximum value is the same with a lightly higher value of the mean velocity, of about 0,007 m/s.

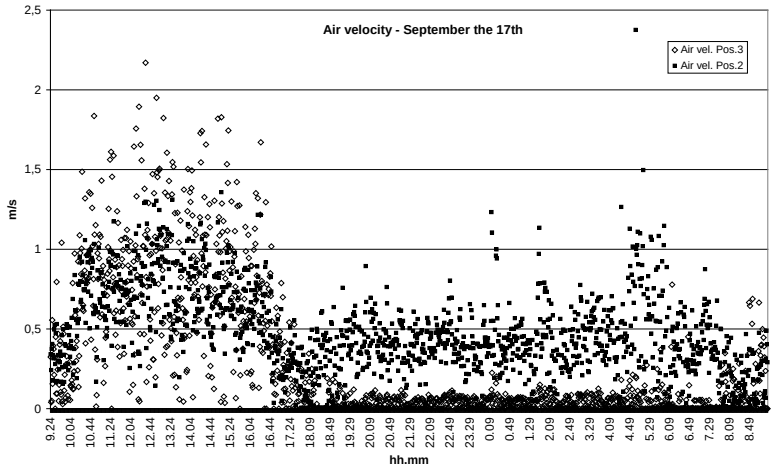

Fig. 8. Inlet and outlet air velocity on September the 17th

Table 2. Minimum, Medium and Maximum air velocity in positions 2 and 3 on September the 17th

	DAY		NIGHT	
	Pos 3 - inlet	Pos 2 - outlet	Pos 2 - inlet	Pos 3 - outlet
Min. air velocity (m/s)	0	0,021	0	0
Med. Air velocity (m/s)	0,7	0,64	0,39	0,05
Max. air velocity (m/s)	2,17	1,36	2,38	0,78

In Fig. 9 data about wind direction on November the 5th are shown. In daily conditions from 10.30 am and 6.30 pm the medium wind direction angle from North is 132°, while a medium value of about 195° is verified in night conditions. This is a less favourable situation than in summer, particularly in daily condition, nevertheless the VIW seems to assure acceptable performances also in this case, thanks to an efficacy stack effect.

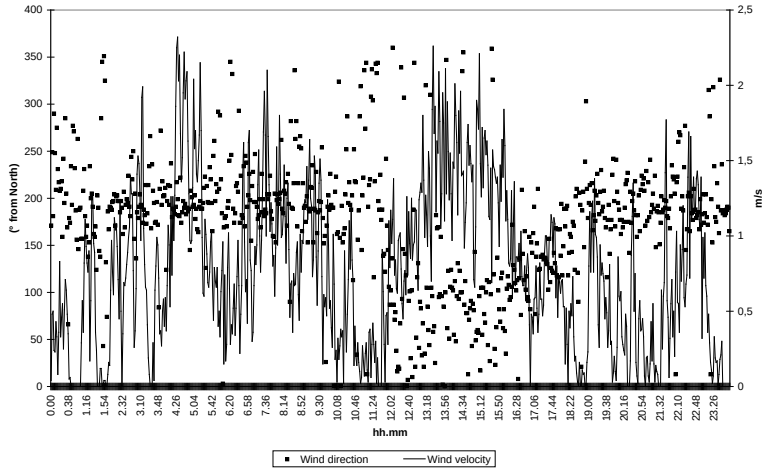

Fig. 9.Wind direction and velocity on November the 6th

In Fig 10 air speed in positions 2 and 3 are shown with winter configuration of openings. During the day the inlet and outlet air speeds are similar because they are only influenced by the difference of temperatures between internal and external environments, while during the night a more favourable wind direction allows to obtain higher values of inlet air velocity.

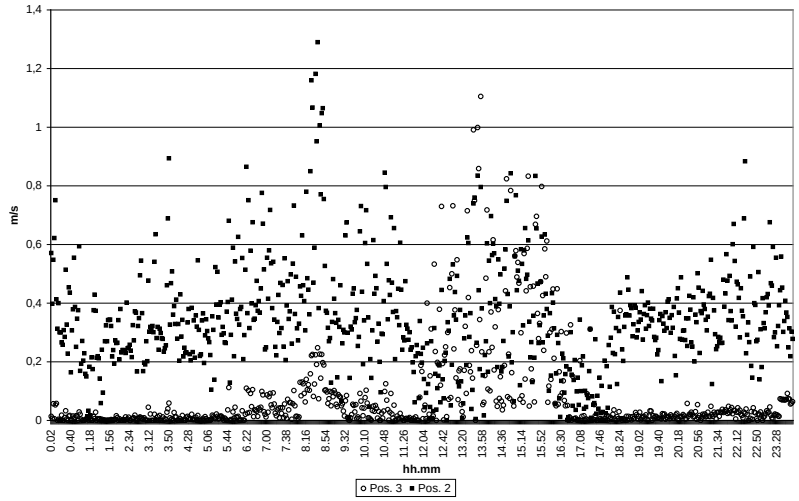

Fig. 10. Air velocity on November the 6th with winter configuration of openings

5. Conclusions

The V.I.W. is a new daylight technological device able to make also an efficacy natural ventilation in underground areas of buildings or rooms without direct outward interface. The building steps of the V.I.W. are described and the first experimental data of indoor illuminances and air speed are shown. The V.I.W. seems to allow an efficacy change of air of the test-room, although the mixing of air does not probably involve the whole environment. The daylighting efficacy is completely satisfactory in presence of high external illuminance, but must be improved with low external illuminance, by an efficient cleaning of the reflective film. The continuous monitoring the V.I.W may prove its efficacy in terms of energy saving and the spin-off uses of the system, particularly in museums or large exhibition rooms in which it may be used together with traditional or double light pipes.

Abstract: The authors propose a comparison among the first experimental and numerical results of an analysis carried out about the theme of the natural ventilation and the energy efficiency relatively to a device called Ventilated Illuminating Wall (VIW). The VIW is represented by a 1:1 prototype scale model, constituted by a precast removable manufactured product set to a window of the room, able both to transport the natural light, captured by the coverage, in underground area, and to introduce outside air for the required indoor ventilation. The experimental data, object of a work previously carried out, are obtained from temperature and air speed measurements in different points inside the tested room.

Based on some meaningful environmental parameters, internal and external temperature of the building, direction and wind speed in different times of the year, the device performances are evaluated through the software Fluent/Airpak, able to make fluid dynamics modeling and simulations, with the aim to calculate the air flow rate distributions, air speed and temperature field inside the room. The numerical analysis is carried out in steady state condition and produces results that, sometimes, are overestimated with respect to experimental ones. The results may be improved by a transient analysis.

1. Introduction

The energy consumption of buildings takes a significant role in the energy question, because buildings are responsible of about 40 % of the whole world energy demand [1]. In buildings in which underground areas are present the energy consumption is increased because they need to be artificially enlighten and ventilated. Particularly mechanical ventilation is generally adopted in these cases. Moreover, when internal environments of buildings are used as museums or exhibition rooms, they need a particularly uniform luminance distribution of the walls with low illuminances all over the work plane in order to allow the correct perception of works of art on display, particularly in the case of paintings, with the right contrast of luminances between the visual task and the background, avoiding the risk of glare. Since this risk is often present when natural light is introduced in the room through traditional daylight sources, for the presence of intense direct solar radiations that can be reflected by shiny walls, in these cases it is better avoiding natural light entering through windows or skylights and technological daylight systems, as light pipes or double light pipes [2, 3], can be used in order to provide better conditions for visual comfort. The absence of windows makes it impossible the natural ventilation of the room. In some cases light pipes, used to introduce daylight in underground areas, are equipped with technological systems able to ensure air extraction from the room [4, 5]. The innovative system presented in this paper, named Ventilated Illuminating Wall (VIW), has been developed by the authors in order to simultaneously allow natural lighting and ventilation for the environment. So, when underground areas are used or rooms without any direct interface to outwards the VIW allows air ventilation and natural light inlet, giving the room a high quality of light and comfortable conditions of indoor air. It is a combination of a daylight transport system and a passive solar system set up in a real scale by the authors. In this paper a numerical analysis of the device is presented and the results are compared with some experimental data of air circulation parameters.

2. Methodology

Moving from the availability of some data obtained by the experimental analysis, such as internal and external temperatures, wind direction and speed in different times of the year, the authors carried out a numerical analysis with the aim to evaluate the performances obtainable by the VIW. In particular they analyzed the system in steady state conditions and compared the numerical results with experimental ones in order to test the used numerical code with the aim to be sure that it is a suitable tool of analyzing the performances of the VIW.

2.1. Numerical analysis

The numerical analysis was carried out by the software Fluent with the aim to calculate the air flow rate distributions, air speed and temperature field inside the room. Due to the complexity of the geometry and the 3D characteristics of the flow, only numerical methods, often referred to as CFD, can be used to solve the velocity, pressure and temperature field. The fundamental set of partial differential equations (PDEs) describing fluid flow, known as the Navier-Stokes equations [6], can be applied to the problem under consideration, assuming the hypothesis of incompressible flow.

The governing PDEs of fluid flow (conservation of mass, momentum and energy) can be written in a generic form as the following:

$$\frac{\partial(\rho\Phi)}{\partial t} + div(\rho\vec{v}\Phi) = div\left(\Gamma_\phi \overrightarrow{grad}\Phi\right) + S_\phi \qquad (1)$$

in which Φ represents the predicted variable, ρ the density of the fluid, Γ_Φ the diffusion coefficient and S_Φ the source term. If Φ =1 the continuity equation is obtained. The actual form of the variables in Eq. (1) is summarized in Table1.

Table 1 - Variables in eq. 1

Φ	Γ_Φ	S_Φ
v_x	μ_{eff}	$-\partial P/\partial x$
v_y	μ_{eff}	$-\partial P/\partial y - g$
v_z	μ_{eff}	$-\partial P/\partial z$
C_pT	$k+k_t$	Q

In order to simulate the turbulent behaviour of the flow, the RNG (“renormalization group") k-ε model was used, which requires the solution of two additional equations [6]. Details of turbulence model are referred in [7, 8, 9 and 10].

In this work, a commercial program package called Ansys/Fluent (Airpak) was used to simulate the airflow. It adopts a control-volume-based technique. The linearization of the discretized equations is accomplished using a first-order accuracy upwind scheme.
The pressure field is computed by the body-force-weighted scheme, which is good for high-Rayleigh-number natural convection flows. The problem domain was subdivided into 2.034.334 tetrahedral elements whit 352.215 nodes.

The linearized governing equations are written in an “implicit" form with respect to the dependent variable of interest. The calculated variables are used within the various

postprocessing with the aim of determining the volume flow rate, which is a derived scalar quantity computed from the velocity field.

2.2. Experimental analysis

The experimental analysis was carried out by measuring the environmental parameters (air temperature and speed, wind direction and speed) in a test room properly built in the Laboratory of Technical Physics of the Faculty of Architecture of Pescara, between September and November in various external climatic conditions.

2.3. Experimental apparatus

The experimental apparatus is constituted by a 5x3 m plant area room, 2,7 m high in which a 1:1 scale prototype of the Ventilated Illuminating Wall (VIW), is placed against the window in the north-west wall perimeter of the room. The VIW is a removable structure applied to the window able to introduce natural light and ventilation in the room. The daylight is captured by a horizontal glass plate cover applied on the top of the system and redirected in the room thanks to a multilayer highly reflecting film applied on the vertical internal closing panel of the device.

Fig. 1. External and internal views of the VIW.

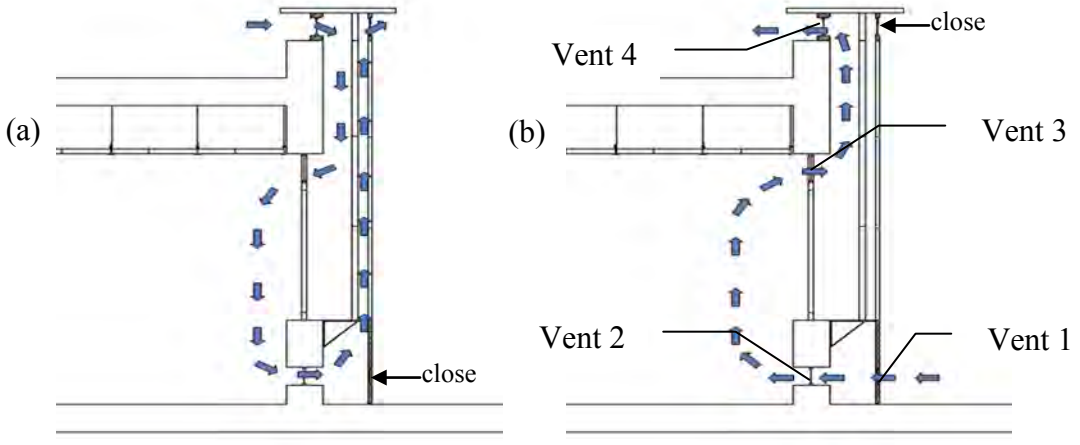

Fig. 2. Section of the VIW with qualitative air circulation and the positions of inlet and outlet vents

In Fig. 1 two external and internal views of the device are shown. The natural air circulation necessary to ensure favorable hygienic conditions in the room is guaranted by fifteen openings with wire mesh practiced on the internal and external closing panel of the system. In

Fig. 2 a qualitative representation of the expected air circulation is shown. In particular, the Fig. 2 (a) shows the expected natural ventilation in daily summer condition and Fig. 2 (b) in night summer and in winter (night and day) conditions.

The experimental line consists of a data-logger type LSI/BABUC-ABC, characterized by 20 inputs, by which data are registered and elaborated, three internal hot wire anemometers type BSV105#S-LSI, range 0-20 m/s, accuracy 0,01 m/s, four temperature probes PT 100, type LSI BST101#S – DIN IEC 751, class A; one tacho-gonioanemometer with direct output, model DNA021-LSI. The air temperature and speed are measured in three positions, in the centre of the room (1), near the opening at the bottom of the wall (2) and near the opening at the top of the wall (3), as indicated in Fig. 3.

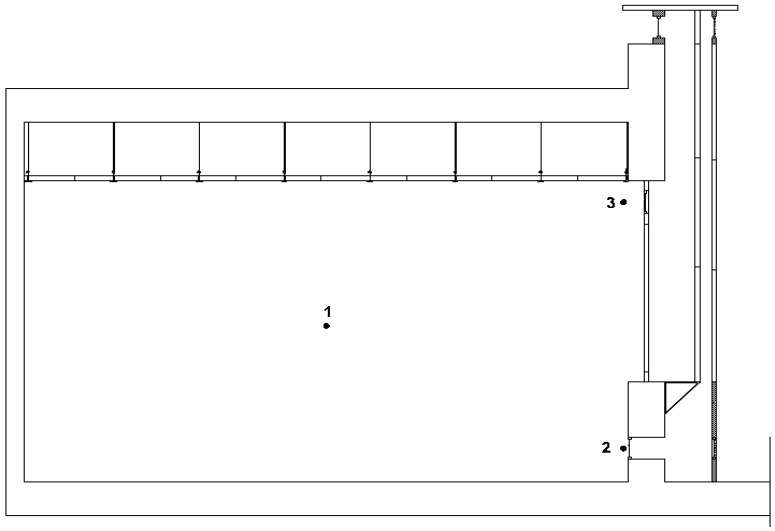

Fig 3. Air temperature and velocity sensors positions.

3. Numerical Results

The Figg. 4-8 show the steady numerical results by Fluent/Airpak in winter configuration, with the following boundary conditions, experimentally measured on November the 7th at 9 a.m.:
External air temperature: t_{ext} = 11°C;
Mean internal surface temperatures (floor, walls and ceiling): t_s = 22°C;
Inlet air velocity close to the vent 1: v_{in} = 0,6 m/s;
Wind direction: 210° from North;
Wind velocity: 2,8 m/s.
Surface temperature on the glass plate cover: t_g = 18°C;
Surface temperature on the external polycarbonate vertical panel: t_p = 15°C.
In Fig. 4 the air speed field and the flow lines in the room are shown while in Figg. 5 and 6 the air velocity distribution on two horizontal planes, 2,4 m high on the floor, close to the vent 3, and 0,3 m from the floor, close to the vent 2, are illustrated. The comparison between the two images highlights the different trend of the air speed distribution in correspondence of the two inlet and outlet vents of the wall. The inlet and outlet velocities involve a mass flow rate of =0,0854 m^3/s, which correspond to about 6,6 air changes per hour, considering that the volume of the room is equal to 46,1 m^3. A second test carried with data of the same day at 2 p.m. allowed to calculate a mass flow rate of 0,058 m^3/s, corresponding to 4,5 air changes per hour.

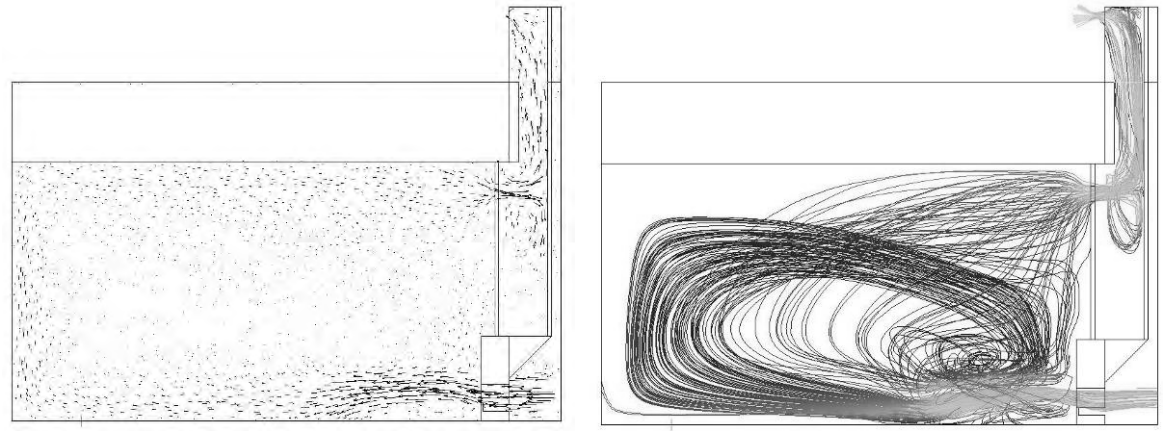

Fig 4. Air speed field and flow lines in the room.

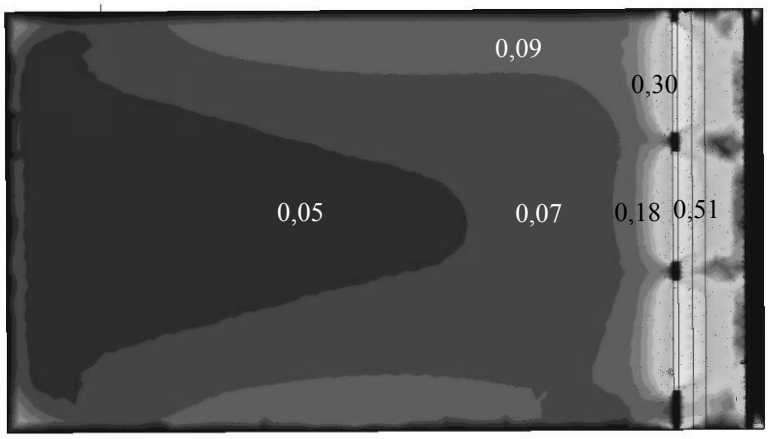

Fig 5. Air velocity (m/s) on a horizontal plane 2,4 m high on the floor, close to the outlet vents.

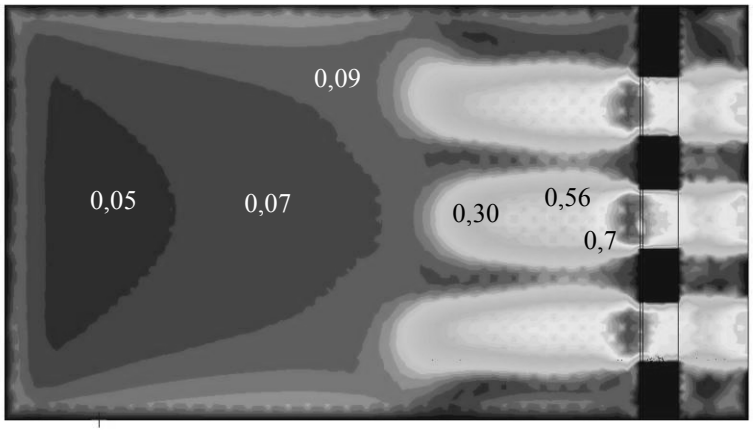

Fig 6. Air velocity (m/s) on a horizontal plane 0,3 m high on the floor, close to the inlet vents.

In Figg. 7 and 8 the temperature field in the room and the temperature vertical trend in the centre of the room and on a vertical plane containing the measure positions 2 and 3 close to the inlet and outlet vents are shown. It's evident how the temperature profile is influenced by the absence of any heating system and the introduction of low temperature air from the opening at the bottom of the wall, particularly close to the vents.

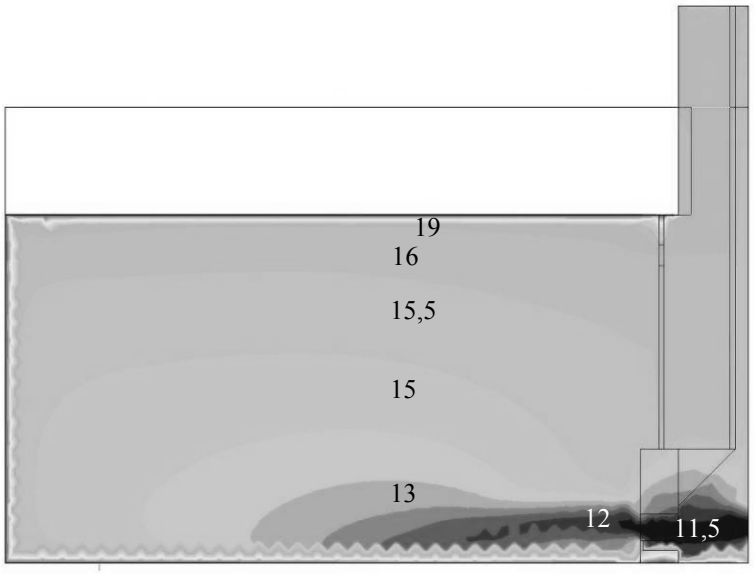

Fig 7. Air temperature field (°C) in the room.

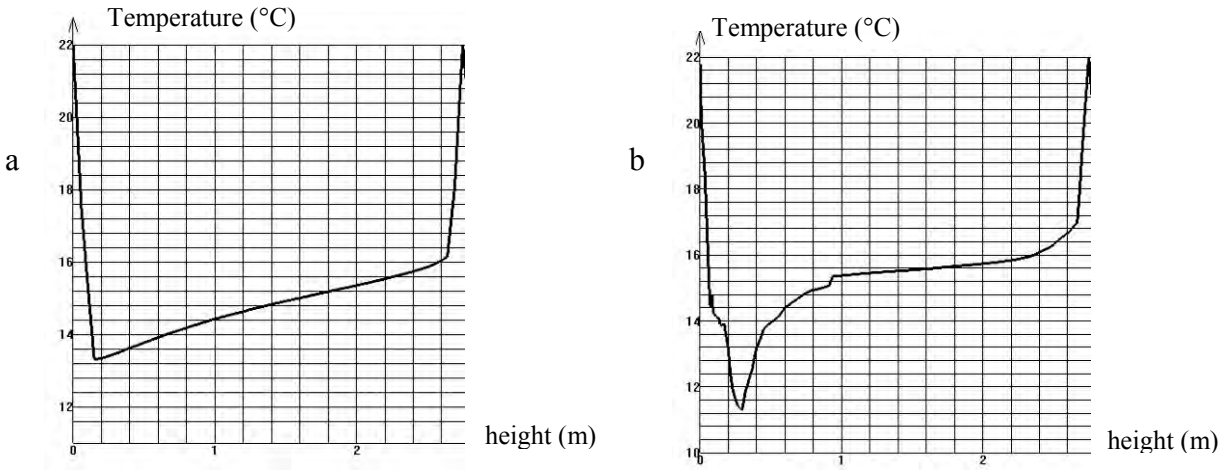

Fig 8. Air temperature vs height on the floor in the centre of the room (a) and close to the outlet and inlet vents (b).

4. Comparison between numerical and experimental results

A comparison was carried out between the numerical results by Fluent/Airpak and the experimental data in the measure positions 1, 2 and 3. The comparison was made with reference to the data of November the 7th at two different times: 9 a.m. with a wind velocity of about 2,8 m/s and a favourable direction (210° from North), and 2 p.m. with a very a lower wind velocity of about 0,9 m/s and a different wind direction (45° from North). This last does not give any contribution to air inlet, and in this case the only stack effect allows the air circulation.

As shown in table 2, a good agreement is obtained between numerical and experimental air temperatures both at 9 a.m. and at 2 p .m. On the contrary, the comparison between the numerical and experimental air velocities shows a good agreement in position 1, in the centre of the room, while a more significant discrepancy is verified in positions 2 and 3, close to the air inlet and outlet vents, partially due to the influence of the boundary conditions. This disagreement is verified in both the situations considered.

As an example, in Figg. 9 and 10 the air velocities comparison is shown between data at 9 a.m.

Table 2 – Comparison between numerical and experimental air temperature T_a

	Position 1		Position 2		Position 3	
	Exp.	Num.	Exp.	Num.	Exp.	Num.
T_a (°C) at 9 am	14,75	14.74	11,77	11.37	17,74	16.1
T_a (°C) at 2 pm	17,4	18,7	16,8	16,8	18,2	19,3

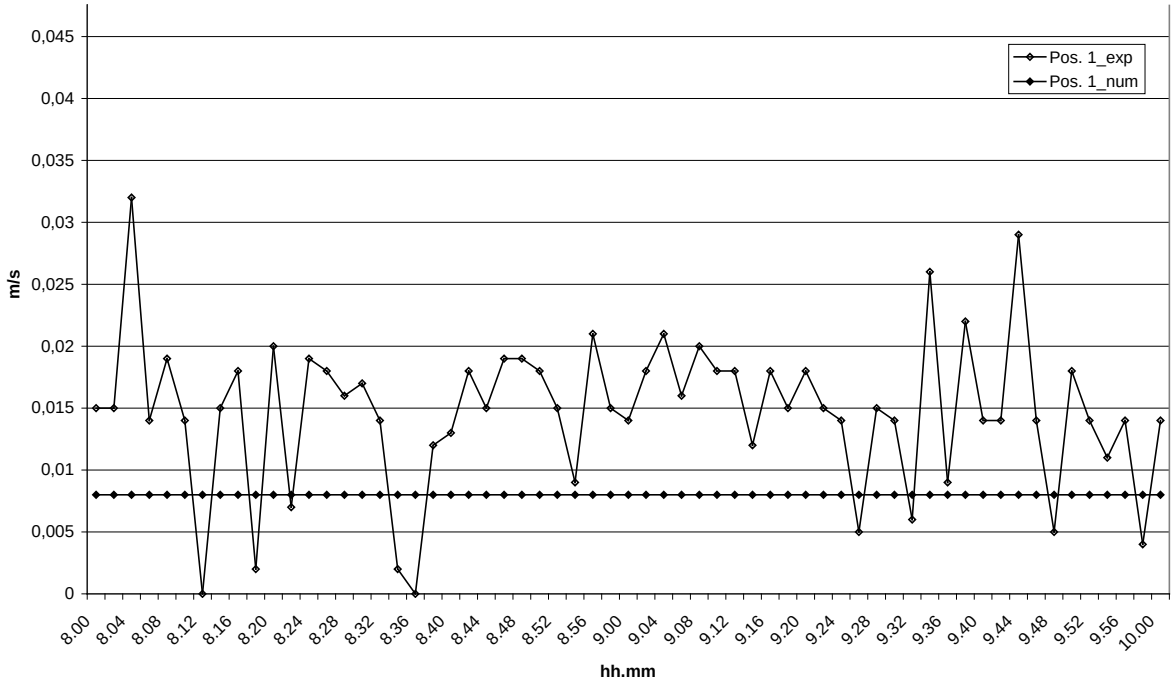

Fig 9. Experimental and numerical air velocity in position 1 in the centre of the room

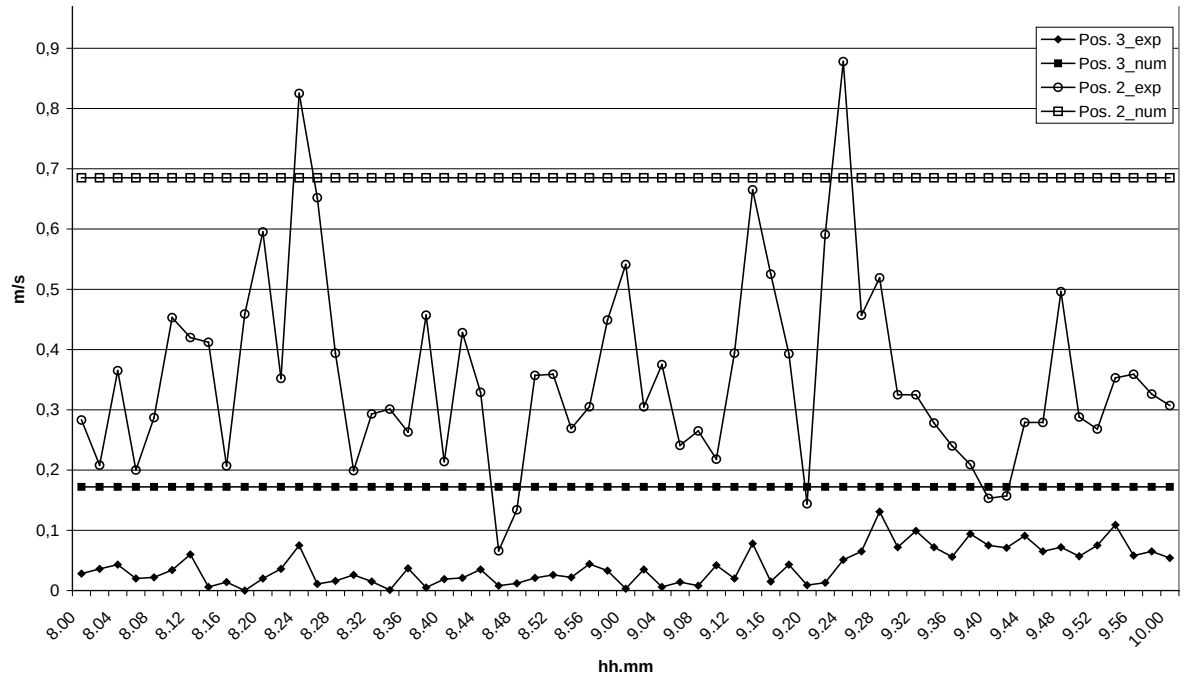

Fig 10. Experimental and numerical air velocity in positions 2 and 3, close to the inlet and outlet vents

5. Conclusions

The numerical analysis carried out by the sw Fluent/Airpak allows to determine the main features of the VIW in terms of its capacity of making an efficacy natural ventilation in rooms without direct interface to outwards. Data about the temperature field are satisfactory if compared with experimental ones, while the air velocities seems to be affected by a significant degree of error partially due to the steady state analysis and the boundary conditions. Even if overestimated, data of mass flow rate show how the VIW can assure an efficacy change of air only by natural ventilation. A transient analysis may certainly provide a more precise determination of the behavior of the system. The availability of a large quantity of experimental data will be a useful tool for the validation of the sw. In any case the first results encourage the authors to carry on the analysis, since the VIW seems to be an efficacy system of daylight transport and natural ventilation for underground areas of buildings or rooms without any direct interface to outwards. It seems particularly suitable for large exhibition rooms or museums where the absence of windows or skylight makes it impossible daylight and natural ventilation of the environment.

Abstract: This article focuses on the behavior of an accommodation with Trombe walls in a Mediterranean climate, in terms of energy savings and comfort during wintertime and summertime.
The aims of this study are to identify experimentally temperatures and heat fluxes of the solar wall; compare the solar wall's behavior with a traditional wall from the point of view of consumptions and comfort; optimize the wall in relation to energy savings. In order to do that, various activities were carried out: a series of monitoring activities for several years in different seasons (in this paper only the results obtained for winter and autumn are reported); dynamic simulations with software EnergyPlus on a virtual model calibrated by comparison with experimental results; parametric analyses for the optimization of the wall.
The results demonstrated that solar wall is an efficient system in temperate climates, with an energy savings of 12,2% and summer comfort comparable to that provided by traditional housing. Finally it was possible to identify optimal design features (Thickness of the wall, absorbance, type of glass).

Keywords: *Trombe walls, Building envelope, Thermal comfort, Monitoring, Parametric analyses.*

1. Introduction

The recent European Directives on the energy performance of buildings established a common direction for the reduction of buildings energy consumptions. Consequently the Member States set up a series of minimum requirements and made it necessary to achieve high building envelope performances. Solar passive systems can give a significant contribution to achieve these performances and they may help to save energy both for winter heating and for summer cooling. However there are still few studies in literature on the behavior of solar passive systems, especially on solar walls, in summer [1, 2], on design recommendations [3, 4, 5], on comfort conditions produced [6], in Mediterranean climates and in well-insulated envelopes required by national regulations.

Solar wall is a passive solar system used to store heat and transfer it inside the building. It is generally made of a concrete or masonry wall painted black, an air layer and glazing on the exterior. Trombe wall is a particular type of solar wall equipped with vents for the air circulation. Precedent studies [7, 8], focusing on the mode of use of Trombe walls, highlighted that recirculation vents determine consistent heat losses during the cold season and problems of powder rising. For this reason this study focuses on unvented solar walls.

The objectives of the study are: the assessment of solar walls' effects on energy consumptions and indoor comfort of residential buildings; the development of design recommendations for solar walls in a Mediterranean climate. The methodology used comprehends experimental and analytical activities: a series of monitoring activities on a case study to collect data related to the thermal behavior of solar walls; numerical simulations in dynamic conditions on a model calibrated by comparison with the experimental data; simulations and parametric analyses to extend the results.

2. Case study

The case study is a residential building in Ancona, central Italy, and it was built in 1983 to test many passive solar systems. The building includes nine flats on three floors, each equipped with a different passive solar system on the south-facing wall (Fig. 1). The house has a compact shape and it is oriented along the E-W axis in order to maximize solar supply.

The research focused on the accommodation with Trombe walls (Fig. 2), that resulted from precedent studies [7] the best solar system among the ones in the house. The system is made up of a 40 cm concrete wall painted black, a 10 cm air layer and glazing on the exterior. Adjustable vents are placed on the top and on the bottom of the wall and on the top of the external glazing to activate ventilation. Roller shutters and horizontal overhangs provide solar radiation control. The configuration of solar wall considered in this study is: ventilation not active (closed vents); movable shading open in winter and middle seasons, closed in summer.

Fig. 1. View of the case study.

Fig. 2. External view of Trombe wall.

3. Methodology

The research consisted of experimental activities in autumn and winter and analytical activities to extend the study to other periods.

3.1. Experimental activities

Monitoring activities in the case study were performed for several years in different seasons. In this paper we report only a part of the data measured, regarding these periods:

- Autumn monitoring: 12th October 2007 – 21st October 2007
- Winter monitoring: 20th December 2008 – 7th January 2009

Trombe walls were used with closed vents during experiments to reproduce unvented solar walls. Heating system was off during autumn monitoring, while it was switched on in winter with set point 20°C and program: 1:30-3:30, 7:30-9:30, 17:30-21:30.
Experimental set-up is described in Fig. 3 and Fig. 4. Data loggers and different types of probes were used to carry out the following investigations: survey of the outdoor climate conditions using an external weather station that included hydro-thermal probe, wind speed

and direction probe, solar radiation probes (Fig. 5); survey of indoor environmental conditions using indoor microclimate stations with hydro-thermal probe and black-globe temperature probe (Fig.6); detailed thermal survey of Trombe wall using a set of thermo-resistances to measure internal and external surface temperatures and heat flux sensors (Fig.7). External probes were screened from direct solar radiation to avoid values alteration.

Fig. 3. Experimental set-up: plan of the house

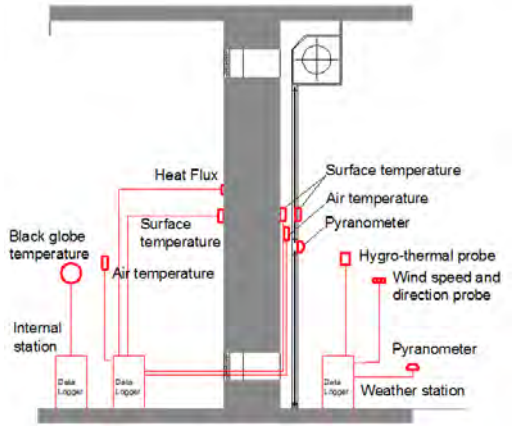

Fig. 4. Experimental set-up: vertical section of Trombe wall indicating the position of probes.

Fig. 5. View of weather station.

Fig. 6. View of indoor microclimate station.

Fig. 7. View of the probes on the outside face of Trombe wall.

3.2. Analytical activities

Numerical simulations were performed in dynamic state using software EnergyPlus. Trombe walls can be modeled in EnergyPlus using the algorithm *"TrombeWall"* validated BY ELLIS [9].

3.2.1. Model inputs and comparison with experimental data

Data collected during experimental activities were used as inputs for the model in order to reproduce the real conditions: we developed a climatic input file containing the outdoor conditions measured during experiments, then we defined programs regarding the real users profiles for the building (occupancy, air ventilation, heating system program and set point). The values obtained by calculations were compared with data collected during experimental activities in order to verify the reliability of the simulation tools in reproducing real situations. Indoor air temperatures, surface temperatures and the heat fluxes of the trombe wall were compared. Once the model had been calibrated, it w as possible to generalize the results running the calculation for a whole year and setting standard input data for the model, according to national reference UNI/TS 11300:2008.

3.2.2. Analytical studies on solar walls

Numerical simulations were performed all over the heating season (1st November to 15th April in Ancona, according to national requirements) in order to determine the thermal behavior of solar walls. Total energy contribution, defined as the difference between solar gains and heat losses through the wall, was used to evaluate the performance of solar wall compared to a traditional one, with the characteristics in Table 1.

Table 1. Thermal characteristics of solar wall and traditional wall according to ISO 13786:2007.

Type of wall	s (cm)	U (W/m^2K)	|Ymn| (W/m^2K)	fd (-)	φ (h)
Solar wall	51,4	2,267	0,12	0,10	12,48
Traditional wall	34,5	0,343	0,12	0,54	6,83

3.2.3. Analytical studies on building envelopes with solar walls

In order to assess how solar walls can contribute to the performances of a building complying with current energy regulations, the insulation level of envelope components of the case study (except solar walls) was varied to meet national requirements. Then the energy performance of the same accommodation was calculated varying the type of south-facing wall between solar wall and traditional wall, defined above, to assess the energy efficiency of solar wall in comparison with the traditional one.

Indoor thermal comfort analyses were performed to assess indoor quality. Thermal comfort conditions were estimated for the whole year with simulations. PMV method, according to UNI EN ISO 7730:2006 and UNI EN 15251:2008, was applied in winter when the heating system is on. PMVe method [10] was applied in summer (with coefficient e = 0,7) with the hypothesis that the cooling system is not present. Category II, according to UNI EN 15251:2008, was assumed in the assessment of comfort limits.

3.2.4. Parametric study on solar wall characteristics

A parametric study was performed using the *level factorial plan* technique [5]. With this technique it is possible to calculate the effect of variations of single parameters and combinations of parameters on a given phenomenon. The parameters listed in table 2 were chosen. For each of the eight combinations of parameters in Table 3 a simulation was run to determine the effects of variations on the seasonal energy needs for heating of the house.

Table 2. Parametric analyses on the solar wall system.

Parameters	Designation	Minimum value	Maximum value
Storage wall thickness (cm)	X1	30	40
Absorbance	X2	0,85	0,90
Type of glazing	X3	Single glass (SG)	Double glass (DG)

Table 3. Combinations of parameters.

Parameters	1	2	3	4	5	6	7	8
X1	30	40	30	40	30	40	30	40
X2	0,85	0,85	0,90	0,90	0,85	0,85	0,90	0,90
X3	SG	SG	SG	SG	DG	DG	DG	DG

4. Results

4.1. Results of experimental activities

Monitoring activities allowed the assessment of the thermal behavior of solar walls in different conditions and periods.

4.1.1. Autumn monitoring

Data measured during three typical sunny days in October are reported in Fig. 8 and Fig. 9. On sunny days the wall reaches temperatures over 50°C on the external surface. Internal surface reaches temperature peaks during nighttime, with a time shift of about 10 hours, and maintains an average temperature of 23,6°C. Internal surface temperature is higher than room temperature all time, consequently heat flux is directed from the wall to the room and determines a daily heat gain of 0,95 MJ/m^2. It can be noticed that heat flux is higher during nighttime, when the difference between surface and air temperature is higher. This contributes to maintain a constant temperature of about 20°C inside the room, with benefits for thermal comfort.

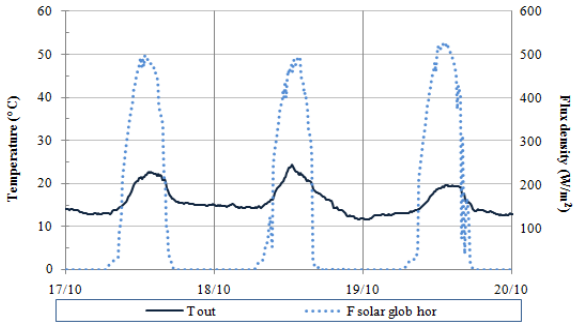

Fig. 8. Climatic data.

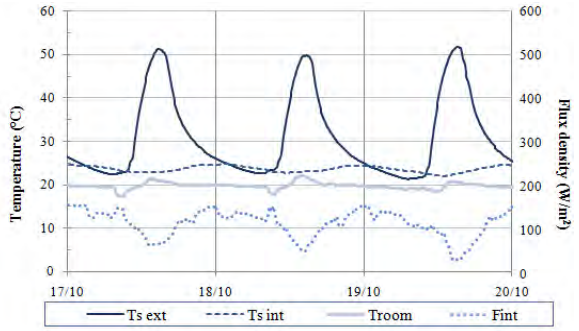

Fig. 9. Temperatures and heat fluxes of Trombe wall and temperature of the room.

4.1.2. Winter monitoring

Fig.10 and Fig.11 show the results of monitoring during three winter days, the first sunny, the second cloudy the third sunny again. On sunny days external surface temperatures can get up to 35-40°C, while on cloudy days the temperatures are not far from outside air temperature. After a sunny day, internal surface temperatures remain higher than room temperatures and heat flux is directed toward the room, with daily heat gains of 0,45 MJ/m^2. On cloudy days internal surface temperatures are lower than room temperatures and this fact causes the inversion of heat flux, from the room to the wall, and daily heat losses of 0,54 MJ m^2.

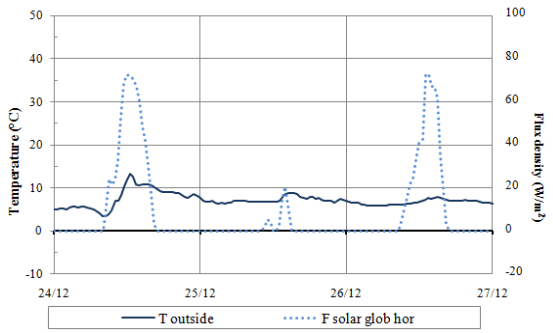

Fig 10. Climatic data.

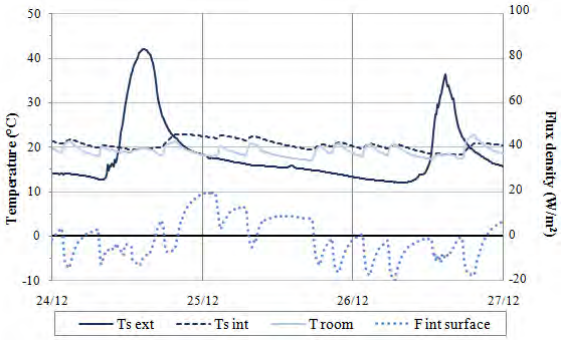

Fig. 11. Temperatures and heat fluxes of Trombe wall and temperature of the room.

4.2. Results of analytical activities

4.2.1. Comparison with experimental data

The comparison demonstrated a good agreement between experimental data and simulated data. Fig. 12 shows the results of surface temperatures comparison, the same analysis was performed for heat fluxes. Deviations for internal surface temperatures and heat flux densities are lower than 5%. Deviations for external surface temperatures are around 10%.

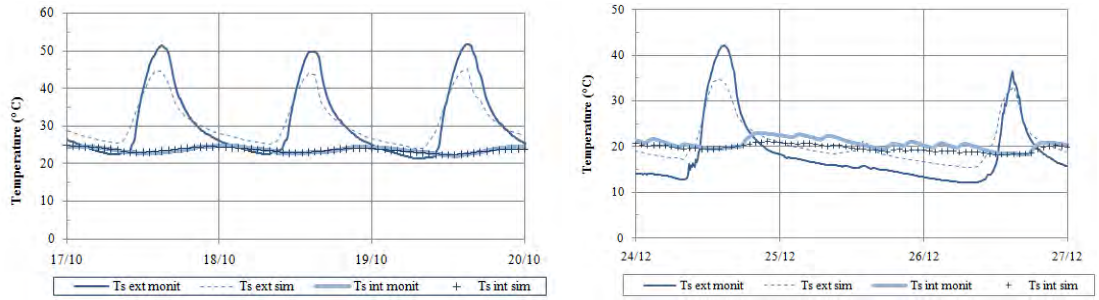

Fig. 12. Comparison of surface temperatures measured and calculated in autumn and winter.

4.2.2. Energy performance of solar walls

Total energy contribution was used to compare the performances of solar and traditional wall in winter (Fig. 13) and in summer (Fig. 14).

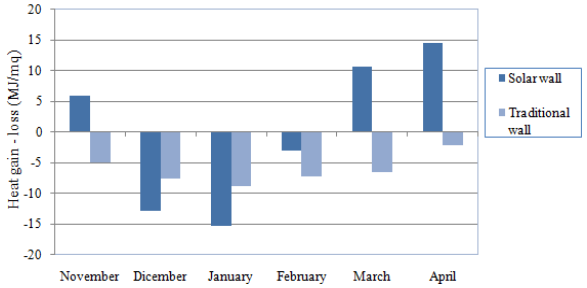

Fig. 13. Total energy contribution of solar wall and traditional wall in winter.

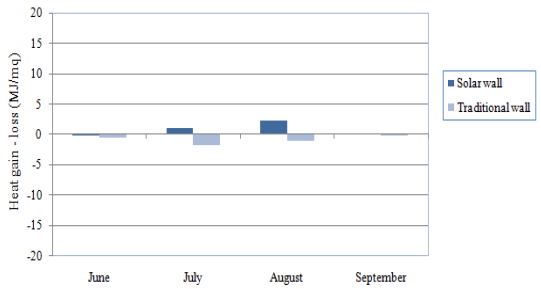

Fig. 14. Total energy contribution of solar wall and traditional wall in summer.

Solar wall's heat losses are higher in the coldest months, due to the high transmittance, but these losses are balanced in other months when solar gains are higher. Considering the whole heating season, traditional wall disperses 37,29 MJ/m^2 while solar wall disperses 0,20 MJ/m^2. In summer solar wall, even if shaded from solar radiation, behaves worse than traditional wall, because the high transmittance determines higher unwanted heat gains. Considering the whole summer season, solar wall produces heat gains equal to 3,21 MJ/m^2, while traditional wall determine heat losses equal to -3,47 MJ/ m^2.

4.2.3. Energy performance of building envelope with solar walls

Energy analysis confirmed that the house with solar walls has a saving of 12,2 % in heating energy needs compared to the house with traditional walls (Fig. 15). The energy saving is 0,46% for each square meter of surface of solar wall.

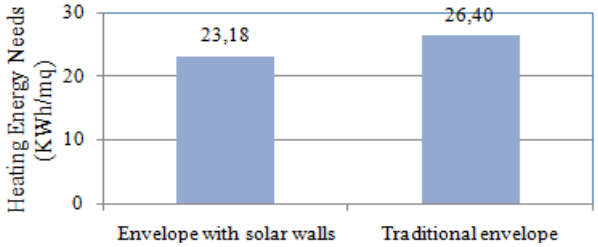

Fig. 15. Seasonal heating energy of building with different types of envelope.

The results of thermal comfort analysis in winter (Fig. 16) are very similar for the building with solar wall and with traditional wall because the influence of heating system is relevant in this season. However in the middle seasons solar walls' heat gains determine higher indoor air temperature and consequently higher PMV values. In these periods it could be necessary to shade solar walls to avoid overheating problems.

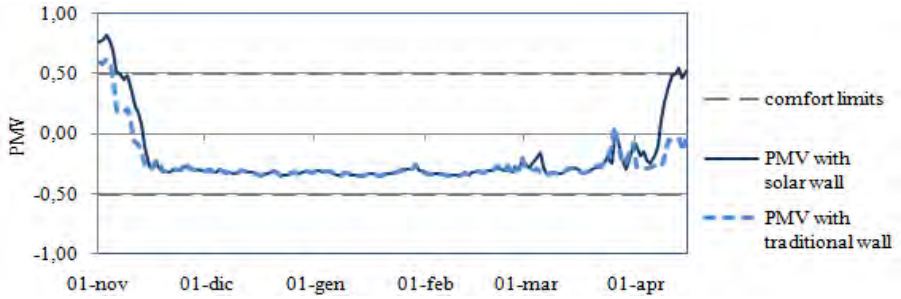

Fig. 16. Comfort analysis with PMV method in winter.

In summer the building with solar walls, shaded from solar radiation, has indoor comfort level comparable to the traditional one. The results of PMVe analysis for summer (Fig. 17) highlighted overheating problems for the hottest days, when PMVe exceeds the comfort superior limit of 0,5 for both the cases considered.

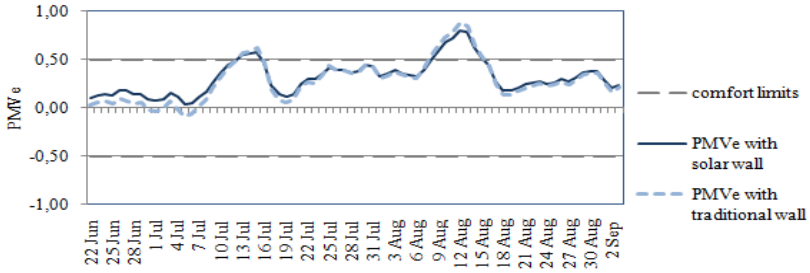

Fig. 17. Comfort analysis with PMVe method in summer.

4.2.4. Optimization of solar walls

Results of parametric analyses on the configuration of solar wall are in Fig. 18. The single variation of wall thickness from 40 cm to 30 c m (X1) increases energy needs; the single variations of external surface's absorbance (X2) or the type of glazing from single to double (X3) decrease energy needs. The type of glazing resulted to be the parameter with a greatest influence, with a reduction of -4,28 kWh/m^2 on energy needs.

The interactions between parameters are small, except the one between wall thickness and type of glazing. This implies that, even if the single effect of reducing wall thickness is disadvantageous, combining this variation with the variation of glazing from single to double

has a beneficial effect. The best performance as obtained with a wall thickness of 30 cm, absorbance 0,90 and double glasses.

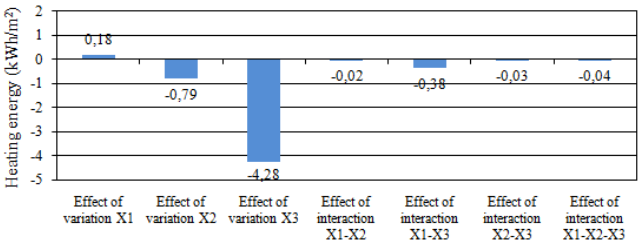

Fig. 18. Results of parametric analyses with level factorial plan.

5. Conclusions

An experimental and analytical study on the performances of solar walls in a residential building in central Italy was carried out. The study confirmed that solar wall is an efficient system in reducing energy needs for the heating season and assuring suitable comfort levels. Some problems of overheating emerged in summer in buildings with well-insulated envelope. This drawback can be reduced using adequate solar protections for solar walls; however we consider necessary further investigations on the behavior of the system in summer. Parametric analyses made it possible to compare different configurations of solar wall; the results may be used as design recommendation for solar walls.

Abstract: Domed roofs (DRs) have been used in Iran and many other countries to cover large buildings such as mosques, shrines, churches, schools, etc. They have been also employed in other buildings like bazaars or market places in Iran due to their favorable thermal performance. The aim of this research is to study about DRs thermal performance in order to determine how they can be helpful in reducing the maximum air temperature of inside buildings during the warm seasons considering all parameters like air flow around them, solar radiation, radiation heat transfer with the sky and the ground as well as some openings on the building. The results of the study show that the thermal performance of the investigated DR is better than the building with flat roof (FR), particularly when the dome is covered with glazed tiles. In addition to their aesthetic values, domes covered with glazed tiles have thermal benefits of keeping the inside air of these buildings relatively cool during the summer. Moreover, openings cause passive air flow inside building, which is helpful for human comfort.

1. Introduction

DRs have traditionally been used throughout the world to cover large areas. Solar energy absorbed by a DR causes its temperature to rise above the ambient air temperature. Wind blowing over the dome increases the convection heat transfer to the ambient air. Furthermore, the heat loss from the roof is increased by thermal radiation to the sky. The rest of the heat absorbed by the dome is conducted through the dome material, and is finally transferred to the

inside air by convection, and to the interior walls by radiation. The geometry of these roofs causes the wind velocity to increase over them, resulting in an increase in the convection heat transfer coefficient. Furthermore, the heat transfer from these roofs is increased by the fact that their areas are greater than the comparable flat ones. In addition to their structural applications, DRs have been employed in Iran for natural ventilation and passive cooling of buildings. A cross section of a typical DR employed in such applications is shown in Fig. 1.

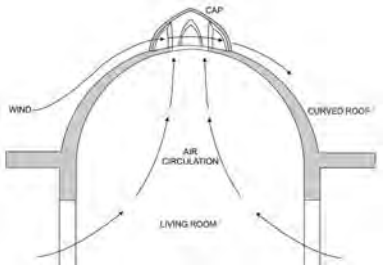

Fig. 1. Cross section of a typical DR, with air circulation in and over it [1]

In 1978, Bahadori introduced the important role of DRs in providing cold water in cistern as well as indoors air condition in warm and dry areas in Iran [1]. Konya [2] showed that the temperature of domed roof buildings (DRBs) is lower compared to flat ones. Mainstone [3] professed that the main reason of lower temperature of inside DRBs in comparison with FRs is the higher ground and sky reflected radiation heat loss. Olgyay [4] guessed that lower indoor air temperature in DRBs is due to the lower absorbed solar radiation in comparison with FRs. Tang [5] showed greater solar radiation and heat transfer through DRs and refused what Bahadori [1] had been asserted before. The aim of this research is to study about DRs thermal performance considering all parameters like air flow, solar radiation, radiation heat transfer with the sky and the ground as well as some openings on the building by using the thermal network method. Constant wind velocity and direction is assumed, and the IAT during a day is the comparison index.

We investigated air flow over domed and FRBs numerically [6] and experimentally [7] to find proper data for our own study. In these studies we consider the three-dimensional model of the dome of the School of Theology (the reference dome) shown in Fig. 2 which is located in Yazd, Iran (a city with very high solar radiation) with a specified boundary layer air flow. For this study, the absorbed solar radiation reported by the authors in [8] for the reference dome and the corresponding flat one with the same base area is used. In [8] it is found that DRs receive more solar radiation in comparison with flat ones.

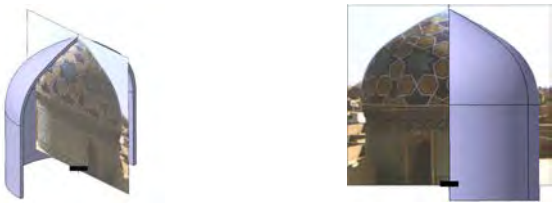

Fig. 2. Model of the reference DR

2. Absorbed Heat

In Eq. (1), solar radiation (Q_s) in each hour is assumed to be constant and is equal to its exact amount in the middle of the specified hour. The convection heat transfer between the ambient air and the outer surface of the building is defined in Eq. (2) [9].

$$Q_{abs} = Q_s + Q_c + Q_{rs} + Q_{rg} \quad (1)$$

$$Q_c = h_0 A(T_{ao} - T_W) \quad (2)$$

$$h_o = \sqrt{h_n^{\,2} + \left[2.38 V_W^{\,0.89}\right]^2} \quad (3)$$

V_W is the air flow velocity near the wall which is defined by the authors numerically and experimentally in [6, 7]. Boundary layer air velocity profile near the ground defined in Eq. (4) [10] is assumed in those studies. V_{400} is the wind velocity at height 400 m. h_n in Eq. (3) is the natural convection coefficient defined in Eq. (5) and (6) for upward and downward heat transfer respectively [11].

$$\frac{V_h}{V_{400}} = \left[\frac{h}{400}\right]^{0.28} \quad (4)$$

$$h_n = 9.482 \frac{\sqrt[3]{|\Delta T|}}{7.238 - |Cos\beta|} \quad (5)$$

$$h_n = 1.810 \frac{\sqrt[3]{|\Delta T|}}{1.382 + |Cos\beta|} \quad (6)$$

β is the slope of each surface and ΔT is the temperature difference between the ambient and each surface in the specified time. The ambient air temperature is defined using Eq. (7) [12].

$$T_{ao} = \left(\frac{T_m + T_n}{2}\right) + \left(\frac{T_m - T_n}{2}\right).Cos\left(180\left(\frac{t-15}{12}\right)\right) \quad (7)$$

The radiation heat transfer between the outer surface of the building and the sky and the ground is defined by Eq. (8) and (11). Note that ε is assumed to be 0.85, T_s is the sky temperature defined in Eq. (9) [13] and T_g is the ground temperature which is similar to the ambient temperature at each time.

$$Q_{rs} = \varepsilon\sigma(T_S^{\,4} - T_W^{\,4})\left(\frac{1 + Cos\beta}{2}\right) \quad (8)$$

$$T_S = \varepsilon_S^{\,0.25}(T_{ao} + 273.15) \quad (9)$$

$$\varepsilon_S = 0.74 + 0.006 T_{dp} \quad (10)$$

$$Q_{rg} = \varepsilon\sigma(T_g^{\,4} - T_W^{\,4})\left(\frac{1 - Cos\beta}{2}\right) \quad (11)$$

3. Boundary Conditions

The outer surface: This surface receives absorbed heat transfer which is discussed in Section 2. The absorbed coefficient of the ordinary material and the glazed tile are assumed to be 0.8 and 0.4 respectively. The FR and the wall are covered with the ordinary material, but both the ordinary material and the glazed tile are considered to cover the DR. wall thickness: Conduction heat transfer parameters are k=1.4 $w.m^{-1}.k^{-1}$, C=880 $J.kg^{-1}.K^{-1}$, and $\rho = 2300$

kg.m^{-3}. The inner surface and the floor: For simplification, constant convection heat transfer coefficient (3 w.m^{-2}.k^{-1}) is considered. The wall base: assumed to be insulated.

4. Initial Conditions

The initial temperature of the walls, roof, floor, and inside air are equal to the ambient air temperature at initial time, which is 6 A.M. lumped system is considered for the IAT and changing of this parameter can be determined by Eq. (12). Δt is time step, m is the inside building air mass, and C_v is assumed to be 717 J.kg^{-1}.K^{-1}. Deviations of the IAT during a specified day (6 August) in the city of Yazd, in the central desert region of Iran (31.54 N; 54.17 E; maximum air temperature: 37.9 ^{o}C; minimum air temperature: 21.7 ^{o}C; dew point: 8 ^{o}C), for the domed and the FRBs are compared.

$$\frac{\Delta T_{ai}}{\Delta t} = \frac{\sum h_i A(T_{Wi} - T_{ai})}{mC_v} \qquad (12)$$

5. Thermal Network

A cylinder with the height of 3m and diameter of 6m is assumed to be a building for both models (Fig. 2). The height of the dome and the wall thickness in both models are 3m and 15cm respectively. In the air flow study of these models V_{400} = 48.6 m/s, therefore according to Eq. (4) the air flow velocity on top of the DR (6 m) is 15 m/s (Re=5.8×10^5). In this method, the geometry of the building has been simplified to take the radiation heat transfer between inner surfaces of the building into account. Fig. 3 shows the simplified geometry. All view factors can be determined in this simplified geometry. In this geometry, the heights are similar to the actual model, but the dome is assumed as a triangular pyramid. Each surface of this pyramid faces to the north, south, east or west. To have similar base area, the base width and length are assumed to be 5.32m.

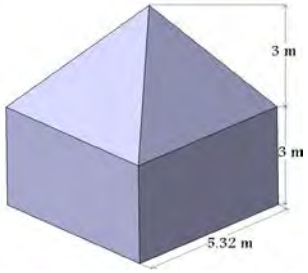

Fig. 3. The simplified model of the DRB used in the thermal network method

5.1. Heat Transfer Equations

The thermal network of the DRB used in this study consists of 18 nodes. 8 nodes are located on the outer surfaces (4 nodes on the roof surfaces and 4 nodes on the wall surfaces), 8 nodes are located on the inner surfaces, 1 node representing the inside building air and 1 node representing the floor. There are 12 nodes in the thermal network of the FR. Fig. 4 shows the thermal network of the southern roof in the simplified DRB. As shown in Fig. 4, the inner surface of the southern roof has radiation heat transfer with the three other inner surfaces of the roof (north, east and west) as well as four inner surfaces of the wall. There is a convection heat transfer with the inside building air as well. Eq. (13) and (14) show the energy balance of the inner and outer nodes of the southern roof.

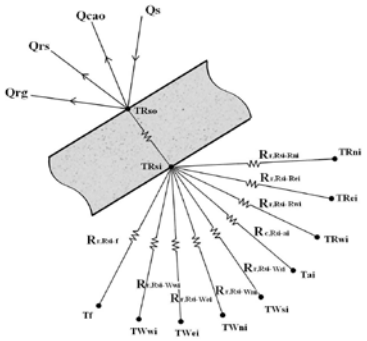

Fig. 4. The thermal network of the southern roof in the simplified DRB

$$(\dot{q}_s + \dot{q}_{cao} + \dot{q}_{rs} + \dot{q}_{rg}) + k\frac{T_{Rsi} - T_{Rso}}{D} = \rho_W \frac{D}{2} C \frac{T'_{Rso} - T_{Rso}}{\Delta t} \tag{13}$$

$$kA_{Rsi}\frac{T_{Rso} - T_{Rsi}}{D} + \frac{A_{Rni}\sigma({T_{Rni}}^4 - {T_{Rsi}}^4)}{\frac{1-\varepsilon_{Rni}}{\varepsilon_{Rni}} + \frac{1}{F_{Rni-Rsi}} + \frac{1-\varepsilon_{Rsi}}{\varepsilon_{Rsi}}\frac{A_{Rni}}{A_{Rsi}}} + \ldots + \frac{A_f\sigma({T_f}^4 - {T_{Rsi}}^4)}{\frac{1-\varepsilon_f}{\varepsilon_f} + \frac{1}{F_{f-Rsi}} + \frac{1-\varepsilon_{Rsi}}{\varepsilon_{Rsi}}\frac{A_f}{A_{Rsi}}} + h_{c,Rsi-ai}A_{Rsi}(T_{ai} - T_{Rsi}) = \rho_W A_{Rsi}\frac{D}{2}C\frac{T'_{Rsi} - T_{Rsi}}{\Delta t} \tag{14}$$

In Eq. (13), $\dot{q}_s$ is the averaged absorbed solar radiation of the quarter of the dome face to the south. $\dot{q}_{cao}$ is the convection heat transfer which is calculated based on Eq. (2) and (3). Air flow velocity is the average air velocity near the quarter of the dome face to the south. Energy balance equations for all nodes are derived similarly. Emittance of all surfaces is assumed to be 0.85 in this study. Fig. 5 shows the thermal network of the floor. As shown in Fig. 5, there is a conduction heat transfer between the floor and the depth of the ground (l'=5m) [14] with the annually averaged temperature ($\overline{T}$) of the under study area (Yazd) which is reported 18 ^{o}C. Eq. (15) shows the energy balance of the floor node.

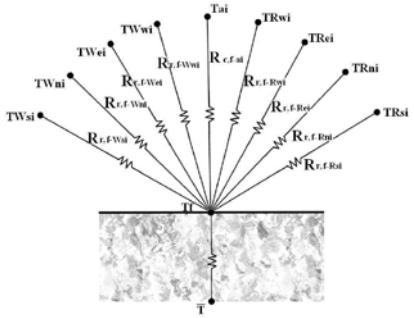

Fig. 5. The thermal network of the floor

$$k_f A_f \frac{\overline{T} - T_f}{l'} + \frac{A_{Rsi}\sigma({T_{Rsi}}^4 - {T_f}^4)}{\frac{1-\varepsilon_W}{\varepsilon_W} + \frac{1}{F_{Rsi-f}} + \frac{1-\varepsilon_f}{\varepsilon_f}\frac{A_{Rsi}}{A_f}} + \ldots + h_{c,f-ai}A_f(T_{ai} - T_f) = \rho_f A_f \frac{l'}{2} C_f \frac{T'_f - T_f}{\Delta t} \tag{15}$$

In this study ρ_f =1300 kg.m^{-3}, k_f=0.75 w.m^{-1}.K^{-1} and C_f=970 J.kg^{-1}.K^{-1}. Eq. (16) shows the energy balance of the inside building air. In this Eq. $\dot{m}$ is the air mass flow rate (kg.s^{-1}) which is equal to zero, when there is no opening on the building.

Energy balance equations define all temperatures for next time steps. This method is not sensitive to the time step. We consider the time step of 15 seconds for both the domed and the FRBs. The simulation starts from 6 A.M. and it continues until we get 0.1 ^{o}C difference between the IAT for the specified day (6 August) and a day after that at 6 A.M.

$$h_{c,ai-f} A_f (T_f - T_{ai}) + h_{c,ai-Rsi} A_{Rsi} (T_{Rsi} - T_{ai}) + ... + \dot{m} C_p (T_{ao} - T_{ai}) = \rho_a V C_v \frac{T'_{ai} - T_{ai}}{\Delta t} \quad (16)$$

5.2. Thermal Network Results

Fig. 6 shows the sky, the ambient, and the IAT for the DRB covered with the ordinary material, when the wind direction is south. There are similar figures for other cases, but they are not presented here for the sake of brevity. Table 1 compares the maximum IAT. The reference DRB has better thermal performance in comparison with the FRB with similar conditions. It can be also seen that using glazed tiles improves DRB thermal performance. Wind direction does not have considerable affect on the thermal performance of buildings.

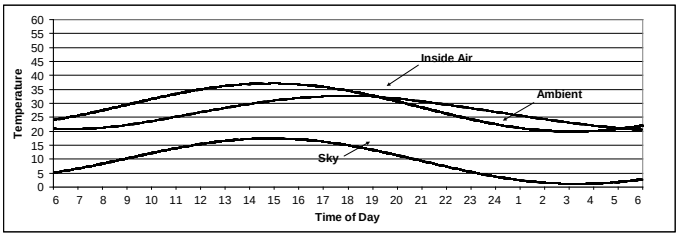

Fig. 6. The sky, the ambient, and the IAT for the DRB covered with the ordinary material

Table 1. Maximum air temperature, using the numerical simulation method

Time	Max. Temperature	Roof Absorb Coefficient	Type of Roof	Wind Direction
16:43	37.30	0.8	Flat	South
17:35	37.09	0.8	Dome	
17:35	36.04	0.4	Dome	

Fig. 7 shows the deviation of all heat transfer to the outer surface of the DRB covered with the ordinary material, when the wind direction is south. Convection heat transfer between the outer surface of the building and the ambient air is always negative except from 4.5 to 7 A.M., which shows that most of the time the walls and the roof are warmer than the ambient.

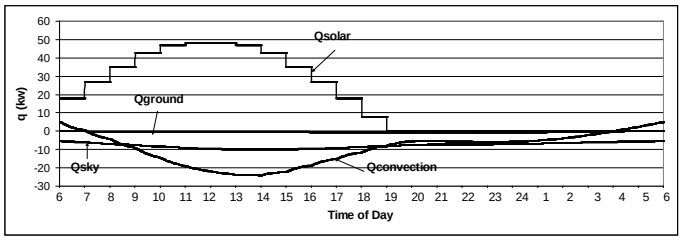

Fig. 7. The deviation of all kinds of heat transfer to the outer surface of the DRB

5.3. Openings

To investigate the effect of openings, we consider the model shown in Fig. 8. This Fig. depicts the locations and dimensions of two openings on the wall and one hole on its apex. One opening faces to the wind flow (windward) and the second one is behind (leeward). In the following, we study two scenarios which are "no wind flow" and "with wind flow".

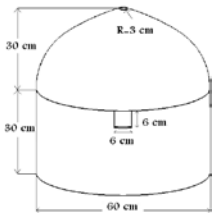

Fig. 8. The locations and dimensions of two openings on the wall and one hole on its apex

5.3.1. No Wind Flow

Air temperature difference causes air flow in this condition. Air flow rate can be defined by Eq. (17) or (18) [11]. C_D in these equations is opening discharge coefficient [11]. Considering Eq. (16), as well as the air flow rate we can define the IAT in the next time step (T'_{ai}). The convection heat transfer coefficient between the inner surface of the building and the IAT is assumed to be always 4 $w.m^{-2}.K^{-1}$.

$$\dot{V} = C_D A \sqrt{2g\Delta H \frac{(T_{ai} - T_{ao})}{T_{ai}}} \qquad T_{ao} > T_{ai} \qquad (17)$$

$$\dot{V} = C_D A \sqrt{2g\Delta H \frac{(T_{ao} - T_{ai})}{T_{ao}}} \qquad T_{ao} < T_{ai} \qquad (18)$$

$$C_D = 0.4 + 0.0045\left|T_{ai} - T_{ao}\right| \qquad (19)$$

The results show that the maximum IAT in this scenario is 42.95 which is at 16:27. In the same situation when the wind direction was south in section 5.2, the maximum IAT was 37.09. This means that without wind flow, openings cannot be helpful. Furthermore, we see that the convection heat transfer reduces in this situation. It is due to the reduction in the air flow velocity near the building's roof and wall. Increasing in radiation heat transfer with the sky is sensible because the temperature difference between walls and the sky increases.

5.3.2. With Wind Flow

In the wind flow scenario, both air temperature difference and air pressure difference between openings cause air flow inside the building. To define the air flow caused by pressure difference, flow network method is used in this study. In this method, air volumetric flow rate from each opening (j) is defined by Eq. (20). Where P_i is the inside air pressure and P_j is the air pressure on the related opening. P_j can be determined by Eq. (21). C_{pj} is defined in previous surveys [6, 7]. C_p is assumed to be -1.1, 1, and 0.3 for the hole on apex, windward opening, and leeward opening respectively. In this study all openings discharge coefficients are assumed to be 0.65. The inside air pressure coefficient (C_{pi}) is defined by using Eq. (21) with i as its index. Combining Eq. (20) to (22), the air flow rate of the opening can be found by Eq. (23).

$$\dot{V}_j = \frac{P_j - P_i}{R_{ij}} \qquad (20)$$

$$P_j = C_{pj} \frac{1}{2} \rho V_0^{\,2} \qquad (21)$$

$$R_{ij} = \frac{\sqrt{\frac{1}{2}\rho (P_j - P_i)}}{A_j C_{dj}} \qquad (22)$$

$$\dot{V}_j = A_j C_{dj} V_0 \left[\frac{C_{pj} - C_{pi}}{\sqrt{\left|C_{pj} - C_{pi}\right|}} \right] \qquad (23)$$

Using Eq. (21) with i as its index and (23) and try and error method, C_{pi} and $\dot{V}_j$ can be determined. For the wind velocity profile similar to (4), the network flow method leads to the value of 1.28 m^3/s. We use the reference velocity of 15 m/s. This amount is assumed to be constant during the day. The convection heat transfer coefficient between the inner surface of the building and the inside building air is assumed to be constant and equal to 6 $w.m^{-2}.K^{-1}$. This coefficient is the greatest one in comparison with the other cases (3 and 4 $w.m^{-2}.K^{-1}$) due to the higher air flow velocity near the inner surface of the building. Maximum air temperature in this condition is 37.46 occurred at 15:09. In similar conditions with no openings, maximum air temperature was 37.09. So again in the wind flow condition the thermal performance of the building with no opening is better, however the air flow inside the building caused by openings can be helpful for human comfort on warm days.

6. Conclusions

Based on the analysis carried out the following conclusion can be made: Thermal performance of the DRB under investigation is better than the building with FR on warm days, particularly when the dome is covered with glazed tiles. Wind flow direction is not an important parameter in decreasing room temperature of the DRB of the specified cases. For no wind flow condition, the FRB performs better than the DR one. The passive air flow inside the DRB caused by openings can be helpful for human comfort on warm days.

Abstract: Passive design strategy is an important approach to reduce energy consumption of a building such as improving indoor thermal comfort through enhanced natural ventilation performance. This is crucial in achieving a more sustainable building especially for a tall high density residential development where energy consumption is huge. This paper looks into the potential of high-rise residential buildings to utilize abundant naturally available prevailing wind by mean of passive design strategy. Its objective is to investigate the potential to improve the ventilation performance of a single-sided ventilation strategy of high-rise residential buildings by introducing a series of balconies on their façades. Computational Fluid Dynamics (CFD) was used as a tool for investigation. Since CFD requires a validation process to investigate its reliability, existing wind tunnel experiments and empirical models were used in the validation process. This study found that an appropriate combination of balcony configurations and single-sided ventilation strategy could improve indoor ventilation performance of high-rise residential buildings; however, incorrect combination could further reduce the ventilation performance of an already inefficient ventilation strategy. Therefore, understanding the concept of single-sided ventilation strategy is crucial, and application of appropriate tools such as CFD is important to ensure ventilation performance optimization is achieved.

1. Introduction

The only solution to solve the human's basic need for shelter in urban environment through vertically constructed high-density residential buildings leads to either favorable or unfavorable impacts to the environment as well as to its occupants. There are various opportunities associated with high-density tall residential buildings such as optimization of land with less floor plinth, greater control of water and energy usage through central management, reduced transportation distance to workplaces, opportunities to waste recycling, utilization of natural lighting and ventilation for indoor environmental quality, etc. Therefore, vertical construction such as high-density residential building is an option of sustainable building approach if properly designed and managed.

This study looks into the potential of high-rise residential buildings to utilize naturally available prevailing wind. Optimization of the outdoor wind environment for indoor air quality and thermal comfort by mean of passive design strategies can reduce dependency on mechanical ventilation and, subsequently, reduces the energy consumption of buildings. Optimization of the prevailing wind for ventilation requires micro and macro investigations to ensure the objective of enhanced indoor airflow is achieved. This includes better understanding on the relationship between local wind climate and indoor ventilation performance.

While cross ventilation strategy is a well accepted and recognized ventilation approach, the potential of single-sided ventilation strategy is always neglected by designers and policy-makers. Coupled with a common provision of balconies in high-rise residential buildings, this paper discusses the relationship between single-sided ventilation strategy and the provision of balconies in the context of high-rise residential buildings. Therefore, the outlined objective of this paper is to discuss and investigate the potential to improve the ventilation performance of single-sided ventilation strategy of high-rise residential buildings by introducing a series of balconies on the façades of the buildings.

2. Ventilation

2.1. Single-sided ventilation

Ventilation strategies for building are categorized into two: single-sided ventilation and cross ventilation. In the context of this study, single-sided ventilation is defined as a condition where one or more openings exist only at one façade of a closed room or building, whereas, for cross ventilation, two or more openings are exist at two or more façades. Existence of an opening at more than one building facades in cross ventilation strategy potentially creates a much higher pressure gradient encouraging better natural ventilation performance. Therefore, generally, cross ventilation has a greater potential to manipulate the pressure gradient developed around buildings. However this is not the case for single-sided ventilation where it is limited to pressure gradient developed only at a single façade. Thus, ventilation performance of cross ventilation is always assumed to be better than single-sided ventilation. Despite the disadvantage of single-sided ventilation strategy in ventilation performance, it is still commonly used as a ventilation solution for apartments. This is due to various factors such as site constraint and unit number optimization. Since there is a greater potential of single-sided ventilation to fail in ventilating indoor residential spaces, but still, it is widely adopted as ventilation strategy in many residential apartments, greater understanding of its potential and limitation shall be attained to ensure that the potential of single-sided ventilation strategy is optimized and to avoid failure in indoor ventilation performance.

The ventilation performance of a single-sided ventilated apartment can be enhanced through appropriate façade treatments. There are various façade treatments and detailed building configurations which may change the pressure distribution across the building façades. For examples, the provision of balconies on the façade of a building as well as protruding and sunken floor plan layout. Complex façade treatment and floor plan result in a more complicated pressure distribution across building's façades and, consequently, causes changes in indoor ventilation performance. Therefore, these changes, if positively utilized, can enhance indoor ventilation performance by optimizing the available prevailing wind.

2.2. Balcony as a passive design strategy

Balcony is defined as "a platform projecting either from an inside or an outside wall of a building" [1]. A balcony can provide various benefits from the aspects of social, economy and environmental, for examples, it provide private outdoor spaces, enhanced the monetary value of a building and provides protection from extreme outdoor climate, respectively [2,3]. There are many studies on the impact of balcony on airflow [3, 4, 5, 6]; however, none of researchers looking into the affect of the provision of balcony on the performance of single-sided ventilation strategy in the context of tall buildings. Since a provision of balconies could change the pressure distribution on the façades of a building [4, 6], it is seen as a potential

which can be utilized to induce indoor ventilation performance of single-sided ventilated buildings.

3. Methodology

Computational fluid dynamics (CFD) is the main tool for this study which has been widely used to predict indoor ventilation performance. However, CFD comes with two great setbacks: it requires huge computational effort and validation and verification process. With current advances in computer technology and greater affordability, CFD has been widely used by researchers such as van Hooff and Blocken [7] and Cheng et al. [8] to investigate ventilation performance of large buildings.

There are various approaches to predict indoor ventilation performance for tall buildings. The followings are commonly used approaches:

A. Combination of small-scale models and empirical models (Approach A).
B. Combination of CFD models with empirical models (Approach B).
C. Coupled CFD simulation (Approach C).
D. De-coupled CFD simulation (Approach D).

According to Jiru and Bitsuamlak [9], Approach C is a preferred approach compare to Approach D since the accuracy of Approach D can easily be compromised though it gives an advantage of lower computational effort. Among all the approaches, only Approach D was excluded in this study, while the others were used to predict ventilation rate. Empirical models used for the validation study were Equation 1 [10] and Equation 2 [11]. The value of discharge coefficient of opening, C_D, used for this study was 0.5 since the opening area was less than 10% of the area of the façade. In the case of single opening, the inlet area, A, was taken to be half of the opening, and the reference pressure is taken to be at the middle of the inlet. For Equation 2 the value of opening effectiveness, C_V, was 0.025.

$$Q = C_D \cdot A \cdot \sqrt{(2 \cdot \Delta P / \rho)} \quad (1)$$

$$Q = C_V \cdot A \cdot V \quad (2)$$

This study utilized existing wind tunnel experimental data [12] to validate its results with initial validation study for cross ventilation strategy with perpendicular wind direction which was completed earlier [13]. An additional validation study for single-sided ventilation strategy (wind angle 45° only) and cross ventilation strategy (0° and 45°) was completed, where Approach C was validated against Approach A and Approach B.

3.1. Computational Fluid Dynamics (CFD)

This study used commercial code CFD software which was Ansys CFX 12.0. The turbulence model used is standard k-epsilon turbulence model. The turbulence model was selected due to its robustness which was important in this complex and huge coupled outdoor and indoor simulation study though it may be less accurate in areas with vortex shedding [14, 15]. It was a steady-state CFD simulation simulated under isothermal condition where the effect of buoyancy force on ventilation was not included. Mesh independence study is an important procedure in CFD simulation to understand the simulation accuracy as well as to optimize computational effort. Since this paper is a subsequent study to the previous investigation [13] which uses similar overall building forms, mesh independence study and the setup of computational domain were not discussed in this paper. The maximum number of element

used in this study was around $2.4x10^7$ which consists of mainly tetrahedral mesh except at the ground of outdoor domain where prism shape was used. Tetrahedral mesh was selected due to its robustness where it can easily mesh all building configurations used in this study.

3.2. Simulation setup and model configurations

Table 1. A list of case studies tested.

Test case	Ventilation strategy	No. of opening	Façade treatment	Wind angle
Case 1	Cross	2	Flat	0°
Case 2	Single-sided	1	Flat	0°
Case 3	Single-sided	1	Balcony (1.5m)	0°
Case 4	Single-sided	2	Balcony (1.5m)	0°
Case 5	Cross	2	Flat	45°
Case 6	Single-sided	1	Flat	45°
Case 7	Single-sided	1	Balcony (1.5m)	45°
Case 8	Single-sided	2	Balcony (1.5m)	45°

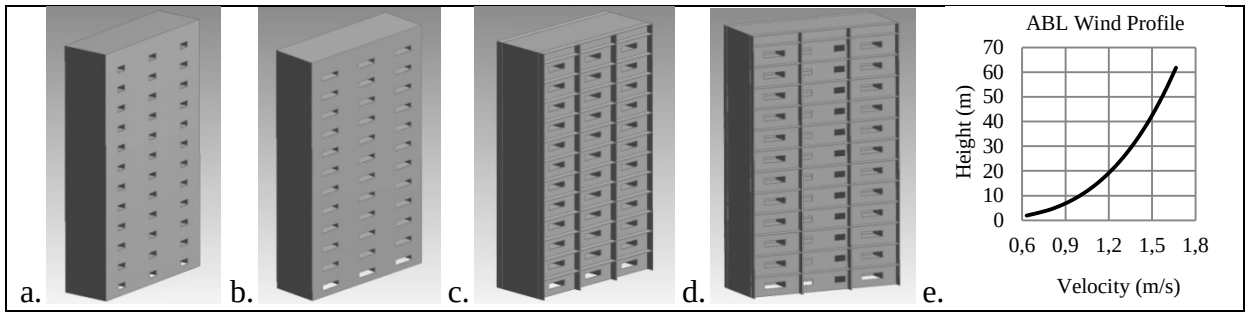

Fig. 1. The building configurations for Case 1and 5 (a), Case 2 and 6 (b), Case 3 and 7 (c) and Case 4 and 8 (d), together with ABL wind profile with mean speed exponent of 0.28 (e).

This study used the building configuration similar to the models used in wind tunnel experiment by Ismail. The overall dimension of the model was 30m (width) x 50m (height) x 10m (depth) to resemble 36 units apartment with 12-storey height. Three units were located at each floor with floor to floor height is 4m. While Ismail's models did not include opening an indoor space, this study provided a single or double openings (Fig. 1). The dimension of the opening was 4.4m (width) x 1.15m (height) for setup with single opening, and 2.2m (width) x 1.15m (height) each for double openings located at a single façade or at two opposite façades. The total opening area provided at each unit was $5.06m^2$, which was approximately 5% of the floor area. This study only focused on units located at the middle.

4. Analysis and Findings

4.1. Validation Study

Fig. 2 and Fig. 3 (see below) show that CFD predictions of wind pressure on facades of a building were inaccurate at areas located at the bottom leeward of the building where CFD over predicts the values of wind pressures. Therefore, if the wind pressure data were used in Approach B to predict indoor ventilation rate, it will result in under prediction on units located at the bottom of the building. The figures also suggest that if Approach C is used, it might also result in under prediction of indoor ventilation rate for lower units. Generally, the wind pressure distribution predicted by CFD was found to be acceptable.

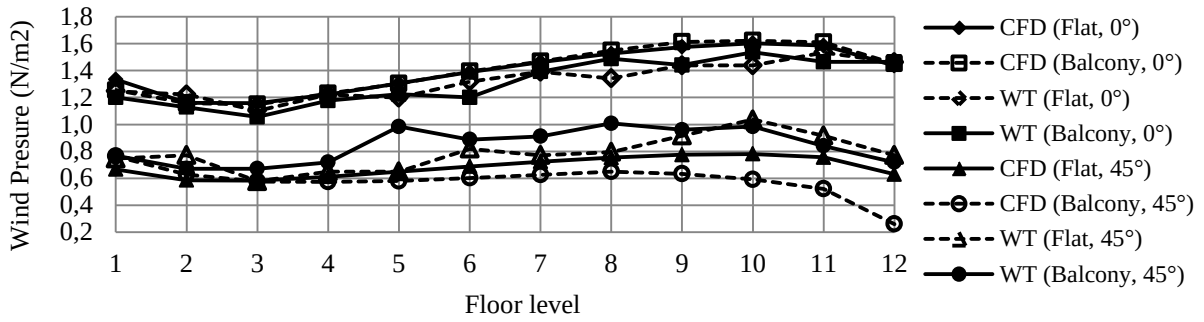

Fig. 2. Windward wind pressure distributions for flat façade and façades with balconies (opening is not provided).

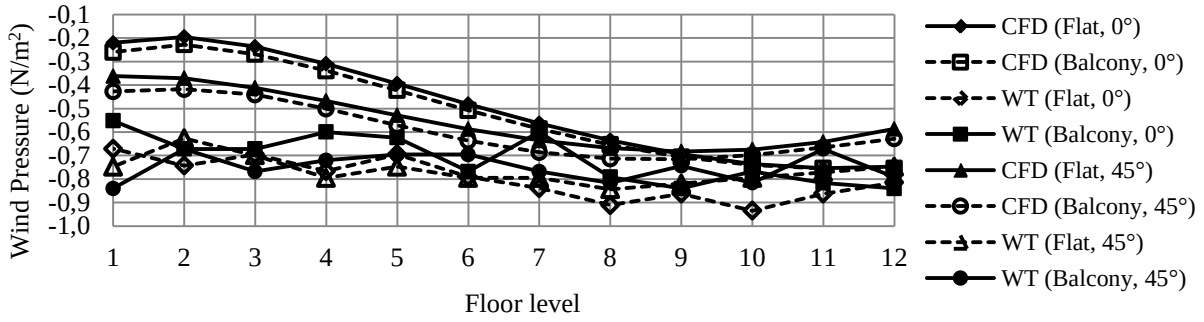

Fig. 3. Leeward wind pressure distributions for flat façade and façades with balconies (opening is not provided)

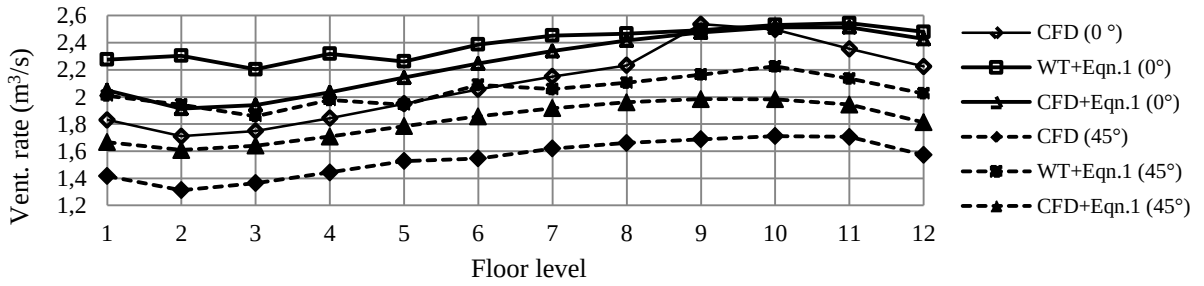

Fig. 4. Predicted ventilation rates for Case 1and Case 5 using Approach A, B and C.

For cross ventilation strategy (Fig. 4), it was found that Approach B and Approach C provided acceptable ventilation rate predictions for 0° wind angle with the worst prediction occurs at units located at lower floors. The average inaccuracies for Approach B and Approach C were found to be 6% and 12.5%, respectively. The inaccuracy at the lower level was expected due to the difficulty of the selected turbulence model to predict the recirculation zone at the bottom leeward side of the building.

For wind angle of 45°, it was found that Approach B and Approach C under predict indoor ventilation performance in comparison to Approach A, with the average inaccuracies of 24% and 11%, respectively. It was also found that the inaccuracies were relatively similar to all units. These greater inaccuracies can be due to the fact that the value of discharge coefficient of opening, C_D, used was 0.5 even though the wind direction close to the opening is travelling almost parallel to the facade of the building which shall suggests that the value may not be appropriate and shall be lower. This is supported by Equation 2 which suggests that the ventilation rate for wind angle of 45° shall be between 50 to 70 percent of the ventilation rate for 0° wind angle based on the suggested values of opening effectiveness, C_V, by ASHRAE

[11] (ASHRAE suggests the value to be 0.25-0.35 for 45° and 0.5-0.7 for 0°). This is also supported by an experiment completed by Larsen and Heiselberg [16] which found that the ventilation rate for a cross ventilated single cell building at 45° wind angle is reduced by around 55% in comparison to 0°.

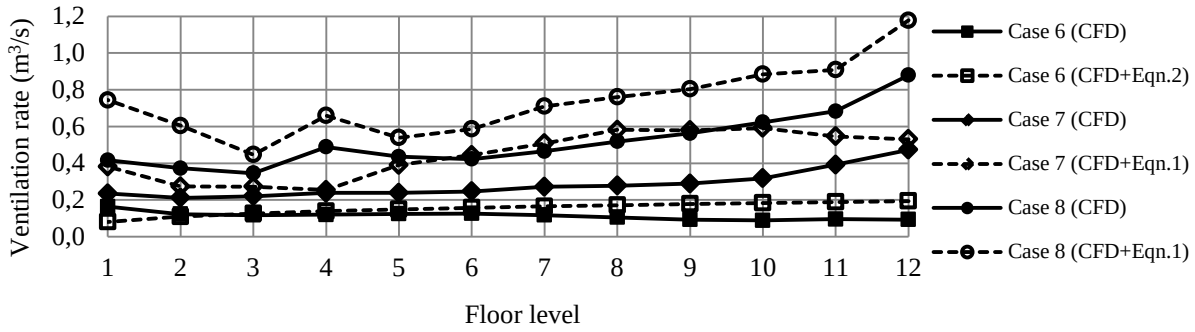

Fig. 5. Predicted ventilation rates for Case 6, 7 and 8 using Approach B and C.

In the case of single-sided ventilation strategy, only wind direction of 45° was used for validation study. For Case 6, Approach B with Equation 2 was used. Approach B with Equation 1 was used for Case 7 and Case 8 assuming that the CFD wind pressure difference across two reference point is acceptably describing the reality though it may come with some inaccuracies. Even though, both approaches might have not provided accurate predictions due to being applied to a difference building context, more or less, it shall give some idea on the ventilation rate. Fig. 5 shows that Approach C under predicted ventilation rate for all cases. The average percentage of difference between Approach C and Approach B for Case 6, 7 and 8 were 25%, 45% and 30%, respectively. Though the prediction differences for the values of ventilation rate were found to be high, Approach C was found to acceptably predict ventilation rate improvement due to changes on façade treatment.

Validation of single-sided ventilation strategy for building with 0° wind angle was not performed in this study. This is due to the limitation of Equation 1 and Equation 2 in predicting single-sided ventilation for the building configuration under the 0° wind angle. For example, in Equation 1, two reference pressures (if taken at a midpoint of each opening) are equal or almost equal, thus prediction of ventilation rate is zero or almost zero. In reality, this is not the case since there is a distinct pressure difference across each of the openings, thus inlet and outlet exist within the opening itself. On the other hand, Equation 2 is not appropriate due to the immediate outdoor air characteristic of airflow is different from low rise building where the equation is normally used and derived from. Thus, it was assumed that if Approach C was acceptably validated in earlier validation studies, the approach should also give an acceptable prediction under the 0° wind angle.

4.2. Ventilation Rate for Various Façade Treatments

Fig. 6 (see below) shows that cross ventilation strategy was far more effective in comparison to single-sided ventilation strategy. Cross ventilation strategy was also able to optimize the increased wind speed at upper floors. However, this was not the case for single-sided ventilation trategy with wind direction of 0° wind angle. This finding shows that under the circumstances, the ventilation performance of units located at upper units was relatively lower than units at the lower floor. This was due to the units being located within the stagnation zone, where the pressure difference across the facades was very low (see Fig. 2). Under 0° wind angle, the provision of balconies (Case 3) was also found to reduce indoor ventilation

performance of single-sided ventilated apartments, however, by splitting the opening into two (Case 4), it slightly increased the ventilation performance.

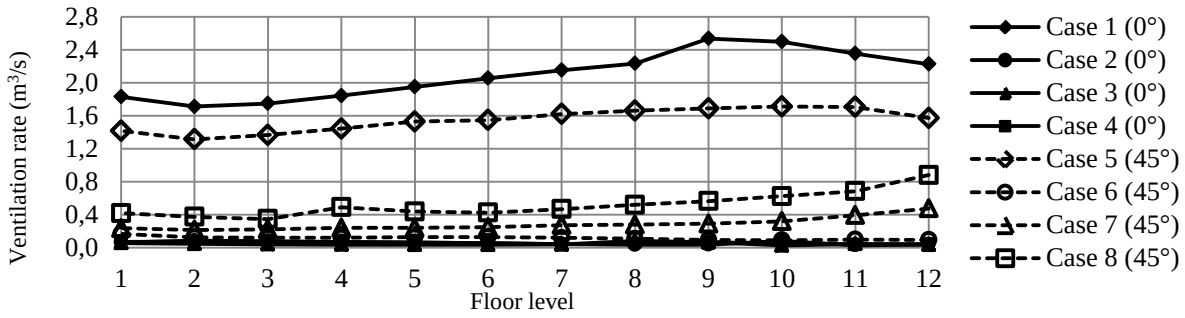

Fig. 6. Comparison between predicted ventilation rates for Case 1 to 8 using Approach C.

In the other hand, in the case of 45° wind angle, it was found that ventilation performance of single-sided ventilation strategy was improved in comparison to 0° wind angle, while for cross ventilation strategy, it was slightly reduced. For units with a balcony, their ventilation performances were higher than units with flat façade. This was due to external airflow travelling almost parallel to the openings at the building with flat façades, thus reducing its impact on ventilation performance. Additional to this, with a simple reconfiguration of opening from a single opening to double openings located close to protruding vertical walls of a balcony (Case 8), it has enhanced indoor ventilation rate by almost four times the ventilation performance of the model with a single opening with flat façade (Case 6).

5. Conclusions

Being a less effective ventilation strategy, single-sided ventilation strategy should be adopted in building design with clear understanding of its effectiveness and potential. This study found that cross ventilation strategy is a preferred option. However, if single-sided ventilation strategy is the only option, its ventilation performance effectiveness can be improved with appropriate façade reliefs such as a balcony. Below are the findings on the potential of balconies to enhance ventilation performance of single-sided ventilation strategy for tall buildings:

a. Perpendicular wind towards the façade of a tall building shall be avoided, where an introduction of a series of balconies could reduce indoor ventilation performance. This can be observed in Case 3. Under this wind condition, it is found that the balconies act as a buffer protecting the indoor spaces from direct penetration of wind.
b. For 45° wind angle, it was found that the provision of balconies, such as in Case 7 and Case 8, significantly improve indoor ventilation performance in comparison to a flat façade building (Case 6). However, the improvement shown in Case 7 and Case 8 was still much lower than Case 5, which adopt cross ventilation strategy.
c. Opening configuration plays an important role to improve an indoor ventilation performance. An appropriate combination of a balcony and opening configurations improves indoor ventilation performance (Case 8); otherwise, it reduces the indoor ventilation performance (Case 7).

Abstract: In this study we analyze the primary energy implications of ventilation heat recovery (VHR) in residential buildings, considering the entire energy chains. We calculate the operation primary energy use of a case-study apartment building built to conventional and passive house standard, both with and without VHR, and heated with electric resistance heating, bedrock heat pump or district heating. VHR increases the electrical energy used for ventilation and reduces the heat energy used for space heating. The primary energy savings of VHR are greater for the passive building than for the conventional building. Significantly more primary energy is saved when VHR is used in resistance heated buildings than in district heated buildings. For district heated buildings the primary energy savings are small. VHR systems can give substantial final energy reduction, but the primary energy benefit depends strongly on the type of heat supply system, and also on the amount of electricity used for VHR and the airtightness of buildings. This study shows the importance of considering the interactions between heat supply systems, VHR systems, building thermal properties and its airtightness to reduce primary energy use in buildings.

Keywords: *Mechanical ventilation; Heat recovery; Heat supply systems; Electric resistance heating; Heat pumps; District heating; CHP plant; Primary energy.*

1. Introduction

Ventilation has a significant impact on the energy performance of buildings, accounting for 30 to 60% of the energy use in buildings [1, 2]. Energy is used to cover the heat losses due to the ventilation air and to move the ventilation air for mechanical ventilation. The ventilation system also influences the air infiltration through the building envelope.

Building regulations currently require high energy efficiency of buildings, and therefore considerable efforts have been made to improve airtightness and insulation of buildings. In such buildings mechanical ventilation with heat recovery (VHR) is often used to recover heat from exhaust air to reduce ventilation heat losses. Ventilation heat losses can be typically 35-40 kWh/m^2-year in residential buildings, and up to 90% of this can be recovered with VHR depending on airtightness and insulation of buildings [3]. VHR is therefore gaining increasing interest in low energy and retrofitted buildings. In very low energy buildings, such as passive house buildings, VHR units are often equipped with additional air heaters to cover the space heating demand.

Sweden has set targets to reduce the final energy use per heated building area by 20% and 50% by 2020 and 2050, respectively, using 1995 as the reference [4]. Heat recovery from exhaust ventilation air is considered an important means to reach this target, and increased attention is being placed on VHR. There is a technology procurement project to develop and promote VHR systems which can be adapted for existing Swedish apartment buildings [5].

Most studies on the energy impact of VHR have focused on final energy use [e.g. 6-8]. Primary energy use, in contrast to final energy use, largely determines the natural resource use and the environmental impact of end-use energy services. The concept of primary energy is used to denote the total energy needed in order to generate the final energy service, including

inputs and losses along the entire supply chains. Fewer studies have analyzed the primary energy implication of VHR in buildings. In this study, we analyze the impact of VHR on the operation primary energy use for residential buildings. We determine situations where mechanical ventilation with heat recovery can reduce primary energy use for building operation.

2. Methodology

This analysis is based on simulation modeling of a case-study apartment building with mechanical ventilation. We model the primary energy use for the original and improved level of energy efficiency of the building, both with and without VHR. Next we compare the primary energy use of the buildings and calculate the net primary energy savings achieved by the VHR, taking into account the changed electricity use due to VHR, as well as the changed heat demand due to VHR and changed air infiltration.

2.1. Building description

Our case-study building is a 4-storey multi-family wood-frame building with 16 apartments and a total heated floor area of 1190 m^2. Persson [9] describes the construction and thermal characteristics of the building in detail. A new building is then modeled with thermal properties of passive house but otherwise identical to the existing building. Table 1 shows the thermal characteristics of the existing, conventional building and the new, passive building. In addition to lower U-values, the passive building is assumed to have much better airtightness than the conventional building.

Table 1. Thermal properties of the building components

Building	*U-value (W/m^2K)*					*Air leakage*
	Ground floor	External walls	Windows	Doors	Roof	l /s m^2 at 50 Pa
Conventional	0.23	0.20	1.90	1.19	0.13	0.8
Passive	0.23	0.10	0.85	0.80	0.08	0.3

For both the conventional and passive buildings, we analyze the use of mechanical ventilation with and without VHR. The designed airflow rate for the building is 0.35 l/s m^2, based on Swedish regulations [10]. For the buildings without VHR, exhaust air is extracted from the kitchens, bathrooms and closets with fan and duct system, and fresh air is supplied through slot openings under windows in the bedrooms and living rooms. For the buildings with VHR, the ventilation system provides the same airflow rate as in the buildings without VHR. For the existing, conventional building the existing ventilation system is complemented with ventilation ducts for incoming air and a heat recovery unit [5].

2.2. Heat supply

We analyze cases where space heat is delivered by electric resistance heating, heat pump or district heating. For the electric resistance heating and heat pump we assume that the electricity is supplied from a stand-alone plant based on biomass steam turbine (BST) technology. We assume that the district heat is supplied from a combined heat and power (CHP) plant based on biomass steam turbines technology (CHP-BST). We consider scenarios where the CHP plant accounts for either *50%* or *90%* of the district heat production, with oil boilers accounting for the remainder. To show the impact of energy supply technology being developed, we also analyze a case where biomass integrated gasification combined cycle (BIGCC) technology is used instead of the BST technology for both CHP and stand-alone

power production. Furthermore, Gustavsson et al. [11] explored the structure of district heat production under different environmental taxation regimes. They found that the CHP production should be 80-83% of the total district-heat production when using BST technology and 76-78% when using BIGCC technology. The difference in share of district-heat production between the technologies varies because the BIGCC technology is more efficient and capital intensive than the BST technology. To explore the implications of this for VHR, we calculate the primary energy savings when district heating is based on s uch CHP production systems.

2.3. Final energy calculations

We simulate the annual final energy use of the conventional and the passive buildings, both with and without VHR, using the ENORM software [12]. This software calculates the space heating, ventilation, domestic hot water, and household and facility management electricity use of a building based on the building's physical characteristics, internal and solar heat gains, occupancy pattern, outdoor climate, indoor temperature, heating and ventilation systems, etc. We use climate data for the city of Växjö in southern Sweden, and assume an indoor temperature of 22°C. Table 2 shows principal values used to calculate the electricity use for ventilation. Other values including fan efficiency and operation mode of the ventilation systems are based on the default assumptions of the ENORM software.

Table 2. Major ventilation input values

Description	*Value*
Air change rate (l/s m^2)	0.35
Heat recovery efficiency (%)	85
Ventilated volume (m^3)	2861
Supply air flow rate (m^3/h)	1540

2.4. Primary energy calculations

We use the ENSYST software [13] to quantify the primary energy that is used to provide the final energy use in the different cases. The software calculates primary energy use considering the entire energy chain from natural resource extraction to final energy supply. We credit the electricity cogenerated by the CHP plant to the district heat system, assuming that it replaces electricity produced by a stand-alone plant with similar technology and fuel [14]. We assume the increased electricity use due to VHR is covered by stand-alone plant with similar technology and fuel as the heat supply system used.

3. Results

Table 3 compares the annual final energy use of the conventional and the passive buildings with and without VHR. The annual total final energy use of the passive building with VHR is about 21% lower than for the alternative without VHR. The corresponding value for the conventional building with VHR is 10%. VHR decreases the final energy for space heating, but increases the electricity used to operate the ventilation system. Overall, VHR reduces the final energy for space heating and ventilation by 55 a nd 22% for the passive and the conventional building, respectively, relative to the alternatives without VHR.

Table 3. Annual final operation energy use for the building scenarios

Building	*Final energy use (kWh/m^2-year)*				
	Space heating	Ventilation electricity	Tap water heating	Household and facility electricity	Total
Conventional building	70	4	40	52	166
Conventional building with VHR	50	8	40	52	150
Passive building	43	4	40	52	143
Passive building with VHR	13	8	40	52	113

Table 4 shows the annual operation primary energy use for the conventional and the passive buildings when using different end-use heating systems with energy supply based on BST technology. Ventilation accounts for 2-11% of the operation primary energy use. The primary energy for heating for the district heated buildings is low due to the high overall efficiency of district heating systems with CHP plants. The cogenerated electricity replaces electricity that otherwise would have been produced in a stand-alone plant with much lower efficiency.

Table 4. Annual operation primary energy use for the building with different end-use heating systems with energy supply based on BST technology

Description	*Primary energy use (kWh/m^2-year)*				
	Space heating	Ventilation electricity	Tap water heating	Household and facility electricity	Total
Resistance heating:					
Conventional building	209	12	119	155	496
Conventional building with VHR	149	24	119	155	448
Passive building	128	12	119	155	415
Passive building with VHR	39	24	119	155	337
Heat pump:					
Conventional building	78	12	45	155	290
Conventional building with VHR	55	24	45	155	280
Passive building	48	12	45	155	260
Passive building with VHR	14	24	45	155	239
District heating, 50% CHP:					
Conventional building	66	12	38	155	271
Conventional building with VHR	47	24	38	155	264
Passive building	41	12	38	155	246
Passive building with VHR	12	24	38	155	229
District heating, 90% CHP:					
Conventional building	42	12	24	155	233
Conventional building with VHR	30	24	24	155	233
Passive building	26	12	24	155	217
Passive building with VHR	8	24	24	155	211

Table 5 compares the percentage primary energy savings of VHR in relation to the primary energy use for space heating and ventilation, and to the total primary energy use for operation, including space heating, ventilation electricity, tap water heating and household and facility management electricity. The VHR primary energy savings ranges from 0-55% of space heating and ventilation primary energy use.

Table 5. Percentage primary energy savings of VHR, in relation to the primary energy used for space heating and ventilation for the different end-use heating systems with BST energy supply technology

Building	*Relative primary energy savings*			
	Resistance heating	Heat pump	District heating, 50% CHP	District heating, 90% CHP
Conventional	22%	12%	9%	0
Passive	55%	37%	32%	16%

The change in annual primary energy use for space heating and ventilation electricity when using VHR with different end-use heating system with BST or BIGCC energy supply are shown in Figure 1. The net savings are shown in Figure 2 for both BST and BIGCC technologies. The primary energy savings of VHR is significantly greater when using resistance heating, followed by heat pump and district heating with *50% CHP*. However, much smaller or no primary energy savings is achieved when using district heating with *90% CHP*. The savings of VHR are larger for the passive building than for the conventional building. The BIGCC technology gives similar results as the BST technology, but the net primary energy savings are lower compared to the case of BST.

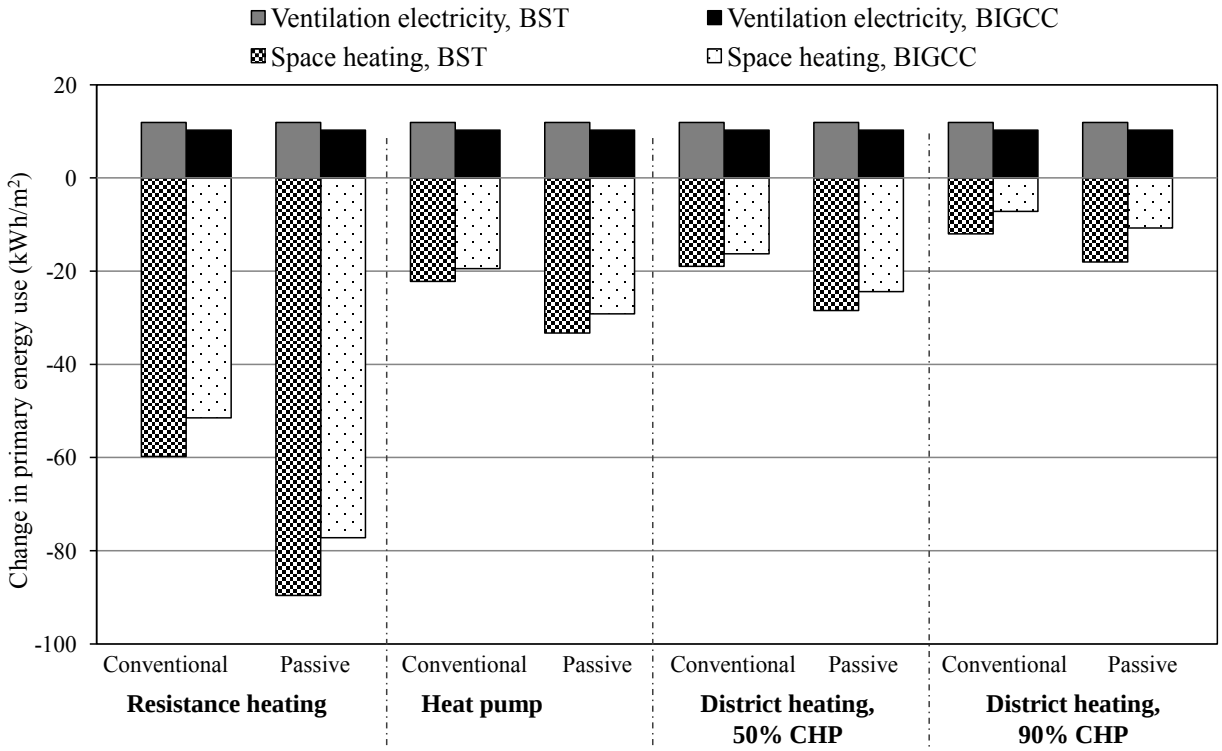

Figure 1. Change in annual primary energy use for space heating and ventilation electricity when using VHR with BST or BIG/CC energy supply

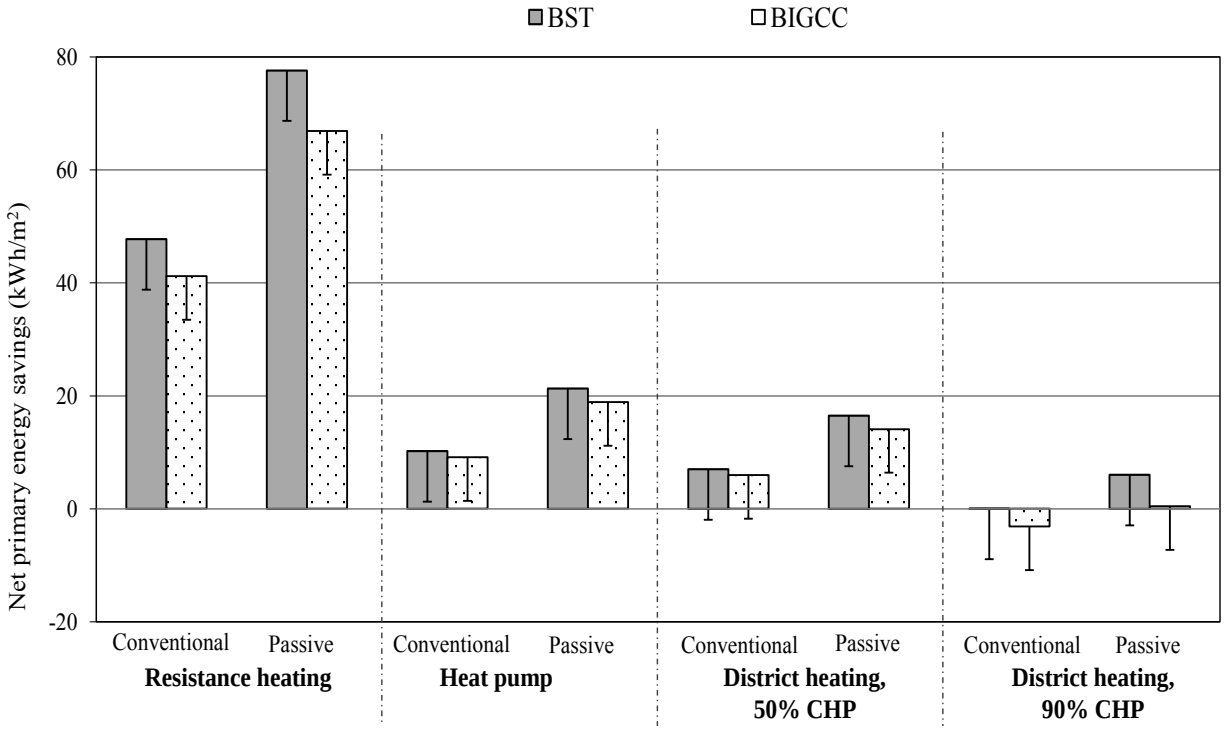

Figure 2. Net annual primary energy savings for VHR when using BST or BIGCC energy supply. The error bars show the savings when electricity use by the VHR is 7 kWh/m^2

In cold climatic regions VHR systems usually encounter frost during severe winters, and additional energy may be needed for defrosting. VHR systems may be fitted with additional preheating device to overcome this problem, increasing the electricity use for VHR [15]. Our base calculations are based on electricity use of 4 kWh/m^2 for the VHR and do not include electricity to defrost the system. Tommerup and Svendsen [3] reported that electricity use in VHR system of 80-90% efficiency is typically 7 kWh/m^2 under Danish conditions, and suggested this might be reduced to 3 kWh/m^2 with more efficient systems. In Figure 2 the error bars show the change in net primary energy savings for VHR, when the electricity use for VHR is 7 kWh/m^2 instead of 4 kWh/m^2. The higher electricity use for operating VHR reduces the net primary energy savings, in particular for the district heated buildings. In fact, a ventilation electricity use of 7 kWh/m^2 increases the net primary energy use for the buildings with district heating based on *90% CHP*. Hence low electricity use for VHR is important. For the conventional building with lower airtightness together with district heating based on a large share of CHP production, VHR may be counterproductive and increase primary energy use.

In our base case calculations, the CHP production accounts for 50 and 90% of the total district heat production [16]. In this section, we show the net primary energy savings for VHR when more optimally designed CHP production systems are used. Figure 3 shows the net primary energy savings for VHR when district heating is based on the lower and upper optimal CHP productions according to Gustavsson et al. [11]. VHR increases net primary energy use for all buildings when the electricity use for VHR is 7 kWh/m^2. The net savings is positive, but very low, for the conventional buildings with VHR systems using 4 kWh/m^2.

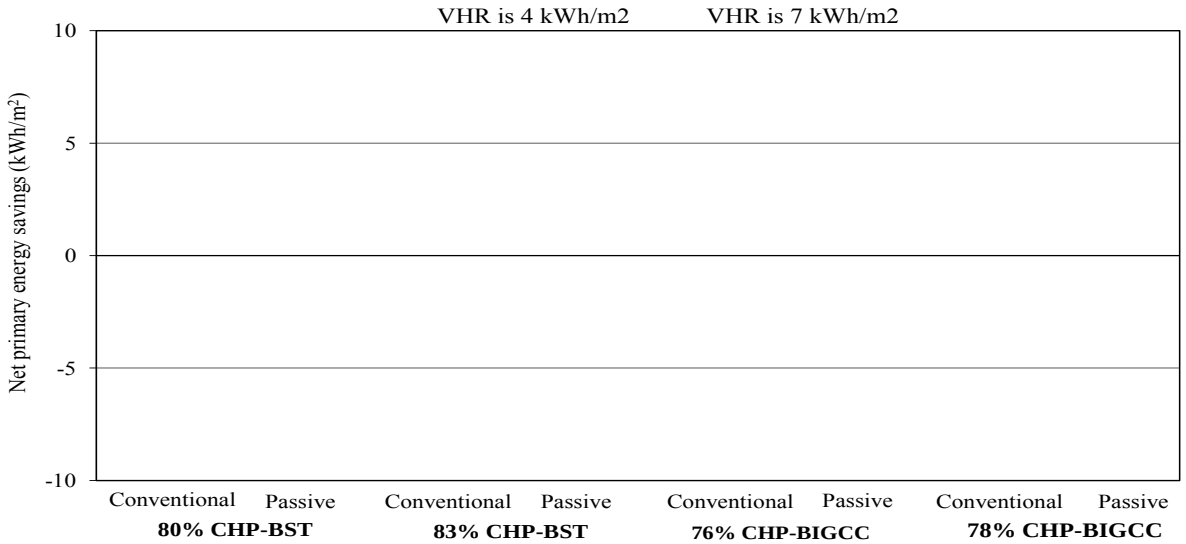

Figure 3. Net annual primary energy savings for VHR when more optimally designed CHP production systems are used

4. Discussion and conclusions

Our results show that primary energy savings of VHR can be very significant, depending on the type of heat supply system, the airtightness and thermal properties of buildings, and the amount of increased electricity used to operate the VHR system. The biggest savings is achieved when VHR is installed in a resistance heated building. However, small primary energy savings is achieved when the VHR is installed in CHP-based district heated buildings. VHR gives much smaller primary energy savings for the district heating with 90% CHP than with 50% CHP, supporting the findings of Dodoo et al. [16] and Gustavsson et al. [11]. For district heating systems mainly based on CHP, the reduced heat demand reduces the potential to cogenerate electricity, and is more significant if BIGCC technology is used instead BST technology.

The primary energy savings of VHR are greater for the passive building than for the conventional building, confirming that VHR systems perform better with improved airtightness [3, 6]. Hence, the air-tightness of buildings should be in the range as for newly constructed passive houses to minimize primary energy use when using VHR systems. We found that the greatest primary energy savings is achieved when VHR is incorporated in resistance heated passive building. The primary energy savings of VHR depend on the electricity use to operate the VHR system. Therefore the amount of electricity required to operate VHR system should be minimized.

Our results show that VHR may give low or negative primary energy savings in passive house buildings when combined with energy-efficient heat supply systems. For example, the case-study passive building with VHR in some cases uses greater primary energy than the same building without VHR. It is important to build houses with airtightness comparable to that of passive houses but such houses need to be ventilated using strategies that minimize primary energy use.

When deciding on installing VHR, attention should therefore be given to the interaction between the electricity use for VHR, the airtightness of the building and the type of heat supply system. This is particularly important when using district heating with a large share of

CHP production, as suggested by Dodoo et al. [16]. A primary energy analysis is necessary to evaluate the energy benefits of VHR in residential buildings.

Abstract: The Mediterranean architecture was characterized by passive solutions able to ensure thermal comfort conditions in the built environment during the hot season. This cultural heritage is almost disappeared, delegating the comfort conditions to artificial systems. One of the above mentioned passive solutions concerns the use of light colors to redirect most of the incident solar radiation. Cool roofs are a mix of these old concepts and modern technologies. The paper reports the results of a cool roof application in a senior recreation center, belonging to Roma Tre University. The cool roof was applied on a part of the whole surface of the roof in order to assess the difference in thermal conditions obtained with this solution compared to the original case. The experiment was carried out in two phases. During the first phase the building was monitored with sensors of temperature, humidity and solar radiation. The second phase concerned the creation of a building model inputted in a dynamic simulation tool used to evaluate the building performances due to this cooling technique. This study demonstrate the positive impact of the technology in terms of cooling and total energy savings as well as on the indoor thermal conditions in Mediterranean buildings.

Keywords: *Cool roof, Passive cooling, Reflectance, Emissivity*

1. Introduction

Global warming is a planetary problem monitored depending on latitude and economic development but with completely different intensity and consequences in relation to these two influences. The Mediterranean area is particularly vulnerable, with a predicted temperatures increase of 2 °C by 2030, and with alarming expectations by 2100 (IPCC, 2007). This is the scenario in which lies the need for new energy-saving techniques for conserving nature and preserving public health in every area of development. This problem is present even in the civil sector and in particular it is mainly due to two factors: The emergence of the urban heat island phenomenon and the continuing growth in electricity consumption for summer air conditioning of buildings, not only for the tertiary but recently also for the residential sector. One of the techniques used to limit the dangers associated with the temperature rise is the passive cooling of buildings that includes the use of cool roof [1].

Cool materials are those materials that do not rise significantly their surface temperature under solar radiation. They are characterized by a high solar reflectance (high ability to reflect solar radiation incident on the material) and thermal emissivity (high ability to radiate heat in the infrared wavelengths). The high reflectivity is due to pigments characterized by a high reflectance in the infrared portion of the solar spectrum, maintaining the typical profile in the visible spectrum. This means that the material does not warm up significantly during daylight hours. High emissivity allows the material to stay cool during the night, radiating towards the sky the heat absorbed during the day. The employ of these materials is very useful for the construction of roofs, being the most used building materials characterized by high solar absorption (and therefore low reflectance). The application of cool roof technology can produce a surface temperature profile lower than a normal coating. This leads to a reduction of heat flow entering the building, contributing to an effective reduction in the average indoor air temperature or a reduction in consumption for cooling [2]. The large use of materials with these characteristics in an urban area also leads to indirect energy savings related to the high solar reflectance which reduces the temperature of the agglomerate of buildings. The decrease

of temperature induces a better energy balance in the areas involved and facilitates the mitigation of urban heat island effect [3]. Cool roofs are not necessarily realized with paints, in fact different technological solutions exist for the reflective cool coatings: Membranes, sheaths, asphalt, bitumen, paving bricks [4]. The most common construction materials for roofs have a reflectance between 20 and 30%, with a significant solar load for the rooms directly under the ceiling. Fig. 1 shows the trend of the reflectance as a function of wavelength for some cool materials and common materials.

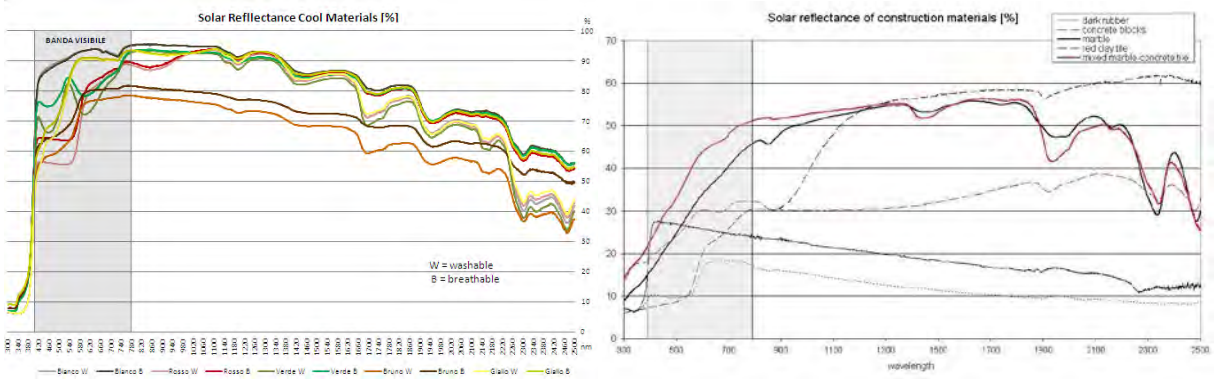

Fig. 1. Solar Reflectance [%] for Cool Materials and Typical Materials

The thermal emissivity of building materials is generally between 0.8 and 0.9. Only the metals have lower values of emissivity and this limits the radiant power towards the sky during night. For this reason, metal cool roofs shall be efficient only if they have extremely high values of solar reflectance (greater than 0.75-0.8). An unexplored aspect is related to the maintenance of the initial properties of the products. A rapid decrease in efficiency of material would render useless the economic investment.

2. Case Study: Social and cultural center "Vasca Navale"

The building examined in this work is situated in Rome close to San Paolo district. It is located on a plot belonging to Roma Tre University, and recently has been used as a senior recreation center.

The choice fell on this building because it has standard features for study to which it was submitted. Indeed it is an excellent test bench to verify the performances of a high reflectance roof. This is due to the extended horizontal surfaces that capture solar radiation. The plan of the structure extends mainly in length and has an area of 275 m^2. The layout of the rooms is very simple: There are five rooms arranged in a row and they are all characterized by a rectangular plan. The orientation of the longer sides is South-North. The entire structure has a low insulation level characterized by transmittance values significantly higher than those established by Italian reference standard for the climate zone of Rome [5]. The Table 1 shows the layers of vertical walls, ceiling, floor, internal walls, their thickness and transmittance.

Table 1. Wall Layers

	Ext.Wall	Ceiling	Floor	Int.Wall	WindowSingleGlazed
Thickness [m]	0.350	0.310	0.475	0.210	-
Transmitt. [W/m^2K]	1.23	0.96	0.91	1.6	2.8

The windows are single glazed (Table 1) equipped with a dark gray aluminum frame for which it was suggested an absorbance of solar radiation of 85%. The frame area occupies about 30% of the total area of a window.

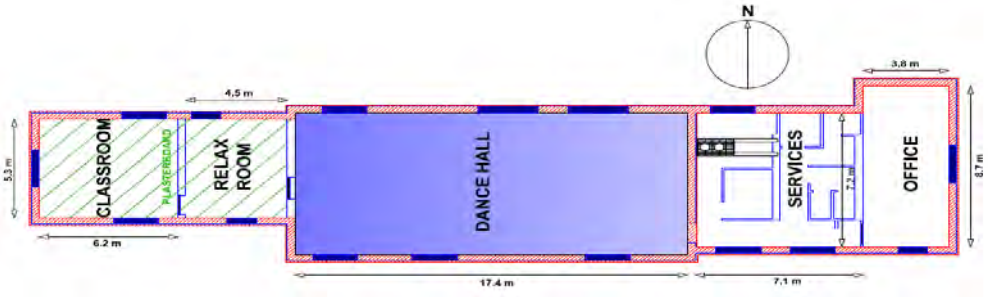

Fig. 2. Plan of Recreation Center

Inside, the ceiling has a height of 3.8 meters except in the classroom and in the relax room (Fig. 2) where there is a suspended ceiling made of plasterboard to 3.1 meters above the ground. In these two rooms the phenomena of heat exchange with the outdoor take on different characteristics compared to the other three rooms, due to the presence of an air gap in the ceiling of 70 centimeters. In blue (Fig. 2) it is shown a portion of the roof of 133 m^2 on which a cool roof was applied, corresponding to the "Dance Hall". The material used for the roof is a white mineral membrane based on milk and vinegar of Ecobios Laboratories. The original roof is a bituminous sheath. The superficial layer is made of slate. Samples of the two types of materials were analyzed with a double beam spectrophotometer from which the trend of the reflectance was obtained as a function of the wavelength of the incident beam between 300 and 2500 nanometers. The bituminous slated sheath does not have a uniform color. For this reason three tests were carried out in three different portions where the beam generated by the spectrophotometer affects the corresponding sample. An arithmetic average was carried out to obtain the trend of the reflectance. With the data obtained by the spectrophotometer, it was performed a weighted average of the reflectance values in the range considered (300 nm - 2500 nm) according to ISO 9050 2003 following the energy distribution of the solar spectrum [6]. The integrated reflectance for the slate is 13.7%. It is very low if compared to the one of the mineral membrane Ecobios which reaches a value of 86.4%. The Fig. 3 shows the comparison between the measured reflectance: In blue it is shown the cool material, the other three trends are the tests relating to slate, they have slight differences depending on the point of incidence of the light beam outgoing from the instrument on this surface. Regardless the expected behavior in the wavelength of visible (the membrane is white mineral, slate is dark gray), the cool material presents very interesting values of reflectance in the wavelength of near infrared. Indeed it has a value of more than 95% in a range that goes from 770 to 1100 nanometers. The reflectance of the slated sheath remains consistently below 20% throughout the measuring range. Both materials have a thermal emissivity of 0.88.

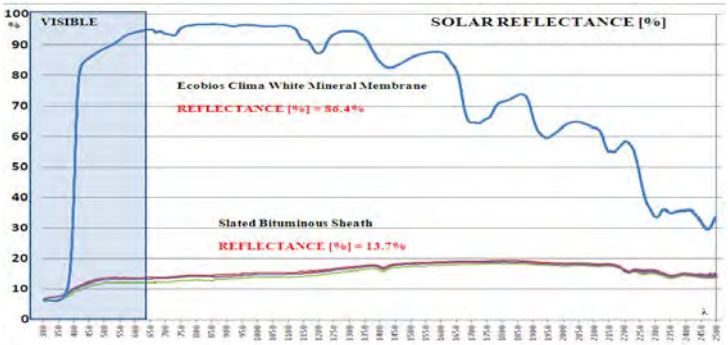

Fig. 3. Solar reflectance [%] of Ecobios Clima cool membrane and a slated sheath

3. Placement of Sensors

A pyranometer to measure the intensity of solar radiation and a sensor for measuring outdoor temperature and humidity were placed on the roof. In this way it was possible to collect data on the weather during the measurement campaign [7]. This data were also inserted into the TRNSYS processor radiation software to obtain more realistic simulation results. To compare the surface temperatures between the two different roofs, two heat-resistance were placed on the cool roof and two on the slated sheath. In order to monitor the temperature on each side of the roof two other heat-resistance were placed in the inner surfaces of it. Sensors for indoor air temperature and humidity were placed in the "Dance Hall" where the cool roof is applied, in "Services" and in "Office". In this way it was possible to verify the efficiency of a cool roof on the indoor temperature of a room in comparison to the other indoor temperatures. On 12th August, after a routine check on the conditions of the cool roof, a layer of dust and soil was found on its surface probably caused by the presence of a dockyard adjacent to the building in question. This incident has caused the depletion of the surface properties of the cool material, decreasing its efficiency. The TRNSYS simulation software was used to determine the new value of reflectance detected in the points most affected by the problem just mentioned. Indeed, after creating a model of roof to simulate the surface temperature, the reflectance of it was changed to obtain a temperature profile very similar to the one measured by the sensors. By performing the above procedure, the new solar reflectance value found is 68%.

4. Comparative analysis of measured data

4.1. Temperature profiles

Through the data stored by the surface temperature sensors, it was possible to produce the temperature profiles of the outer and inner surfaces of the roof slab. The profiles of the "Dance Hall" above which was applied the membrane with high reflectance (blue) were compared to the profiles of the area called "Office" characterized by the slated sheath (red). The comparisons, shown in Fig. 4, refers to two days of August. The temperature of the surface of the reflective membrane is significantly lower than the one of the slated sheath. The maximum of the difference between the two outer surfaces is in the middle of the day at the peak of solar radiation when cool roof has the highest efficiency.

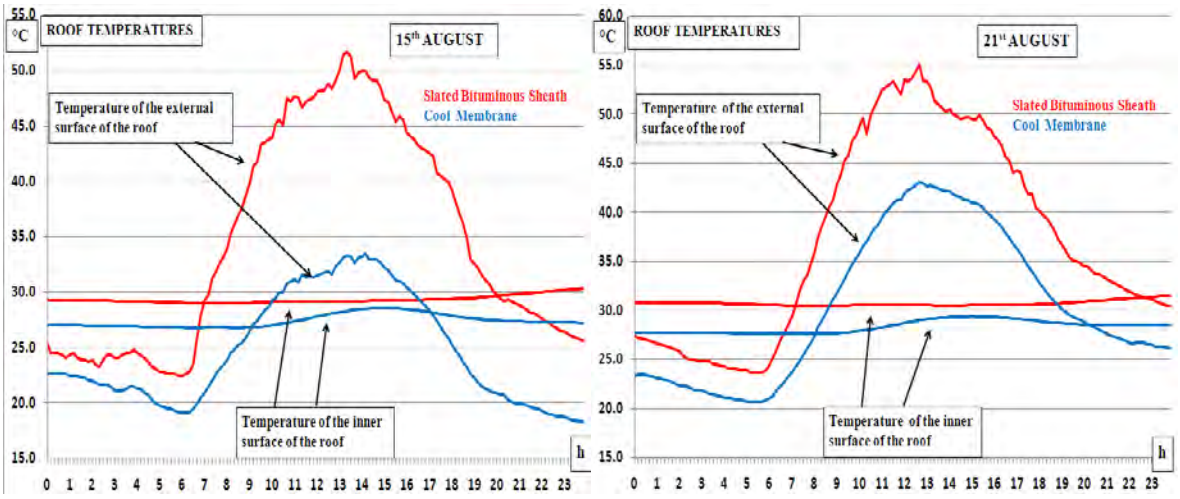

Fig. 4. Surface temperature profiles of the roof (Cool Membrane and slated roof)

The difference in temperature is above 20 °C. A lower surface temperature will decrease the heat flow through the roof changing the indoor temperature.

4.2. Comparison of internal temperatures

It was not possible to monitor simultaneously the difference in indoor air temperature due to the cool membrane and the original slate mantle in the same thermal zone. For this reason two periods of two days were chosen, corresponding to the beginning of two heat waves in July and August whit almost identical trends of solar radiation and outside temperature. In the first of these two periods the cool roof had not yet been applied to the area of interest. In this way it was possible to compare the values of indoor air temperature in a room equipped with and without a cool roof.

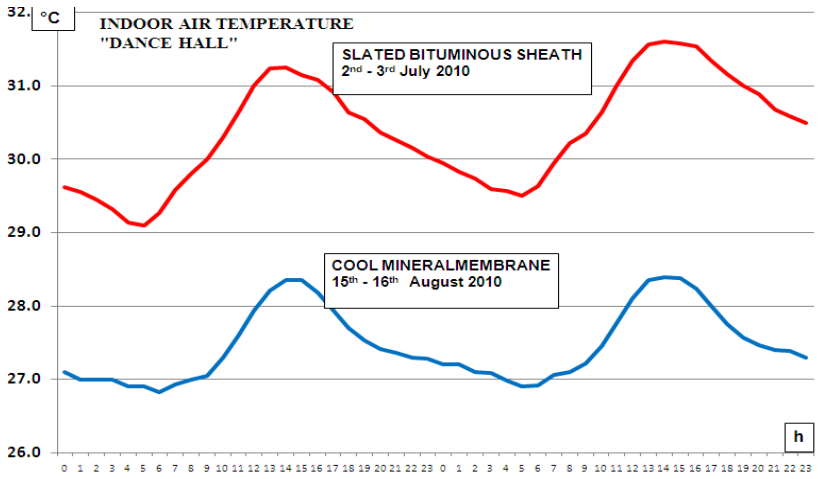

Fig. 5. Indoor air temperature of the "Dance hall"

In the Fig. 5 above, the trend in blue, typical of a cool roof, denotes the positive effect of this technology of passive cooling by limiting the maximum temperature below 28.5 °C. With the slated sheath the values are higher than 31 °C. It is important to remember that the performance measured are relative to a cool roof not at its maximum efficiency, but with limited performance due to dust and soil deposited on it.

5. Simulations Results

The model included in the simulation software TRNSYS was calibrated to the measured indoor temperature profile and to the external surface temperature of the roof. To achieve optimal calibration, the parameters of air infiltration and the values of internal and external shading of non-opaque surfaces were modified obtaining a maximum deviation between the real temperatures and those obtained with the simulator under three tenths of a degree. The first session of simulations is aimed at obtaining a comparison of results for the internal operative temperature with no cooling systems. The second part concerns the evaluation of air conditioning loads. Both sessions were conducted considering three reflectance values of the roof slab.

Three models were created, each one with a different value of insulation:

1. Real values of insulation of the building;
2. Real values of insulation of the building except the transmittance of the roof according to Italian standard reference;
3. Insulation according to Italian standard reference Zone D (vertical wall = 0.36 W/m^{2}K, ceiling = 0.32 W/m^{2}K, floor = 0.36 W/m^{2}K, window = 1.9 W/m^{2}K, window with frame including 2.4 W/m^{2}K) for the entire building.

5.1. Operative Temperatures

The operative temperature of a zone is the temperature which takes into account both the internal air temperature and the average temperature of the inner surfaces of the structure. From the simulations results was extracted the total number of hours in which the operative temperature of the "Dance Hall" exceeds some chosen values in the period from 17th June to 1st September. The values of solar reflectance used are: 16% to simulate the original coating, 86% for the mineral membrane and 68% to simulate mineral membrane with performances compromised by dust and soil. The following are histograms for the three chosen levels of insulation.

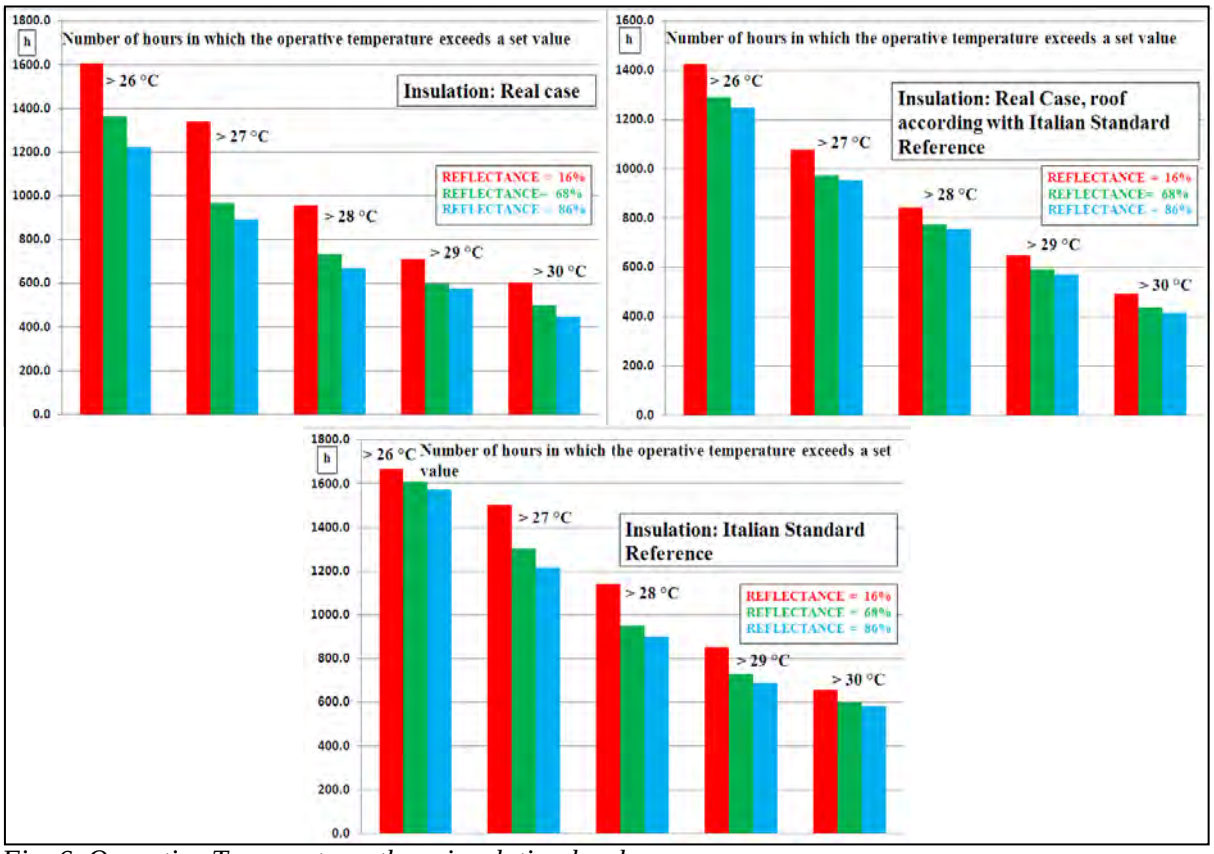

Fig. 6. Operative Temperature, three insulation levels

The use of a high reflectance material is a contributory factor to increase the number of hours in which there are thermal comfort conditions. On the other hand, increasing insulation level, the number of hours in which the temperature is greater than a specific value tends to increase. Indeed, being equal the reflectance, the configuration with insulation according to Italian standard reference has internal temperatures higher than the ones registered in the building with the real level of insulation. This phenomenon occurs in the climatic zone of middle Mediterranean in buildings characterized by high solar gains through non-opaque surfaces. The significant solar gains through windows increase the indoor air temperature. The value of the latter become very similar to the outdoor temperature during daylight. The low transmittance value determines a small outgoing heat flow which lasts even during the night. The heat is trapped inside, creating a sort of greenhouse effect. In warmer climates the gap between indoor and outdoor temperatures is generally high and the phenomenon described above is less evident.

5.2. Air conditioning loads

The simulations performed on the model equipped with an air conditioning system of unlimited power, conducted during summer (17th June - 1st September), are designed to assess the extent of energy savings depending on the reflectance of the roof. The reflectance of the roof of the "Dance Hall" assumes the three values previously used. From the results were extrapolated the net loads for the summer period necessary to maintain the temperature of the zone below the set-point of 26 °C for the three levels of insulation.

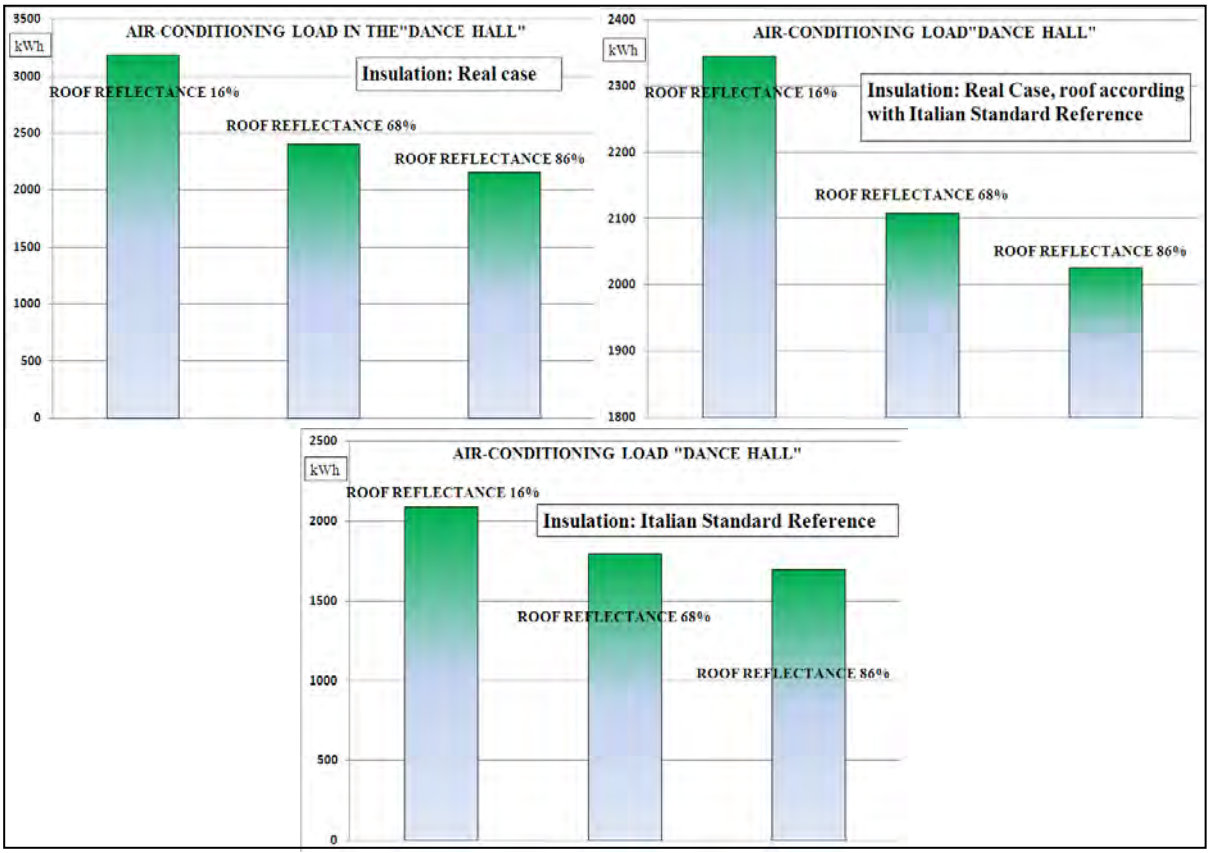

Fig. 7. Air conditioning loads, three insulation levels

Fig. 7 shows a decrease of load proportional to the increasing of reflectance. Again, as in the previous group of simulations, the more insulated building results less sensitive to changes in reflectance. Comparing building with real insulation and roof reflectance of 16% and building with roof insulation level established by Italian standard reference and roof reflectance 86%, the value of energy used to cool the "Dance Hall", decreases from 3200 kWh to 2050 kWh, with a saving of about 9 kWh per square meter. Considering the insulation level in accordance with Italian standard reference for the whole structure of the building, the consumption decreases from 3200 kWh to about 1700 kWh with an energy saving for air conditioning in the area of about 12 kWh per square meter. Considering the entire warm season, including the months of May and September, the savings would be greater, even more if a cool roof were applied over the entire roof surface.

6. Conclusions

The application of a cool roof reduces roof surface temperatures, limiting the incoming heat flow from it and, in any case, decreasing the temperature of the indoor environment. The case study examined in this report has demonstrated, through appropriate measurements of temperature, the potential of a cool roof. The Ecobios Clima reflective membrane has proved

to be an excellent material for this use. The ease of application on any surface is another quality of this product. The area of the building that received the benefits from the application of this membrane is affected by a large number of thermal factors that have tested the capabilities of the cool roof. The large glass surfaces exposed to the South are subjected to heavy solar gains and even if they were shielded from direct sunlight they influenced the indoor temperatures. Adding to this, the poor insulating level and low volume of air circulation make the Dance Hall the more thermally critical zone of the building. The cool roof decreased the indoor air temperatures by 2.5 °C in average. This is a very interesting result considering the fact that it did not work at its maximum value of reflectance because of external agents described above. It was possible to quantify the extent of energy saving on internal loads, noting in this case as it increases in direct proportion to the level of reflectance. Benefits relating to this passive technique of cooling are obtained even only increasing both levels of reflectance and insulation of a roof. From the observations made in this report, it is possible to note that the employ of a cool roof on existing buildings and on new buildings under construction with expected high insulation levels offers significant advantages in both cases.

Abstract: Cooling energy load can be reduced by reflective roofs. The reflective roofs are recognized by Turkish architects, contractors and manufacturers, however, the solar reflectance performance of new and aged roof coverings produced in Turkey is still unknown. Purpose of this paper is to assess short-term and long-term solar reflectance performance of these roof coverings. In this context, solar reflectance measurements were conducted both in laboratory and in field. Firstly, solar reflectance performance of 13 unexposed test samples including clay, cement, bituminous and metal based was measured in laboratory. Then, 6 of these test samples were exposed to simulated solar radiation for a duration that is equivalent to 1-year exposure. The laboratory measurements indicated that white and shiny ceramic tile is the most reflective covering while black corrugated sheet is the most absorptive one. Secondly, two test specimens (red clay tile and bituminous shingle covered surfaces) with an automated weather observation system were set up in a field in order to measure the solar reflectance performance of the roof surfaces. The initial results demonstrated that the clay tile-covered roof surface had higher reflectance values. This paper will enable designers to choose the roof covering appropriate for reflective roofs that can be used to rehabilitate existing roof coverings or to design new roofs.

Keywords: *Solar reflectance performance, Roof covering, Reflective roof.*

1. Introduction

Future climate projections demonstrate that the western part of Turkey will experience temperature increases up to 6^0C notably in summer in addition to urban heat island effect, whereas the temperature increase for the entire country is estimated to be around 2-3^0C (The Ministry of Environment and Foresty, 2007). Increase in temperature will result in increase in summer cooling load, electricity consumption and amount of carbon dioxide in atmosphere. Survey of literature indicates that cooling energy load can be reduced by reflective roofs which comprise high-albedo roof coverings that have high solar reflectance and high infrared emittance and maintain these properties for the service life of the covering (Liu, 2005).

There are many researches that assess short-term and long-term solar reflectance performance of materials both in laboratory and in field. In one of these researches, a series of field measurements was conducted on 9 residential buildings in Florida, USA (Parker et.al., 1995) in order to determine the impact of reflective roof coatings on buildings' air-conditioning energy use. Results of the research indicated that application of white coloured reflective coatings can reduce cooling energy consumption in between 2% and 43%. In the same study, reflective coatings under actual conditions experience a reduction in their solar reflectance rates from 71% to 47% in value at the end of 1-year.

Another research (Prado and Ferreira, 2005) conducted in laboratory presents the long-term solar reflectance performance results of roofing materials commonly used in Brazil. In this study, long-term solar reflectance rates were calculated from a mathematical equation defined by California Energy Commission. The roofing materials' surface temperatures were calculated according to their emittance and reflectance rates. The results demonstrated that same coloured metallic and ceramic materials reached different surface temperatures according to their emittances.

Benefits of reflective roofs are recognized by Turkish architects, contractors, and manufacturers, however, the solar reflectance performance of new and aged roof coverings produced in Turkey is still unknown. Therefore, short-term and long-term solar reflectance performance of roof coverings that are produced and commonly used in Turkey were measured in laboratory and in field. Purpose of this paper is to describe methodology and to present results of the measurements.

2. Methodology

Solar reflectance measurements of the roof coverings were conducted both in laboratory and in field.

2.1. Laboratory measurement

2.1.1. Test specimens

Types of roof coverings were determined according to the research conducted by Çatıder (Association of roofing industrialists and businessmen in Turkey) which presented the market share distribution of roof coverings in Turkey for the year of 2007 (Ozturk, 2008). Clay, cement, metal and bitumen based 13 roof coverings were determined. 2 of them are commonly used in flat roofs while the remaining are the coverings having highest market shares defined at the list of the research. The selected roof coverings with their materials and colour/surface characteristics are given in Table 1.

Table 1. Test specimens.

Roof Coverings/Test specimens		**Colour / Surface Characteristics**	**Roof Slope**
Clay based	Tile	Red	Steep
	Ceramic tile	White	Low slope
	Ceramic tile	White-shiny	Low slope
Cement based	Concrete Tile	Red	Steep
Metal based	Tile	Red/natural granule covered	Steep
	Galvanised sheet	White	Low slope
	Aluminium sheet	Silver	Low slope
	Copper sheet	Bronze	Low slope
	Titanium-zinc sheet	Black	Low slope
	Titanium-zinc sheet	Silver	Low slope
Bitumen based	Membrane	Red/natural granule covered	Low slope
	Shingle	Red	Steep
	Sheet	Black/corrugated	Low slope

Red colour was held constant for a later comparison between some test specimens depending on the material composition and surface roughness since most of the roof coverings can be produced in red colour. Dimensions of the specimens range from 4x4-cm to 10x10-cm as

described in ASTM E 903-96 "Standard Test Method for Solar Absorptance, Reflectance and Transmittance of Materials Using Integrated Spheres".

2.1.2. Test instruments

Spectrophotometer; a radiation measuring device in a sensitivity range between 200 nm and 2500 nm was used for the solar reflectance measurements. It has a 150-mm diameter-integrating sphere attached at its center where the test specimens were placed. At the beginning of the measurements, the spectrophotometer was calibrated with a mirror (as a reference sample) for calculating the reflectances of other materials (ASTM E 903-96, 1996).
Accelerated weathering tester; a device was used for exposure of the specimens to xenon arch light (simulated solar radiation). It can run out at the spectral range of 300 to 800 nm. The environmental stresses on roofing; exposure to wind, moisture, atmospheric gases, pollutants and biological growth were not within the scope of this simulation.

2.1.3. Test protocol

The test method described in ASTM E 903-96 "Standard Test Method for Solar Absorptance, Reflectance and Transmittance of Materials Using Integrated Spheres" was followed for measuring reflection rates of new and aged roof coverings in laboratory.

Initially, the spectrophotometer was calibrated at 1 nm intervals and then a 12-minute measurement was performed for each test specimen. UV-WIN software was used to obtain test results and graphics. The test results and the graphic demonstrations were converted to Excel format, then, calculated and assessed as average reflectance rates at each spectral range (ultraviolet, visible and infrared). After that, 6 of these test samples excluding metallic ones were determined to be exposed to xenon arc light in accordance with the standard ASTM G155-05a "Standard Practice for Operating Xenon Arc Light Apparatus for Exposure of Non-Metallic Materials". The selected specimens were put into the accelerated weathering tester for 50 day-period which corresponds to 1-year exposure. One sample of each material was left as unexposed for making comparison between new and aged situations. Finally, a series of measurement was conducted using the spectrophotometer for aged test specimens.

2.2. Field measurement

Field measurements were performed at the campus of Istanbul Technical University in Ayazağa, Istanbul. For conducting the measurements, approximately 100-m² area was organized.

2.2.1. Test specimens

2 types of test specimens were specified as clay based tile and bitumen based shingle. Both of the roof coverings were in red colour and were applied in order to set up 4.00x4.00-m dimensioned two roof surfaces. The roof surfaces were sloped to provide drainage of rain water.

2.2.2. Test instruments

Automated weather observation system (AWOS) were set up for field measurements. It comprises a pyranometer, a data logger, a solar panel, a temperature sensor, wind direction sensor, a moisture sensor, a rain sensor and a sensor measuring earth's temperature. In addition to AWOS, a pyranometer and a portable data logger were placed in order to measure reflected solar radiation. Thus, incoming solar radiation data was obtained from the data

logger of the AWOS while reflected solar radiation data was obtained from the portable data logger.

Pyranometer; a radiation measuring device in a sensitivity range between 305 nm and 2800 nm was used for the solar reflectance measurements. 2 pyranometers were located back to back to build up an albedometer.

Data logger: Pyranometer's analog data was converted to and collected as digital data by the data logger.

2.2.3. Test setup and protocol

Test specimens were located facing the south direction. The automated weather observation system was erected on wheels to be driven over the two test specimens. Test setup is shown in Fig. 1. The measurements were conducted under the actual environmental conditions according to test method given in ASTM 1918-06 Standard Test Method for Measuring Solar Reflectance of Horizontal and Low Sloped Surfaces in the Field. The data obtained from the measurements in ASCII format was transferred to a PC computer and converted to Excel format. Then the averages of initial solar reflectances were calculated.

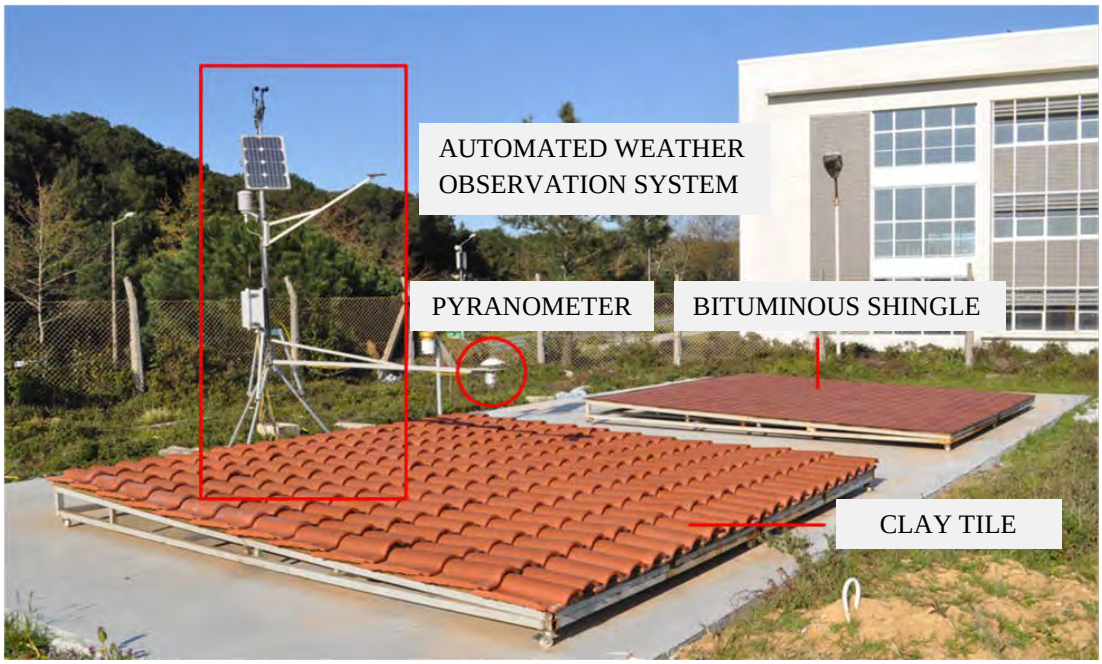

Fig. 1. Test setup.

3. Results

3.1. Laboratory measurement

The test results of new and 1-year aged test specimens are given in Table 2. Solar reflectance rates of each roofing material for each spectral range and situation (new-aged) are presented. Spectral ranges are stated in four sections as ultraviolet (UV), visible (VIS), infrared (IR) and total.

Table 2. Solar reflectance rates of new and 1-year aged roofing materials.

ROOFING MATERIALS / TEST SPECIMENS	SOLAR REFLECTANCE RATES % R							
	NEW (UNEXPOSED)				AGED (1-YEAR EXPOSED)			
	SPECTRUM (NM)				SPECTRUM (NM)			
	UV	VIS	IR	TOTAL	UV	VIS	IR	TOTAL
	200-380	380-780	780-2500	200-2500	200-380	380-780	780-2500	200-2500
CLAY BASED

3.2. Field measurement

Initial results of field measurements are demonstrated graphically for each roof surface in Fig 2. and Fig. 3.

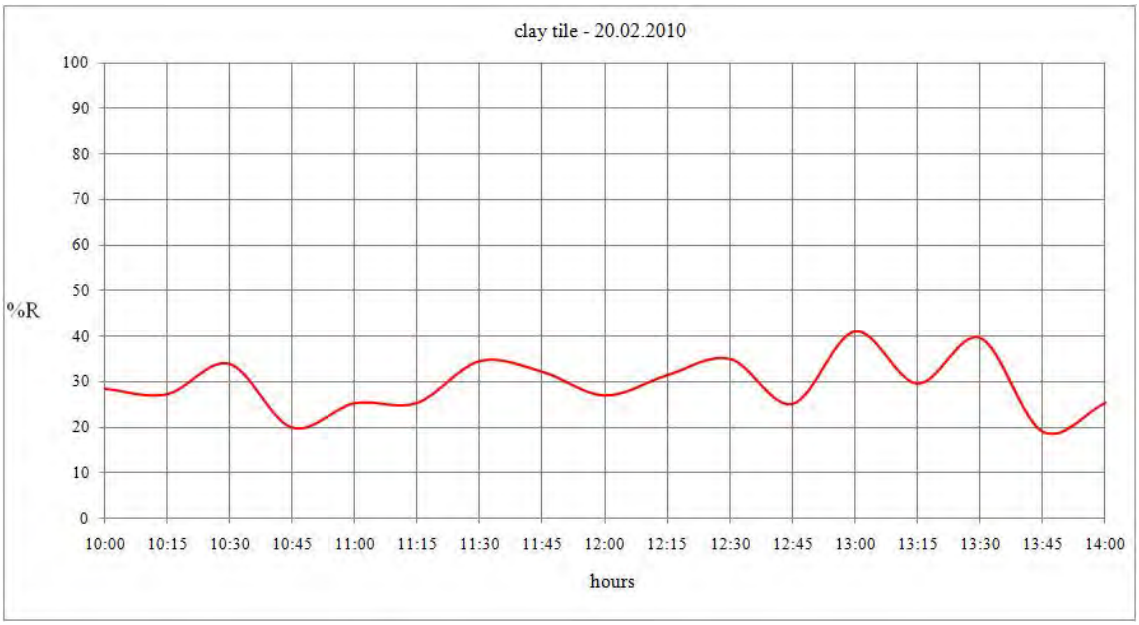

Fig. 2. The initial measurement results of clay tile covered roof surface for 20 February 2010.

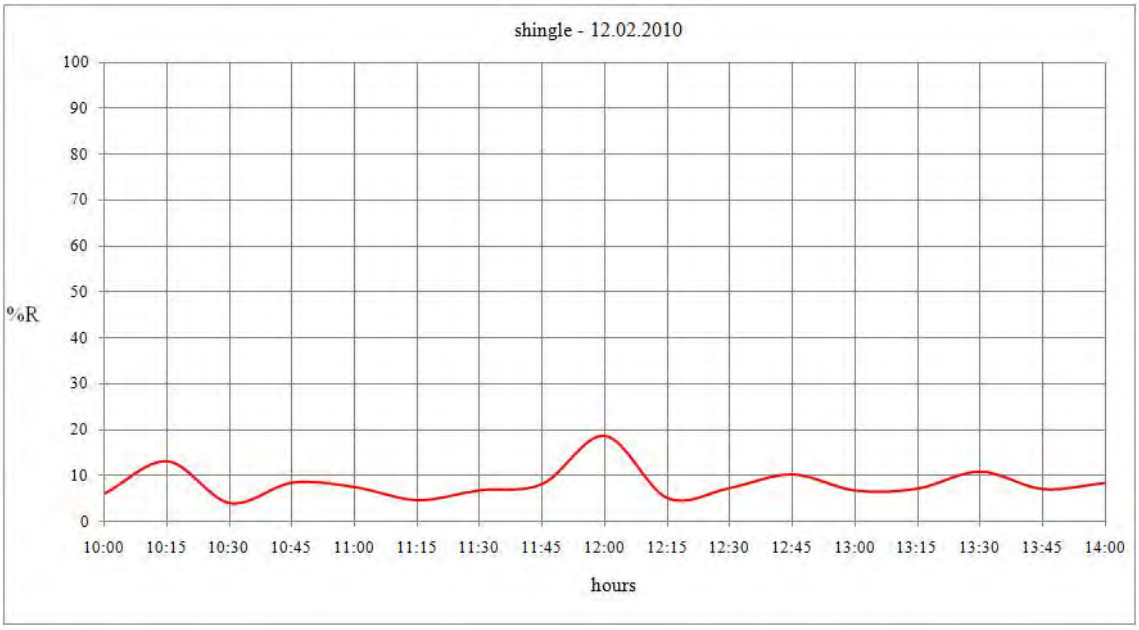

Fig. 3. The initial measurement results of bituminous shingle covered roof surface for 12 February.

The measurement results enable comparative assessment between the same colored and same sloped (3%) roof surfaces under actual weather conditions. The average solar reflectance performance of roof surfaces was calculated from the initial measurement results of the days without rain. Accordingly, the initial solar reflectance performance of clay tile covered roof surface is 29%, while bituminous shingle covered roof surface has an initial value of %8.

4. Discussion and Conclusions

This paper presents the solar reflectance performance of roof coverings used in Istanbul, Turkey. In accordance with this purpose, the laboratory and the field measurements were conducted.

The laboratory measurements' results can be assessed in two ways as short-term and long-term solar reflectance performance of roof coverings. For the short-term performance, the most reflective roofing material is the white and shiny clay based ceramic tiles while the black corrugated bituminous based sheet has the lowest solar reflectivity. On the other hand, only in the ultraviolet spectrum, the silver coloured titanium-zinc is the most reflective material. Reflectivity in the UV region indicates the sensitivity to UV radiation, hence material degradation. After accelerated 1-year exposure, all the materials had almost the same performance with their short-term performance and no change in appearance was observed (Table 2).

The field measurements' initial results enable the comparisons between 2 roof surfaces under the same conditions. The red coloured clay tile covered roof surface is more reflective than the same coloured shingle covering. The laboratory and the field measurements have approximately the same results when initial solar reflectance rates of red clay tile and red bitumen shingle are considered.

Environmental Protection Agency (EPA) had described the reflective roofing materials according to their application on low-sloped or steep roofs. Based on EPA, for instance, the red clay tile can be considered as reflective roof covering while red bitumen shingle as absorptive material.

Field measurements will be conducted for 1-year in order to evaluate effect of weathering on the solar reflectance performance. Then, the long-term solar reflectance performance results of laboratory and field measurements will be compared.

Results of this paper will enable designers to choose the roof covering appropriate for reflective roofs that can be used to rehabilitate existing roof coverings or to design new roofs, which in return will provide cooling energy savings and hence sustainable development of Turkey.

Abstract: The hydrogen economy is a proposition for the distribution of energy by using hydrogen, in order to potentially eliminate carbon emissions and end our reliance on fossil fuels. Some futuristic forecasters view the hydrogen economy as the ultimate carbon free economy. Hydrogen operated vehicles are on trial in many countries. The use of hydrogen as an energy source for buildings is in its infancy, but research and development is evolving. Hydrogen is generally fed into devices called fuel cells, to produce energy.
A fuel cell is an electrochemical device that produces electricity and heat from a fuel (often hydrogen) and oxygen. Fuel cells have a number of advantages over other technologies for power generation. When fed with clean hydrogen, they have the potential to use less fuel than competing technologies and to emit no pollution (the only bi-product being water).
However, hydrogen has to be produced and stored in the first instance. It is possible to generate hydrogen from renewable sources, but the technology is still immature and the transformation is wasteful. The creation of a clean hydrogen production and distribution economy, at a global level is very costly.
Proponents of a world-scale hydrogen economy argue that hydrogen can be an environmentally cleaner source of energy to end-users, particularly in transportation applications, without release of pollutants (such as particulate matter) or greenhouse gases at the point of end use. Critics of a hydrogen economy argue that for many planned applications of hydrogen, direct use of electricity, or production of liquid synthetic fuels from locally-produced hydrogen and CO2 (e.g. methanol economy), might accomplish many of the same net goals of a hydrogen economy while requiring only a small fraction of the investment in new infrastructure.
This paper reviews the hydrogen economy, how it is produced, and distributed. It then investigates the different types of fuel cells and identifies which types are relevant to the built environment, both in residential and non-residential sections. It concludes by examining what are the future plans in terms of implementing fuel cells in the built environment, and discussing some of the needs of built environment sector.

Keywords: *Hydrogen, Fuel cells, Hydrogen economy, PEM Fuel Cells*

1. Introduction- Hydrogen

1.1. The Hydrogen economy

A "Hydrogen Economy" is proposed as an ultimate solution for clean energy and the environment. Hydrogen communities have been formed for the promotion of this goal. They produce publications and organise meetings and exhibitions. The excitement is mainly about having a carbon free world. Electricity is considered one of the main CO2 emission sources relying on burning fossil fuels. A change in the production sources of energy is essential. Hydrogen is seen as a potential electricity carrier which is 100% clean and natural, but the challenge remains in its production, storage and distribution processes. Hydrogen is not found on its own in the globe, so it needs to be extracted from other elements that contain it. A key question is: is mass production of hydrogen physically possible? Similarly one needs to pose the question of: are the costs of producing, storing and distributing hydrogen affordable?

Hydrogen is not a natural fuel, but a synthetic energy carrier. It only carries energy generated by other processes. For example, hydrogen may be produced from electricity by electrolysis of water. In addition, high-grade electrical energy is also required to compress or liquefy it, and to transport, transfer, and store it [1]. Without question, the technology for a hydrogen economy exists or can be developed. In fact, vast amounts of hydrogen are generated,

handled, transported and used in the chemical industry today. But this hydrogen is used as a chemical substance, not an energy source. Hydrogen production and transportation costs are absorbed in the price of the synthesized chemicals. The cost of hydrogen remains irrelevant as long as the final products find markets. However, today's debate for the use of hydrogen as an energy source is governed by economic arguments and not merely theoretical considerations.

In the academic literature, the production and the use of hydrogen have attracted significant attention, while the practical aspects of a hydrogen economy are rarely addressed. Fig.1 below shows that like any other product, hydrogen must be packaged, transported, stored, and transferred to bring it from production to final use. These common market processes require energy [1]. Can we justify the transition to a hydrogen economy, based on practical and financial considerations? Some authors believe not!

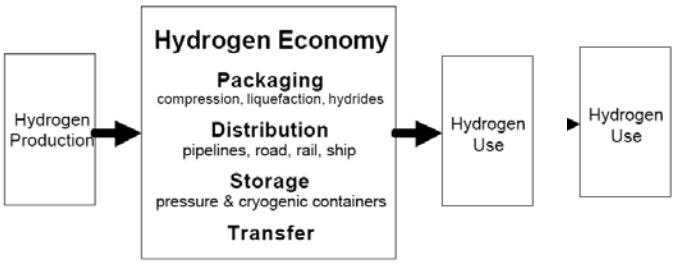

Figure 1: Schematic Representation of an elemental "Hydrogen Economy [1]

On the other hand, some scientists argue that novel energies need long, and sometimes very long periods of time; typically many decades to find their way onto the market. It may require up to half a century in order to establish of a novel energy regime in an irrevocable fashion. Hydrogen is no different. It is the right time to start the implementation of the hydrogen energy economy and see it through [2]. Winter [2] argues that Hydrogen is on track, because sustainable energy without the hydrogen economy is difficult to achieve, although there are still many milestones ahead.

Currently one needs to increase awareness amongst professionals and scientists around new technologies so that further development into realistic solutions becomes possible. "*It takes about 50 years for a new idea to break through and become vogue; no one likes an intruder, particularly when he is upsetting the commonplace*"[2].This paper provides some background to the hydrogen economy.

1.2. Sources of Hydrogen

Dunn [3] pointed that Hydrogen is hard to find on Earth as a separate element. Instead, it is primarily found in combination with oxygen in water, in combination with carbon in a range of hydrocarbon fuels, and in combination with carbon in plants, animals, and other forms of life. Once it is extracted, this colourless, odourless, and tasteless element becomes a useful "feedstock", or input, to a variety of industrial activities and a potentially ubiquitous fuel sufficient to energize virtually all aspects of society, from homes to electric utilities to business and industry to transportation. Therefore, hydrogen production means extracting and isolating hydrogen in the form of independent molecules, at the level of purity required for a given application [4].

Hydrogen is not widely used today in the Built environment sector, but has been tested on vehicles as exemplars and showcases. Winter [2] stated three main sources of Hydrogen, mentioning some of each source requirements and obstacles. He stated that Hydrogen can be produced from fossil fuels, renewable sources, or nuclear fission. (1) From fossil fuels via reformation or partial oxidation or gasification, preferably from natural gas, like today, or from coal, in the future, with capture and sequestration of coproduced carbon dioxide in order to prevent its release into the atmosphere. (2) From renewable electricity via electrolysis, but not before a number of further decades of development and in competition with the direct use of renewable electricity in the power market; or (3) From nuclear fission, if society accepts it.

Hydrogen production systems using renewable energy sources have been developed mostly in the United States (US) [5]. Example of that is the Telonicher Marine Lab in Trindad, California where they have installed the first solar hydrogen-Fuel cell system. The three major renewable hydrogen projects that have been completed in Europe are the Utsira hydrogen project, launched in July 2004 in Norway, the HARI project at West Beacon Farm, Leicestershire, UK, and PURE project in Unst (Shetland), opened in May 2005.

According to the DTI report Meeting, The Energy Challenge [6], Hydrogen and fuel cells are linked technologies with significant carbon-saving potential where the hydrogen is produced from renewable or low carbon sources. Furthermore, Hydrogen would facilitate the shift from limited non-renewable stocks of fossil fuels to unlimited flows of renewable sources, playing an important role in reducing and eliminating Carbon dioxide (decarbonisation) in the global energy system needed to avoid the most severe effects of climate change. Replacement of oil and other fossil fuels with hydrogen would achieve reductions in carbon emissions and avoid a doubling of pre-industrial carbon dioxide (CO_2) concentrations in the atmosphere [3].

Total's company publication [7] on hydrogen and fuel cells indicates that hydrogen can be produced through two broad process technologies:

1. By reforming or gasification of fossil fuels (e.g., natural gas, petroleum, coal) or products derived from the biomass (e.g., ethanol);

2. Alternatively, by electrolysis of water (using electricity generated by nuclear, wind, solar or other power).

According to Pant and Gupta [8], the current global hydrogen production is 48% from natural gas, 30% from petroleum, 18% from coal, and 4% from electrolysis.

1.3. Hydrogen Production in Reality

Hydrogen is a fascinating energy carrier. It can be produced from electricity and water. Its conversion to heat or power is simple and clean. Hydrogen forms water when combusted with oxygen. No pollutants are generated or emitted. The water is then returned to nature where it originally came from. But hydrogen, the most common chemical element on the planet, does not exist in nature in its pure form.

Hydrogen has to be separated from chemical compounds by electrolysis from water or by chemical processes from hydrocarbons or other hydrogen carriers. The electricity for the electrolysis may eventually come from clean renewable sources such as solar radiation, kinetic energy of wind and water or geothermal heat. Therefore, hydrogen may become an important link between renewable physical energy and chemical energy carriers [1].

Hydrogen is considered the "forever fuel", since, like electricity, it can be produced from any primary energy fuel: coal, oil, natural gas, nuclear, all sorts of renewable energies, and from grid electricity. Certainly, because of its environmental and climatic cleanness, hydrogen made from renewable energies is the ultimate aspiration. This is, however, not a pre-requisite for building a hydrogen energy economy.

Dunn [3], stated that about 99 % of the hydrogen produced today comes from fossil fuels. Over the long run, this proportion needs to be shifted towards renewable sources, for hydrogen production to be sustainable. Hydrogen, produced from renewable energy (e.g., Solar) sources, would result in a permanent energy system, which will not need to be changed [9].

Bossel [10] believes that electrolysis may be the only practical link between renewable energy and hydrogen. Although solar or nuclear heat can also be used for high-temperature cyclic processes, it is unlikely that a recognisable fraction of the global energy demand can be served with hydrogen from solar concentrators or high-temperature reactors. Local wind farms are likely to deliver energy at lower costs than distant solar or nuclear installations.

Winter [2] argues that the future of electrolytic hydrogen depends clearly on the price of electricity. If the price of the electrolysis process for the production of hydrogen is high, the production will become harder, and vice versa. He notes that in all likelihood the future average electricity price will increase rather than decrease (at least in industrialized countries), electrolytic hydrogen may get its market only where the electricity demand is temporarily low, e.g., at night, or where base load (nuclear) power station has been underused.

A case study by Bossel in 2006 [10] finds interesting questions and indicates major challenges. He states that if about 50 jumbo jets leave Frankfurt Airport every day, each loaded with 130 tons of kerosene, to replace the energy by hydrogen, 50 tons of liquid hydrogen are needed per plane. The daily needs would be 2500 tons or 36 000 m3 of the cryogenic liquid, enough to fill 18 Olympic-size swimming pools. Every day 22 500 tons of water would have to be electrolyzed. The continuous output of eight 1-GW power plants would be required for electrolysis, liquefaction, and transport of hydrogen. If all 50 planes leaving the airport were converted to hydrogen, the entire water consumption of Frankfurt and the output of 25 full-size power plants would be needed to meet the hydrogen demand of air planes leaving just one airport in Germany. This case study demonstrates that the hydrogen economy is not a panacea and more effort in understanding the cost and the effort is required.

This doesn't prove that hydrogen is not the ideal solution. It does indicate that electrolysis (depending on water and electricity) is not the right solution at least for now, and an alternative should be studied before rising the issue of producing hydrogen from renewable sources. This indicates that current studies could be seen as misleading, from the point of view that they are just seeing and arguing about the benefits of using hydrogen for energy generating, which is true. Yet, more studies about the real life possible applications with all disadvantages must be considered as well. As mentioned before, the development and storage costs of hydrogen are to be explored before committing to using it.

1.4. Storing and transporting Hydrogen

Hydrogen seems to have some difficulties in storing and transporting. Some researchers have made remarkable points about this subject as hydrogen molecules are extremely tiny and will leak from almost any container or pipe, meaning that it needs to be liquefied at temperatures near absolute zero. Compressed hydrogen, at very best, would take up at least 4 times as much

space in a tank as gasoline for the same amount of energy. Plus the storage tanks for compressed hydrogen cost 100 times the cost of a gas tank. Also, stronger materials, like steel, are more likely to react with hydrogen and become brittle. Combined with the high pressure, this makes the tanks susceptible to bursting [11].

Winter [2] added a few words on storage, he stated that: stationary hydrogen storage is at hand, both for gaseous and liquid hydrogen in high pressure steel flasks or cryogenic dewars*.

Large capacity underground storage for gaseous hydrogen in leached salt domes may build on what has been learned from operational underground air or natural gas storage, though special care needs to be taken to prevent leakage of the smallest element of the periodic table of elements: hydrogen! The most challenging venture is the tank onboard motor vehicles. For a usual vehicle range of, say, 500 km, the tank for gaseous hydrogen requires an inner pressure of 700 bar, which from a manufacturing and lifelong safety standpoint, is not at all trivial to achieve and maintain.

2. Fuel Cells

2.1. Main characteristics of Fuel Cells

Stambouli and Traversa [12] stated that, a Fuel Cell is an energy conversion device that produces electricity by electrochemically combining fuel (hydrogen) and oxidant (oxygen from the air) gases through electrodes and across an ion conducting electrolyte. According to the DTI report, Meeting the Energy Challenge [6], the fuel cell does not run down or require any recharging; unlike a battery, it will produce energy as long as fuel is supplied. The battery is an energy storage device where all energy available is stored within the battery itself [13]. According to the European commission summary report [14], because of fuel cells' low noise and high power quality, fuel cells systems are ideal for use in hospitals or IT-centres, or for mobile applications.

Fuel cells generally have a heat to power ratio of roughly 1:1 with overall efficiencies of around 80% when fired on hydrogen. Fuel cells powered with pure hydrogen have potential power efficiencies of up to 45% i.e. 45% of the hydrogen is converted into electrical energy. However, when we add a reformer to convert other fuels to hydrogen, this can drop significantly [15].

Neef [16] argues that hydrogen and fuel cells are technologies that still need to prove their capability in order to produce marketable products.

Three application areas for fuel cells are emerging: (1) In portable electronics fuelled with the help of hydrogen or methanol cartridges (e.g. laptops and mobile phones) (2) in stationary applications, (e.g. buildings) and (3) in the transportation sector in busses, passenger and light duty vehicles, later in heavy duty trucks, in aviation and at sea [2].

*Dewar: a double-walled flask of metal or silvered glass with a vacuum between the walls, used to hold liquids at well below ambient temperature.

2.2. Fuel Cells types for buildings

Stambouli and Traversa [12] explain that there are many types of fuel cells, which are normally sorted by either by their operating temperature or by their classification. The latter is generally done according to the nature of electrolyte. The basic differences in the different types of fuel cells are:

- The electrolytes used;
- The operating temperature of the device;
- The design, and their fields of applications, bearing in mind that each fuel cell type has specific fuel requirements [17].

Operating temperatures of fuel cells vary depending on their type. There are two main categories for classification:

Firstly, the low temperature fuel cells with operating temperatures as low as 80°C. These can be installed in private households, light commercial operations, and large industrial operations. An examples of this type is the Proton exchange membrane fuel cell (PAFC). In low-temperature fuel cells, all the fuel must be converted to hydrogen prior to entering the fuel cell.

Secondly, the high temperature fuel cells, such as molten carbonate (MCFC) and solid oxide (SOFC), may be adapted for larger industrial applications. With operating temperatures between 600-1100°C these high temperature cells can tolerate a contaminated source of hydrogen and hence can use unreformed natural gas, diesel or gasoline. Furthermore, the heat generated can be used to produce electricity by driving steam turbines.

Fuel cells in the stationary sector, i.e. for residential energy and for industrial application, will use different fuels and convert them into hydrogen as long as there is no hydrogen infrastructure in place. In the case of low temperature fuel cells, a reformer is used that converts natural gas into hydrogen and CO2, for example. High temperature fuel cells can convert the fuel, e.g. biogas, internally. Once again, the advantages of such stationary fuel cell systems compared to the competing condensing boilers or conventional heat and power plants consist of higher efficiencies and reduced emissions, but also of a contribution to the decentralised electricity production and to stability of the electric grid [16].

The most common fuel cells types found in the literature today and suitable for buildings are:

- Proton Electrolyte Membrane Fuel Cells (PEMF C),
- Alkaline Fuel Cells (AFC),
- Phosphoric Acid Fuel Cells (PAFC),
- Molten Carbonate Fuel Cells (MCFC) and
- Solid Oxide Fuel Cells (SOFC)

listed in the ascending order of their operating temperature, where the most electrical efficient of them is found to be the SOFC which has a high operating temperature. Lipman *et al*., [18], explain that low temperature PEM fuel cells are considered the leading contenders for automotive and small stationary applications. SOFC, PAFC, and MCFC operate at higher temperatures (from 2001C to 10001C) and are expected to be used for larger stationary applications. Regarding efficiency, generally fuel cells have high efficiency, where they convert up to 50–70% of available fuel to electricity (90% with heat recovery) [12].

Winter [2] stated that depending on the type of fuel cell, it provides the right temperature for heat applications in stationary use: 100 C for proton exchange membrane (PEM) fuel cells (FCs), around 200 C for high-temperature PEMs or phosphoric acid FCs (PAFCs), 600–650 _C for molten carbonate FCs (MCFCs), and 700–900 _C for solid oxide fuel cells (SOFCs).

Low to high temperature PEMs are exactly what is needed for homes or buildings or hospitals, depending under which climate and weather conditions they serve; MCFCs fit the exigencies of many small-to-medium size industries, hospitals and large laboratories, and SOFCs are an excellent topping technology for gas turbine/steam turbine combined cycles [2].

But to be more precise the types we are concerned with in this project, are the types that rely on hydrogen only as their fuel, and from the existing applications. Table 1 below shows that PEM and PAFC are the two fuel cells types that could generate electricity for buildings with the use of hydrogen as their fuel. According to Lidderdale and Jones [15] PAFC type is the most successful technology, in terms of numbers deployed above 200 kWe, where it is used primarily for large back-up and remote power applications in hospitals, schools, and other locations where an engine generator would traditionally be used. Increasingly being used in environments where high availability of either electrical or thermal power is a criterion.

Solid Oxide FC

Table 1: fuel cells types and main characteristics [16]

Realistically speaking and because the technology (Fuel cells) is still newly introduced to the built environment, a definite answer about the most appropriate type for buildings cannot be stated yet, it will take several years and many real life pilots to proove what is and what is not suitable for buildings.

2.3. Future plans for Fuel Cells implementations

Winter [2] stated that like any other energy, hydrogen energy has to meet a range of criteria before successfully entering the market. The two major, perhaps dominating criteria are costs and CO2 emissions. Of course, costs are the key for the entry of any energy into a competitive large scale market, and hydrogen energy is not different.

Same is applicable for fuel cells technology; cost, reliability and lack of experience are the major issues. To resolve these problems and to answer all unclear questions, implementing the technology in several projects is a necessity and this should be supported by the government and large private energy companies as a start, because like any other technology the cost of it at present is considerably high which makes it hard for the end users to even consider installing such technology in their houses or projects, especially that sustainable and clean hydrogen sources are not readily available as yet. Therefore, support is required at this stage to implement the technology for a small community and learn from the experiences.

According the Fuel cells handbook 2004 [13], for a fuel cell to compete with other generation sources, its price must be reduced dramatically and research and development is required to improve the performance and reduce the cost of renewables, storage, and fuel cell technologies. Technologies are needed that can produce hydrogen for the same price as gasoline. Storage technologies must be developed to allow cheap, safe hydrogen storage. Finally, fuel cell technology must advance to improve efficiency.

In addition, Safety is seen as a prime consideration for stationary fuel cells. As fuel cells come closer to the customer, codes must be written and building inspectors educated to allow the introduction of fuel cell power systems.

Another interesting point to be taken care of for moving forward with fuel cells technologies is obtaining insurance for hydrogen projects. This needs to be undertaken by the government to provide a layer of insurance coverage. In addition, insurance companies must be educated as to the proper handling of hydrogen and the associated risks. This would allow for property, liability, and efficacy insurance to be offered at reasonable rates.

3. Future directions and future research needs

Renewbles are one of the few rapidly growing business sectors, and developers are working hard to forge a link between renewable and fuel cell technology in order to put power generation on a sustainable basis. In the next five to ten years biogas fuel cells are supposed to operate worldwide, and active research will take place on wood and biomass gasifiers for hydrogen production. Wind power will be used to generate hydrogen in some locations, while solar hydrogen will be produced in others to power a small fleet vehicles [19].

The fuel cell industry itself is in its infancy. The early products have problems with reliability and affordability. It is as yet unclear which types of fuel cells will prove more appropriate for the different types of buildings and usage. Early piloting of the technology must be facilitated by government organisations and major corporations.

The construction industry is still not prepared for the introduction and maintenance of such eventual novel technologies. The design, implementation, and maintenance of them require specialist knowledge, which is still non-existent within the industry.

Future research needs to be collaborative, including stakeholders from the construction industry, the energy sector and the fuel cell technology sector (i.e. chemical engineers). Possible research areas include:

- Potential solutions for hydrogen production on site;
- Hydrogen harvesting, i.e. the best sustainable source for hydrogen production with the least cost;
- A critical analysis of the different types of fuel cells for different building types;
- Hydrogen onsite storage mechanism;
- Legislative barriers and enablers.

Abstract: The effect of projected climate change on building performance is currently a growing research area. Building designers and architects are becoming more concerned that buildings designed for the current climate might not provide adequate working and living environments in the coming decades. Advice is needed to guide how existing buildings might be adapted to cope with this future climate, as well as guidance for new building design to reduce the chances of the building failing in the future. The Low Carbon Futures Project, as part of the Adaptation and Resilience to Climate Change (ARCC) programme in the UK, is looking at methods of integrating the latest climate projections from the UK Climate Impact Programme (UKCIP) into building simulation procedures. The main obstacle to this objective is that these projections are probabilistic in nature; potentially thousands of equally-probably climate-years can be constructed that describe just a single scenario. The project is therefore developing a surrogate procedure that will use regression techniques to assimilate this breadth of climate information into the building simulation process.

Keywords: *Climate change, Building simulation, Overheating*

Nomenclature

$T_o(t)$ *internal air temperature at hour t..... °C*
θ_0 *regression constants .....*
m_j *regression coefficients .....*
$\chi_j(t)$ *hourly climate parameter .....*

1. Introduction

In the UK, for both new build and building refurbishment sectors, legislation is currently being discussed to achieve low-carbon buildings through the use of new design and technologies [1]. It is therefore inevitable that a level of uncertainty exists with regards to the future energy performance of such buildings. In addition to this, with future climate warming being predicted over the coming decades for the UK, there is an uncertainty with regards to the comfort performance of such buildings – will future climate warming negate certain design assumptions for buildings designed or retrofitted for a current climate? For a naturally ventilated building this might mean internal temperatures exceeding design thresholds for significant periods of the year, whereas a mechanically cooled building might be operating with an under-sized cooling plant. This describes the problem that the concept of "adaptation" is trying to solve; what changes to our current approach should be taken now to ensure a building will maintain adequate levels of thermal comfort in the future? Such an analysis requires a suitable form of future climate projections, which themselves are inherently uncertain. Previous approaches to climate projections have been deterministic [2], in that they specify an estimated value of expected climate change for a specific scenario. The most recent UK Climate Projections (UKCP'09[3]) from the UK Climate Impact Programme (UKCIP) takes a different approach, with climate projections provided in a probabilistic form. These have been constructed from multiple iterations of climate models, which have undergone a degree of downscaling by geography and temporal resolution. The result of this can be many thousands of possible climate files describing just a single future scenario (see section 2). If such information is to be incorporated into building design approaches, it is clear that an

additional step is required which can either simplify this climate information or provide an algorithm which processes this data in a way that might be useful for a building designer. If this goal can be achieved, then the result will be a method for incorporating the uncertainty of climate projections into building design and allowing the designer to choose adaptation options (such as shading or ventilation techniques) which will give a high probability of adequate thermal comfort in that building for a future climate. This work forms part of the Low Carbon Futures project, sponsored by the Adaptation and Resilience in a Changing Climate (ARCC) Programme [4].

2. Methodology

The following section will describe the approach being taken by the Low Carbon Futures project, which includes obtaining weather data, carrying out extensive building simulation and then using the obtained relationships to construct a regression relationship between climate and internal temperatures of a building.

2.1. Weather Generator

The Low Carbon Futures project [5] obtains future climate projections from the UKCP'09 Weather Generator. This can provide a number of statistically equivalent 30-year time series projections which describe a specific future scenario (e.g. low-emission, 2020-2049) for a specific location (based on a grid map of the UK). The weather variables can be generated at monthly, daily or hourly scales and include: total hourly precipitation (mm), mean hourly temperature (ºC), vapour pressure (hPA), relative humidity (%), sunshine fraction (of an hour), downward diffuse radiation and direct radiation (both W/m^2). If the user is downloading 100 time-series (the maximum allowed for each iteration), each run will produce 3000 (30years x 100 files) equally probable climate years at an hourly resolution. The resulting climate information can therefore be vast in scale. If using building simulation, the options might be to either i) choose just one (or a small number) of these representative climate-years to simulate a building with or ii) provide a short-cut or emulation step to make the building simulation process itself, over many climates, more efficient. The Low Carbon Futures project is investigating the latter approach. The timelines looked at for this study will be 2020-2049, 2040-2069 and 2060-2089 (referred to as "2030s", "2050s" and "2080s" respectively). The Weather Generator provides three future emission scenarios, namely "low", "medium" and "high" (as defined by UKCP'09), all of which will be included in the analysis. With two locations currently being investigated by the project (Edinburgh and London), this provides a total of 20 climate scenarios, including a baseline "current" climate (from 1960-1990 data) in both locations.

2.2. Building Simulation

While the described approach could be used with any building simulation software, the project uses ESP-r, an open-source package. To adequately describe internal temperature profiles (and therefore provide useful information with regards to overheating metrics), it is important to carry out these simulations with dynamic simulation software and at a suitable temporal resolution (in this case hourly). Such software will allow for the thermal response of the building over time to be suitably expressed, as well as providing a method for defining various adaptation scenarios. A range of buildings are being simulated by the project, some taken from real case-studies while others are adopted from previous simulation studies such as the Tarbase project [6]. This paper overviews two of these buildings: a standard dwelling [7] and a primary school [8], both of which are naturally ventilated. Different buildings have different overheating definitions and might have specific adaptation options that are related to

the occupancy and construction characteristics. It is therefore important, when assessing overheating risks through simulation, to have a method that can be used for a range of buildings and a range of overheating metrics. The hypothesis of the project is that one initial simulation can identify the relationship between an hourly climate file and hourly internal temperatures of a building, summarised by an appropriate regression equation. This regression equation can then be used for a vast array of climates, without the designer having to resort back to full building simulations for all the other climates. This methodology is seen as an acceptable compromise between maintaining the detailed calculation of dynamic simulation software (as such a calculation will be required to start the process), while providing a means to achieving the equivalent of (up to) thousands of climate inputs through a given building model.

For validation purposes, each building in the project is simulated for a total of 2000 climate-years, encompassing the described range of emission scenarios, timelines and locations. A script has been developed for the project (by University of Strathclyde, who develop ESP-r) that allows many climates to be simulated in succession. While this is still a time-consuming process (and would not be practical for use in industry), it allows the project team to carry out a validation exercise across a large number of climates. For each iteration, the hourly internal temperature profile for the entire year is recorded for use in the regression exercise.

2.3. Validation of regression analysis

Following the building simulations, a large database of hourly climate metrics and hourly internal temperatures (by zone in the building, where the user may choose to focus on the area of the building that is most prone to overheating or has the highest occupancy) is created. The next step is to demonstrate a statistical relationship between the climate projections and the resulting building temperatures. A regression equation can be formulated describing this that is calibrated using just one climate, i.e. calculating the appropriate regression coefficients, and this same relationship can be used for all the other climates to investigate whether the same relationship will hold for that building. A simple regression equation will have a large number of terms; not only should the range of influential climate metrics be included (listed in section 2.1) for a given hour, but also the same metrics for previous hours, due to the dynamic thermal response of a building to such changes over time. It is found that the regression equation can emulate simulation results if climate information from the previous 72 hours is included. Taken across seven different climate metrics this potentially provides 504 terms in the regression equation (i.e. 72 x 7 = 504). However, using the established statistical technique of Principal Component Analysis (PCA), these terms can be reduced to just 33 (this is discussed in detail elsewhere [9]). The resulting regression equation is then of the form:

$$T_0(t) = \theta_0 + \sum_{j=1}^{33} m_j X_j(t) \qquad (1)$$

For adaptation scenarios (e.g. a physical change to the building that might combat overheating), Eqn. (1) can either be recalibrated following another simulation or a series of correction equations applied that are specific to those adaptation choices [9].

The results of the validation exercise, comparing hourly internal temperatures from the calibrated regression equation to that of ESP-r simulation, are demonstrated in Fig. 1. This is for the case of a domestic building, without any adaptation measures and with 100 climate-years representing a London 2030, medium emission scenario (though similar results have been obtained from other buildings and adaptation and climate scenarios).

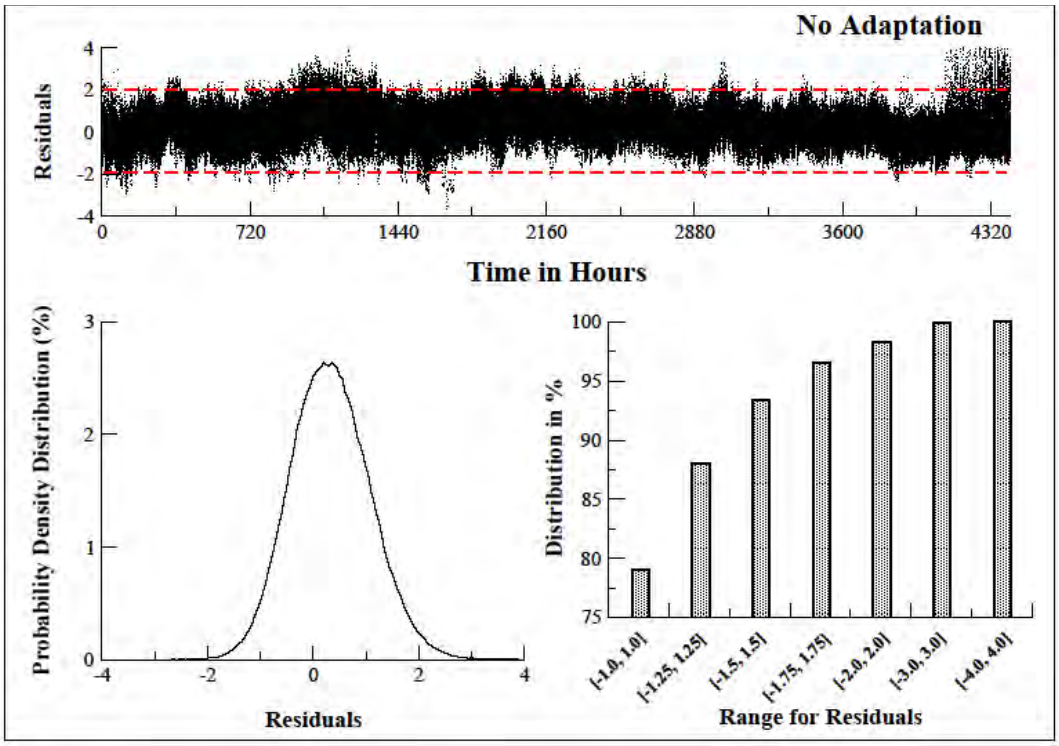

Fig. 1. Comparison of ESP-r and regression equation hourly temperatures scenarios for "no adaptation", London 2030 Medium emission scenario

In summary, Fig. 1 presents (top graph) over 400,000 data points between April and October for the specific scenario, where "residual" is the difference between the internal hourly temperature of ESP-r and the regression equation (in degrees). Due to the large amount of data, it is difficult to discern a typical error from this graph alone, hence the use of the left graph which shows that the majority of the "error" between ESP-r and the regression equation is ±1°C – deemed an acceptable error over such a vast amount of data and for an hourly resolution. The right graph demonstrates that almost 80% of the data is within this error. The validation exercise provides an indication that an appropriately calibrated regression equation can be used to emulate a dynamic simulation over a large number of climates, providing an initial simulation has been carried out to establish the relationship in the first place.

2.4. Design approach

The integration of any future-climate design tool into the building design process involves an understanding of existing design practices. To investigate this, the project is running several focus groups to obtain feedback from a wide range of design professionals in the UK. These focus groups will discuss how current overheating analyses are carried out for domestic and non-domestic buildings, and how low-energy buildings might be more susceptible to future overheating for certain scenarios.

In summary, it is imagined that the methodology discussed in sections 2.1 to 2.3 might be used as follows:

1. A building is designed to current building regulations with an overheating analysis based on dynamic simulation of, nominally, a current hourly climate file
2. The proposed regression tool, working in parallel with the simulation engine for step 1, generates a series of regression coefficients based on the documented principal component analysis framework (see section 2.3)

3. A random selection of 100 climate years for a specific future scenario can be selected from the UKCP'09 database (e.g. the user would choose: London, medium emission, 2020-2049) – this can be integrated into the tool so that the user would not need to access the climate information separately. These climates will not need to be simulated through the dynamic building software
4. The user chooses an overheating metric, such as the percentage of hours over 28°C or another defined threshold, that is suitable for that building type
5. The regression tool provides an overheating risk output, demonstrating the probability of different scales of overheating for that building in a future climate (see section 3 for examples)

If a building is designed to achieve adequate thermal comfort for a current climate, the above methodology can estimate whether that same building will meet thermal comfort criteria for chosen future climates.

3. Results

The project is looking at a selection of buildings, two of which will be used below to demonstrate the way that the analysis described in section 2 can be used to quantify the effect of adaptation scenarios to prevent overheating in a naturally ventilated building. The technique is also being applied to mechanically cooled buildings, with results forthcoming.

3.1. Domestic building

The domestic building case study is designed to represent a typical UK 3-bedroom dwelling, with infiltration rate of 0.7ac/h, with wall U-value of 0.37W/m^{2}K. Detail of the construction and internal activity can be found in previous publications [7]. Fig. 2 shows the simulation diagram used by ESP-r.

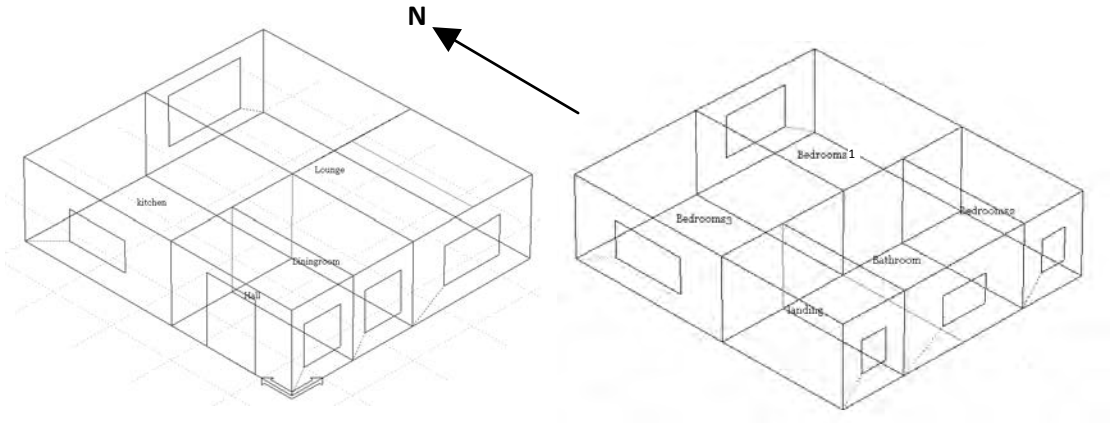

Fig. 2. ESP-r diagram of ground floor (left) and first floor (right) of modelled dwelling

While a large range of overheating criteria could be specified for this building type, the chosen metric for this paper is the number of hours in the bedroom that exceed 23.9°C at night. This definition, justified elsewhere [7], proposes that the lack of options to adapt to overheating at night may cause an occupant to take other measures (e.g. purchase a domestic air-conditioning unit) to provide an improved level of thermal comfort. The building is simulated for all the climate scenarios identified in section 2.1, and for three adaptation scenarios, applied cumulatively: i) "no adaptation", where the occupant does not react to overheating at all; ii) "window opening", where windows are opened in the bedroom zones if that zone exceeds 23.9°C (and closed if the temperature then drops below); iii) "external shading and reduced internal gains", where horizontal slats are placed above every window to

reduce solar gain, while internal heat gains (from appliances and lighting) are reduced by 25% to represent more efficient technologies. For simplicity, Fig. 3 only shows the results for the 2030s medium emission scenario for a London location, though the same format can be applied to any climate scenario. The x-axis of the graph shows relative change in the overheating metric (i.e. number of hours above the 23.9°C threshold at night) against a 1960-1990 baseline. With 100 equally probable climate-years used for this future climate scenario, it is possible to construct a cumulative frequency plot that suggests the probability of different levels of overheating occurring. The effect of the adaptation scenarios is clear, with the overheating risk curves being morphed in the negative direction on the x-axis – representing reduced overheating risk. Such a graph could be used to design a building to be sensitive to a future climate: for example, the "no adaptation" scenario estimates a 96% probability of more overheating (i.e. the part of the cumulative curve that is to the right of the "zero" dotted line representing no change) for the future climate used. Applying both adaptation scenarios reduces this to just 14%; i.e. the building now has just a 14% chance of being warmer in the future. This may be a suitably low future overheating risk, providing the client with the confidence that their building should provide adequate thermal comfort in the future.

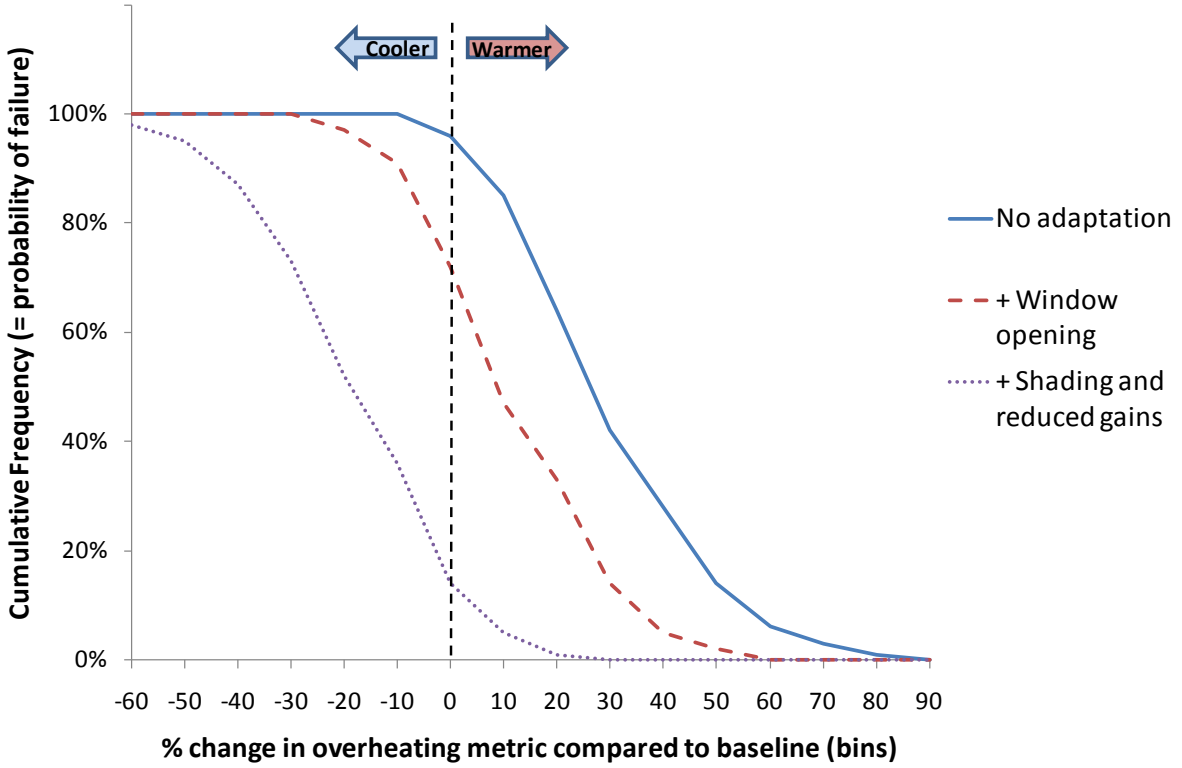

Fig. 3. Predicted increase in dwelling overheating for 100 random climates for London, Medium Emission, 2030 scenario

3.2. Primary School

The exercise is repeated for a primary school building, previously analysed with deterministic climates in the Tarbase project [8]. The construction and internal activity is specified in detail in this aforementioned reference and relates to UK Building Regulations for the assumed build date of 2000. The overheating criterion used for this building is the percentage of hours above 28°C in teaching areas, as suggested by UK building guides [10]. As with the previous case-study, the methodology of section 2 is carried out to assess future overheating risks. Fig.4 summarises the floor plan and building design.

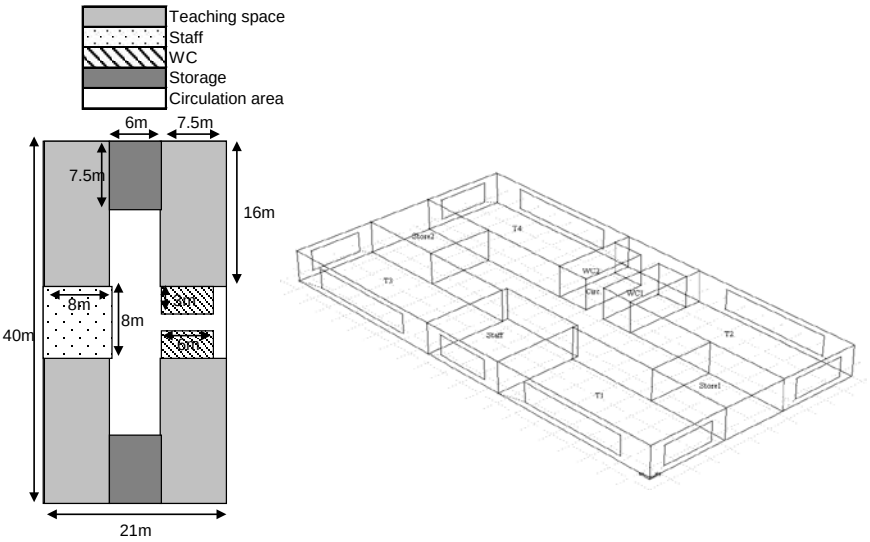

Fig. 4. Layout and plan of primary school case-study

Fig. 5 demonstrates the predicted overheating curves, again for the 2030s medium emission scenario for a London location. The adaptation scenarios are: i) "no adaptation"; ii) "Increase Vent", where maximum ventilation rates are increased from 8l/s/person to 12l/s/person; iii) "Reduced gains", for energy-efficient appliances and lighting that reduce internal heat gains (as quantified elsewhere [8]); iv) "External shading", with simple horizontal shades added above each window. As with the domestic case study (Fig. 3), a substantial improvement is made as a result of the adaptations – ranging from a 96% chance of increased overheating for "no adaptation" to a 0% chance once all adaptations have been applied.

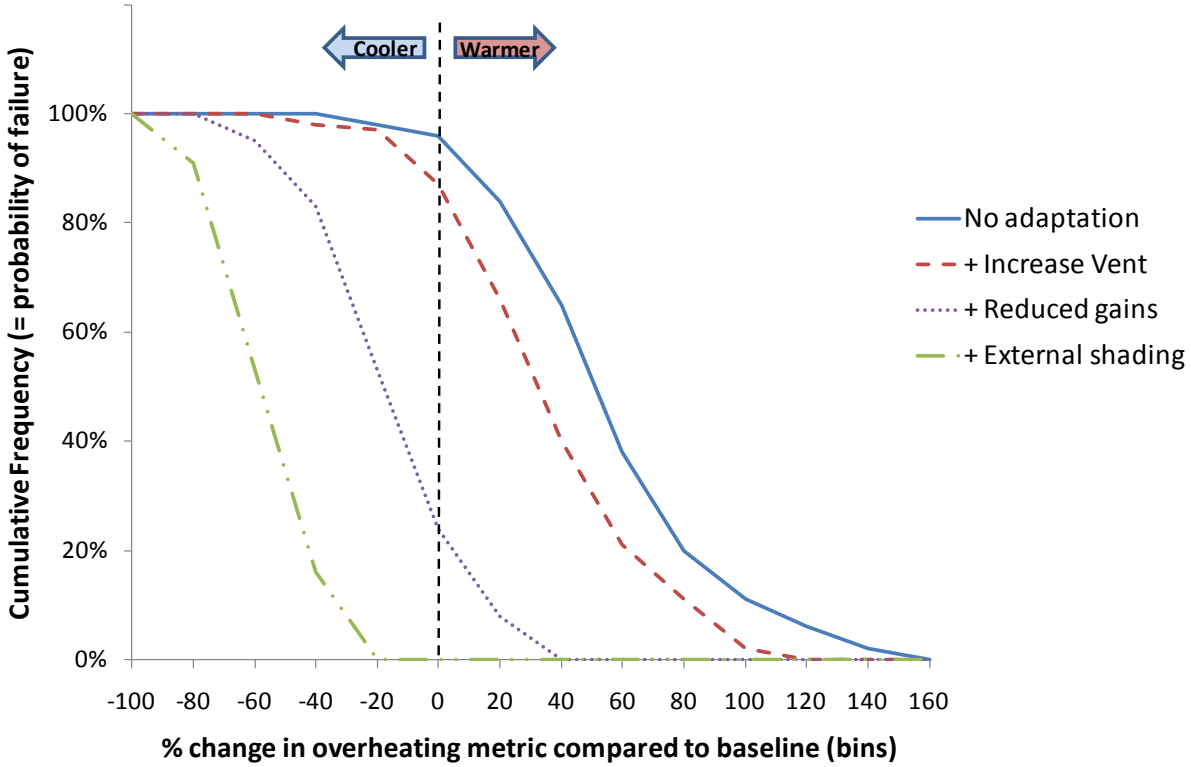

Fig. 5. Predicted increase in school overheating for 100 random climates for London, Medium Emission, 2030 scenario

4. Discussion and Conclusions

The Low Carbon Futures project aims to provide guidance for designing buildings, or retrofitting existing buildings, so that they will provide adequate thermal comfort for a future climate. There are essentially two problems to be addressed: i) how can designers be encouraged to design for a future climate, rather than just using existing climate definitions and ii) if future climates are presented in a probabilistic form (as with UKCP'09), can this be integrated into the design process in an efficient way? If this latter problem provides an additional barrier to building design, then it will not be adopted in practice. However, if this form of climate projection can be linked to an overheating "risk analysis", which might have parallels with existing risk assessments that the building industry are required to carry out, then the described method might be seen as attractive to both building professional and their client. The methodology described in this paper, which produces probabilistic overheating curves for a specific building once that building has undergone a single simulation, is suitable for use in a design tool that would not require a dramatic increase in building simulation time, despite the use of hundreds of climate-years from the UKCP'09 database. The results suggest that it should be possible to find a compromise between an efficient calculation method and a reliable output that maintains the detail from the probabilistic climate projections used, though it should be stressed that the proposed tool emulates building simulation output, not empirical data. The project will subsequently be testing this approach against a wider selection of buildings and adaptation scenarios to determine if the described methodology is truly universal for future overheating analyses of buildings in the UK.

Abstract: The aim of the study is to develop a model for the energy balance of buildings that includes the effect from the radiation properties of interior and exterior surfaces of the building envelope. As a first step we have used ice arenas as case study objects to investigate the importance of interior low emissivity surfaces. Measurements have been done in two ice arenas in the north part of Sweden, one with lower and one with higher ceiling emissivity. The results show that the low emissivity ceiling gives a much lower radiation temperature interacting with the ice under similar conditions. The dynamic modelling of the roof in ice arenas shows a similar dependence of the roof-to-ice heat flux and the ceiling emissivity.
A second part of the study focus on how to realise paints with very low thermal emissivity to be used on interior building surfaces.

Keywords: *Energy balance, Low emissivity, Radiation properties*

1. Introduction

The need for buildings to be highly energy efficient requires that a building envelope must be air tight and well insulated. It is also important that both interior and exterior surfaces has appropriate optical functions. The exterior surfaces (roof and facades) should in a hot climate have high solar reflectance and high infrared emissivity in order to reduce space-cooling loads. Buildings in colder climates should have exterior surfaces with high solar absorptance and low thermal emissivity to reduce space-heating loads. Buildings in all types of climates should have interior walls and ceilings with low thermal emissivity which will reduce the radiation exchange between persons and interior surfaces and thereby the need for decrease/increase the air temperature in order to compensate for too high/low interior radiation temperature.

The research has been extensive in finding solutions for hot climates to prevent over heating and one concept here is the so called cool roof, works from Synnefa et al [1] and Levinson et al [2] shows that it is a large potential for reducing energy use for cooling by use of near infrared high reflectance exterior paints. There has not been as much focus on interior surfaces and how functional optical properties can influence the energy demand in hot or cold climates. Development in paint formulation has made it possible to produce coating with higher reflectance in the long wave radiation spectra. This kind of coatings has been found mainly useful for interior coatings where it is expected to act like a thermal barrier for the radiation energy potentially emitted or absorbed by the surface when the radiation temperature differs significantly from the panel surface temperature. For instance, Daoud et al [3] has shown that low emissive interior coatings can contribute to the energy savings in an in doors ice rink.

In a previous work by Joudi et al [4] introduces a model for calculating the effect of both interior and exterior optical properties of a horizontal roof sandwich panel in terms of net energy flux per unit area. Sandwich panels usually consist of two coil coated steel sheet profiles, which are tightly pressed and glued to an insulation core. They can be manufactured even without trans-sectional supports to avoid thermal bridges. The results from the study indicate potential energy saving by the smart choice of optical properties of interior and exterior surfaces. In the present report we introduce a model that includes a roof panel and a

floor and vertical heat exchange. The model is applied on indoor ice rinks as a case study where it has been performed measurements.

Due to the importance of having low thermal emissivity of the interior surfaces a part of the study was devoted to investigate the potential to further reduce the thermal emissivity in low emitting paints for interior use applied on coil coated stainless steel in sandwich panes. The main components of the paint counted from the steel surface are the primer, and the paint layer comprising the binder, pigment and aluminium flakes. The aluminium flakes are used for enhancing the infrared reflectance and by that reduce the thermal emissivity.

2. Methodology

As a first step we have used two ice rinks situated in the north of Sweden (Luleå) as case study objects to investigate the importance of the emissivity of the ceiling for the ice conditions. One of the ice-rinks has a highly emissive coil-coated steel sheet interior roof whereas the other ice-rink has a low emissive galvanized steel sheet interior roof. These buildings are of comparable design with similar roof heat transfer values. In order to study the dependence of the radiation heat flux on the interior surface thermal emissivity in building interior spaces with considerable surface temperature differences, continuous measurements of surface-, air-, and radiation temperatures in the two different indoor ice-rinks were made. Surface- and air temperatures were measured using T-type thermocouples and radiation temperatures were measured using pyrometers facing the ceiling and the ice floor respectively. The measurement data were collected using Intab loggers.

To investigate the flux of thermal radiation from the ceiling to the ice in indoor ice rinks with both low and high emissive interior roofs surfaces, the simulation environments IDA SE and IDA ICE 4.0 are used to solve a system of non-linear equations simultaneously, based on the work presented in [4]. In this model both interior and exterior surface temperatures, as well as discrete cell temperatures through the roof panel are simultaneously solved and coupled in an hourly dynamic simulation with varying outdoor conditions (i.e. solar irradiance, ambient and sky temperature) and different inside air and interior radiation temperatures (i.e. a radiation temperature as seen by the interior roof surface). Table 1 shows the model input parameters. Note that the location in the simulation is Stockholm, due to presently lack of data for Luleå.

Table 1. Model input parameters

Location		Stockholm	
Insulation	thickness	0.3	m
	Thermal conductivity	0.036	$Wm^{-1}K^{-1}$
	Density	20	Kgm^{-3}
	Specific heat	750	$Jkg^{-1}K^{-1}$
Exterior roof optical properties	Total Solar Reflectance	0.3	-
	Thermal Emittance	0.9	-
Ground reflectance		0.7	-
Air temperature under the ceiling		12	°C
Ice surface Temperature		-4	°C

Effective emittance, ε_{eff} with embodied view factor, f_{ci} are calculated from Eq. (1) where ε and A are long wavelength emittance and area in m^2 and subscript c and i represent ceiling and ice, respectively [5]

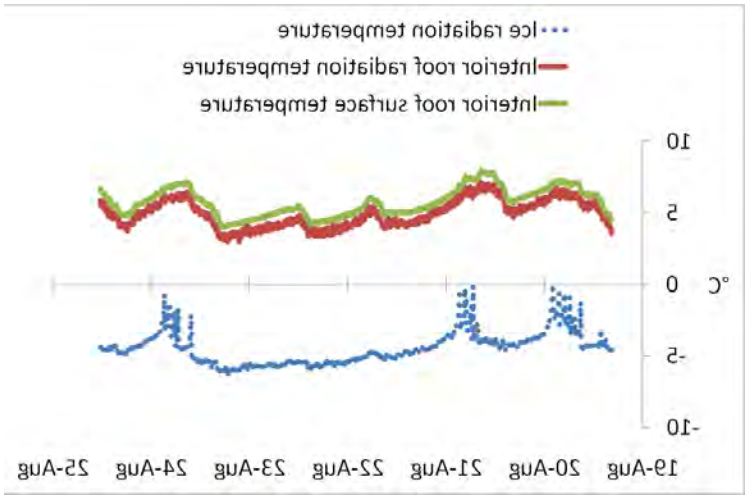
$$\varepsilon_{eff} = \left[\frac{1}{f_{ci}} + \left(\frac{1}{\varepsilon_c} - 1 \right) + \frac{A_c}{Ai} \left(\frac{1}{\varepsilon_i} - 1 \right) \right]^{-1} \quad (1)$$

The emittance of the low emissivity interior paint and its main components were determined from optical measurements of reflectance in the infrared wavelength range. For the primer, binder and the full paint formulation a Bruker Tensor 27 FTIR with gold-coated integrated sphere was used to measure in the wavelength range 2.5 to 20 µm. The flakes could be measured individually using a Hyperion microscope attached to the Technor FTIR. The thermal emissivity is calculated as an average emittance weighted by the black body radiation distribution for room temperature.

The binder was applied with a metal roll stick on optically smooth aluminium substrates. The thickness of the coatings was varied using different applicator rods. The primer was also applied on the same type of aluminium substrate and roll technique. The whole paint formulation was applied on stainless steel in a full-scale roll coating industrial process.

3. Results

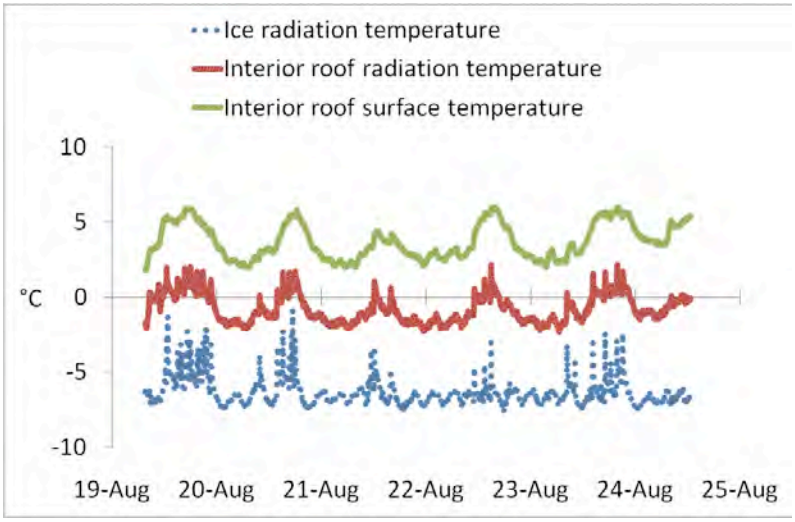
Surface- and radiation temperatures measured in the two ice-rinks during a couple of warm summer days clearly indicate a reduced radiation heat flux from the ceiling to the ice floor in the low emissivity interior roof ice-rink compared to that in the ice-rink with the highly emissive interior roof surface. In Fig. 1a, it can be seen that the radiation temperature seen by the upwards looking pyrometer in the highly emissive interior roof surface ice-rink is very close to the interior roof surface temperature measured by a thermocouple mounted in contact with the surface. In contrast, as shown in Fig. 1b, in the ice-rink with the low emissive interior roof surface the corresponding radiation temperature is much lower and closer to the ice-temperature.



a)

Fig. 1. The interior roof surface temperature, the radiation temperature measured by the upwards viewing pyrometer facing the interior roof surface and the radiation temperature measured by the downwards viewing pyrometer facing the ice are given vs. time during a series of summer days in a) the highly emissive interior roof surface ice-rink.

b)



b) The low emissive interior roof surface ice-rink.

Calculations with the dynamic model show in Fig. 2 the thermal radiation to the ice surface, on monthly basis, for three different sets of effective emittance values of the ceiling. It shows that using low emissive coating on the roof interior decreases the radiative heat dissipation to the ice surface, resulting in less cooling load to maintain the ice surface at desired temperature. On the other hand, the monthly variation in the low emissive ceiling are almost negligible, arguably as the interior air temperature is maintained constant.

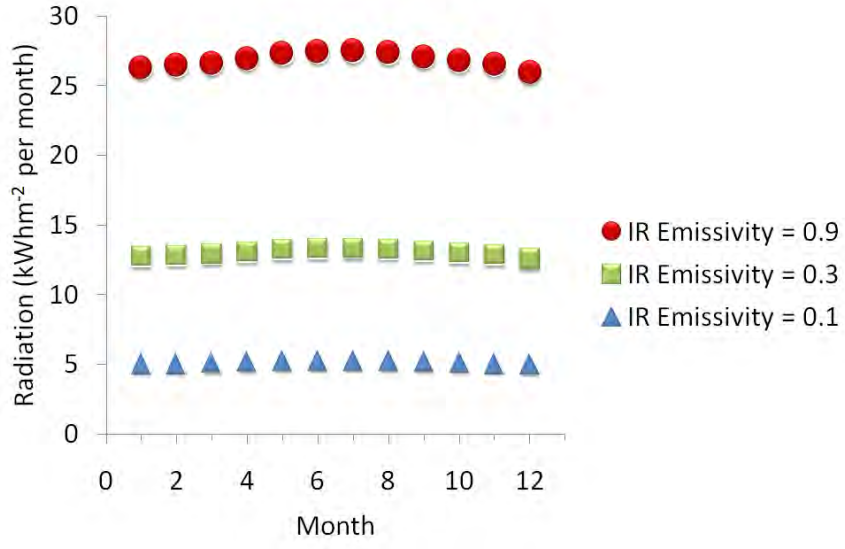


Fig. 2. Thermal radiation to the ice surface for each month for a ceiling for Stockholm climate.

Combining a high TSR (total solar reflectance) exterior roof coating and low emissive interior can reduce the total heat flux into the building; increasing the total solar reflection, TSR of the exterior coating reduces the solar gain, thus total heat flux into the building (heat surplus) will decrease. Further more, low emissive interior, reduces the radiation heat dissipation to the interior surfaces as demonstrated in the Fig 3.

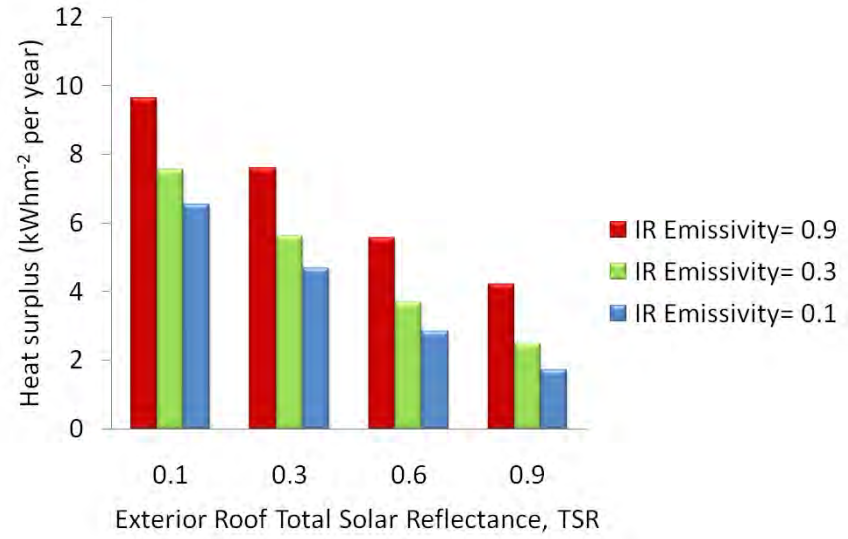

Fig. 3. The effect of combined different infrared emittance interior and high TSR exterior coatings on the heat surplus (cooling load) per roof area for Stockholm climate.

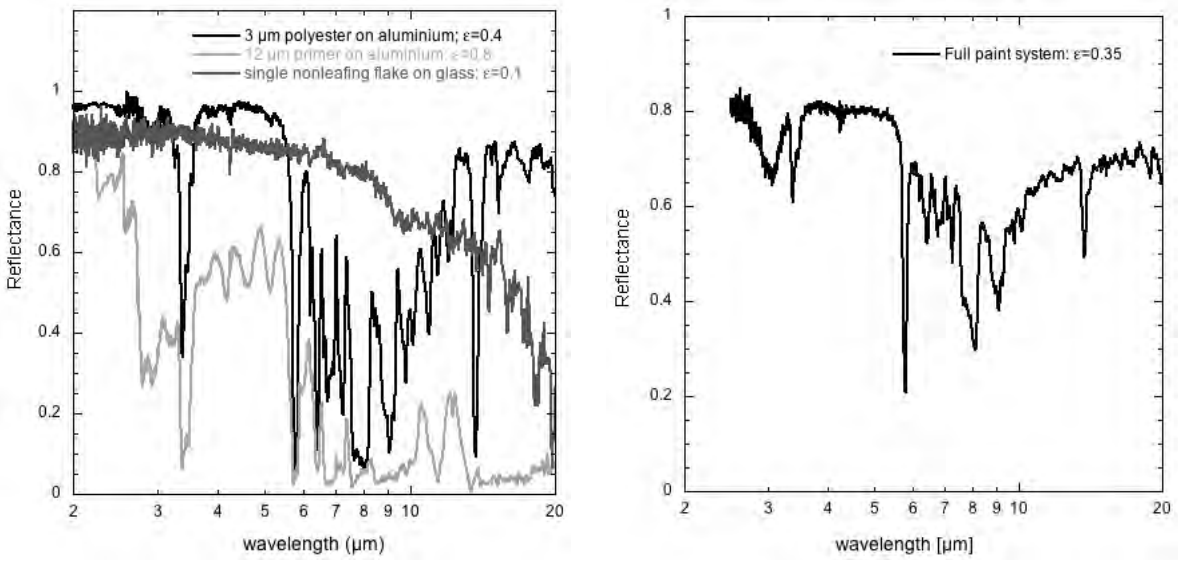
The reflectance measurements of the paint components are shown Fig. 4. The reflectance of the flakes cannot be measured for the longest recorded wavelengths due to the limited flake size (about 50 µm on average). It is notable that the flake reflectance is about 0.90 (emittance 0.10) as the best case for the shorter wavelength, which is considerable lower than for a smooth aluminium surface (0.05). It is seen by visible inspection in the FTIR-microscope that the flakes have surface defects that will cause a reduced reflectance. The binder, which is a 3-micrometer thick polyester shows a thermal emittance of 0.4. Results from optimization of the paint system shows an emittance of about 0.35 for an optimized paint layer. The optimised paint contains 25 % volume fraction of flakes and is about 7 µm thick. The quality of the aluminium flakes that are used in the paints as emissivity-reducing components has also been studied. It was found that the paint with non-leafing type of flakes had lower emissivity than paints with leafing type.



a) *b)*

Fig. 4. The reflectance measured on a) the main paint components: a single non-leafing aluminium flake, polyester binder on optical smooth aluminium and primer on the same substrate and b) a complete paint with the same types of components on galvanised steel.

4. Discussion and Conclusions

The results show the importance of using low-emitting interior surfaces in such applications as indoor ice-rinks. The ice-rink measurements have so far only been presented for a few summer days but are now continuously being measured in order to cover a whole year. The dynamic model of the roof for vertical heat transfer gives an estimate of the amount of energy involved in the radiant transfer from ceiling to ice and also the amount of saved energy on an annual basis. The model will be further developed in order to account for dynamic effects from the convection in the interior space and how it relates to the emissivity of the ceiling. There is obviously a potential to save energy in ice-rinks using low-emissivity paints instead of ordinary paints and it is therefore important to continue the work on paints to reach as low emissivity as possible. However the low-emissivity paints developed so far has about twice the emissivity of a pristine galvanised steel surface and work is needed to develop binders with weaker infrared absorption (especially in the range 8 to 10 µm) and flakes with higher reflectance.

Energy Efficiency in Historic Buildings: a Tool for Analysing the Compatibility, Integration and Reversibility of Renewable Energy Technologies

Elena Lucchi [1],*

[1] *Politecnico di Milano, Milano, Italy*
** Corresponding author. Tel: +39 0396085262, E-mail: elena.lucchi@polimi.it*

Abstract: The paper presents a tool for defining the most appropriate energy and environmental retrofit on cultural heritage, to enhance the historical value of a building, to preserve the surrounding landscape, to reduce energy consumption and to improve human comfort, health and safety. It allowed the evaluation of the conservation risks, energy consumption, spatial layout and maintenance procedures and also led to a proposal on the most appropriate energy actions. The tool examines the synergies and difficulties of integrating green practices with historic preservation, and offers recommendations for ways in which sustainable standards could be more accommodating for historic and bounded buildings. The approach was used in the Renaissance building of Sant'Alessandro University located in the centre of Milan (Italy).

Keywords: *Renewable energy, Cultural heritage, Compatibility, Integration, Reversibility*

1. Introduction

The architectural heritage is a capital of irreplaceable spiritual, cultural, social and economic value. Old buildings help to understand the past and the concerns of the society that created them. The interplay between historic buildings, energy efficiency and sustainability is a topic of great importance. Environmental sustainable and energy savings measurements can be considered as a means of protecting real estate, not necessarily in contrast with conservation policies. There are numerous compelling reasons to believe that preservation concerns with environmentally sustainable development. Historic buildings are often located in densely populated urban areas, where infrastructure and mass transit already exists, thereby eliminating the need for new infrastructure and encouraging alternative models of transportation. Historic buildings are also typically constructed with durable and local materials, and are often sited for having full advantage of their surrounding environment. Furthermore, there is high embodied energy in ancient patrimony, which is defined as the sum of energy required to extract or harvest a raw material, manufacture and fabricate that material into a useful form, and transport it to the place of use. Heritage conservation is also a key component for economic revitalization of cities' centre. Often, historic buildings serve as small business incubators. Finally, to increase the preservation of cultural heritage is an important component of social sustainability.

1.1. Energy efficiency policies

Energy efficiency is a central theme in the European policies. The Directive on energy performance (2002/91/EC) requires minimum energy standards for new and existing buildings that undergo major renovation. Despite the Directive admits a few exception for listed buildings, the International Energy Standards cannot be completely waived. Energy performance requirements can be excluded only "(…) where compliance with requirements would unacceptably alter their character or appearance" (Art. 43). At the same time, recent European policy officially introduces the concept of energy balance towards nearly zero-energy buildings and incentives the decreasing of 20% of environmental emissions and the increasing of 20% of renewable energy technologies within 2020 (2010/31/EU Directive). To achieve these goals, it is necessary to reduce user demand as well as to improve the efficiency

of energy systems and to use renewable sources. Heritage must adapt to changes, physical and intellectual, within its environment. The decision, inevitably, must be faced with the energy efficiency of existent buildings, independently by local bounds. Therefore we should develop techniques to maintain, refurbish and adapt the existing buildings to new requirements.

1.2. Environmental sustainability policies

Preservation-based sustainability is offered as a m ore comprehensive approach to development, as it takes into consideration environmental, economic, social, and cultural implications of buildings. These principles constitute the basis of the more important sustainable tools (1). These programs emphasize design, construction and operation for obtaining a "high green performance" building to reduce environmental impacts through energy efficiency, use of recycled materials, storm water management, and other innovations.

1.3. Sustainable conservation principles

High energy and environmental performances may lead the preservation of a building, but each action on historic and listed heritage gives attention to the matter of vulnerability, physical alteration, and decreasing of immaterial and material value. The most important principles for sustainable conservation regard:

- Compatibility: modern materials tend to be harder, less flexible, and less moisture permeable than traditional ones. For these reasons when are used in direct conjunction with historic fabric can greatly accelerate decay in the original work;
- Aesthetic integration: history and authenticity of historic building should be respected as essential to its significance;
- Reversibility: the unavoidable changes of the building should wherever possible be made to be fully reversible. Adopting this principle, the valuable historic fabric can be returned to its original state without damaging the building;
- Emphasis on e ffective maintenance: care, planned conservation, and management should include regular inspections so that defects can be discovered whilst still small and easily fixable. This permits to preserve historic fabric, minimize cost and disruption to the building's owners and users.

The retention of older buildings or the re-using of components in-situ and allowing for their energy upgrading in benign and sympathetic ways, can provide excellent finished results which are fully in accordance with the principles of building conservation and sustainability.

2. Methodology

Energy efficiency and environmental sustainable programs should be developed on the basis of a thorough knowledge of the property, blending technological and landscape requirements. This means understanding original construction, alterations, actual conditions, qualities, material and immaterial values, lacks, and retrofitting opportunities. The tool is structured in the following phases:

- Historical analysis of city, urban site and heritage building;
- Analysis of functions, performance and needs of users;
- Building energy audit;
- Evaluation of environmental performance;
- Individualization of energy and environmental lacks;
- Definition of possible retrofitting actions;
- Evaluation of the compatibility, the integration and the reversibility of each action.

1) See: U.S. Green Building Council's "Leadership in Energy and Environmental Design" (LEED), "Building Research Establishment Environmental Assessment Method" (BREAM), "Comprehensive Assessment System for Building Environmental Efficiency" (CASBEE), Green Star, Minergie and Ecolabe programs.

The tool allowed the evaluation of the conservation risks, energy consumption, spatial layout and maintenance procedures and led to propose the most appropriate actions (Fig. 1).

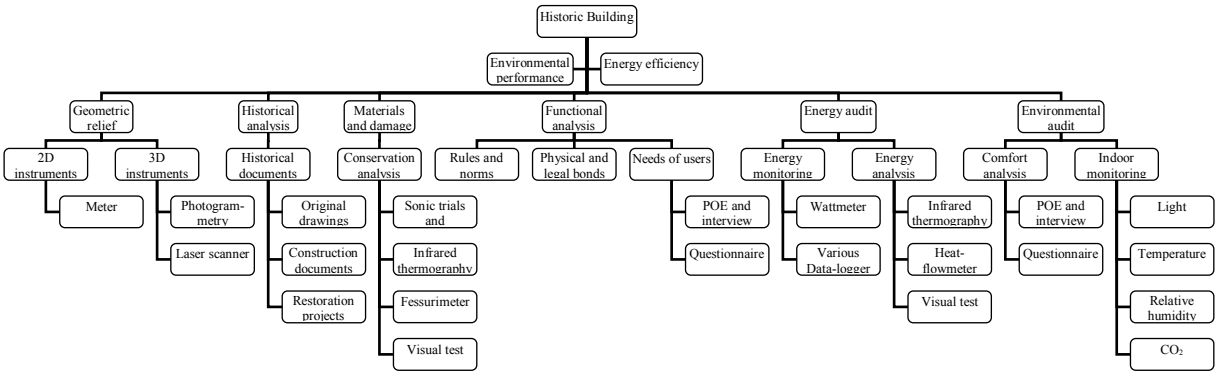

Fig. 1. Method for analyzing energy and environmental performance of historic building.

3. The case study: Sant'Alessandro University in Milan

The tool was used in the Renaissance building of Sant'Alessandro University located in the centre of Milan (Italy). The construction has been modified during the centuries. The most important projects regard the addition of a Baroque Church and the transformation into a Public University in XX^{TH} Century.

3.1. Historical analysis

Technical compatibility and aesthetical integrations are guarantee only by a deep knowledge of history, dimensions, structures, original and restoration materials, and management procedures. Also, it is important to comprehend how modern materials and technical approaches impact on ancient buildings. Failure to understand the nature of the building being inspected can have serious technical consequences, physical damage and possible legal claims. The historical analysis comprehend the physical relief, the study of traditional construction and local techniques, the instrumental tests of original and restoration materials. Cartographic map, land registry, cadastral map, historical and construction drawings permit to reconstruct the original form, the spatial relation and the history of the building. First of all, the original drawings, the construction documents and the restoration projects were collected. The geometric relief was made to verify dimensions, performances, and damage of structures. It was conducted using linear meter, photogrammetry and laser scanner, in order to reconstruct the morphology, the form, the dimensions, the spatial layout, the external and internal features. Final result after processing of the raw data produced drawings, CAD models, 3D surface models and video animations. Particularly, the analyses permitted to verify the reliability of historical documentation and to comprehend the constructive phases and the modifications realized in different ages.

3.2. Performance and functional analysis

First of all, it is important to define the meaning of "high performances" in historic building through the right balance with requirements, rules, norms, physical and legal bonds that condition the quality of life for occupancies. The international literature (ASHRAE, English Heritage) proposes to provide specific "classes of performance" for satisfying needs of access, comfort and security. For this purpose, all activities made by the users (students, teachers, staff, stakeholders) were investigated during different hours and periods of the year. In this way, a specific knowledge of the real requests was obtained.

3.3. Energy audit

Building audit is a process to evaluate the energy consumption of the building in order to identify the opportunities for retrofit actions (2). This means to effect inspection, analysis and survey of energy flow, for reducing energy inputs, improving comfort, health and safety. Energy performance of envelope, functioning of mechanical systems, and management data are necessary to realize the audit. Particularly, the following data was obtained:

- Location, urban planning, orientation and environmental context;
- Dimensions of the buildings;
- Construction features of building envelope;
- Efficiency, functioning and maintenance of mechanical and electric systems;
- Leakage rate or infiltration of air;
- Energy consumption.

3.4. Evaluation of environmental performance

Environmental evaluation considers the opposite exigencies for caring and valorizing the cultural heritage. The balance for conservation and human comfort was defined through the confront among environmental, caretaker and management standards. The evaluation regarded the following analyses:

- Microclimate monitoring of light (illumination level, luminance, UV and IR radiance), temperature (external and internal temperature, daily and seasonal gradient), relative humidity (external and internal relative humidity, daily and seasonal gradient) and air (air change rate, indoor air movement, CO_2 concentration, and pollutants dissemination);
- Thermal, visual and acoustic comfort of users;
- Maintenance procedures and operating data (opening times, operation hours, number and frequency of the visitors).

4. Results: energy and environmental performance

In Sant'Alessandro University was particularly difficult to find information about the technological characteristics because of the lack of original plans and of the alterations of the original asset. In order to individualize the original structure, destructive testing, such as coring or endoscope techniques, were excluded because the methods are not suitable for the architectonic values of the building. For this reason, technological data were estimated comparing handbooks, regulations, heat flowmeter measurements, infrared thermography and computations of energy performances.

4.1. Evaluation of energy performance

Non-destructive testing gave a precise recognition of constructive phases, authentic parts, original and restoration materials, constructive techniques, decay, durability and resistance of the structure. Particularly, infrared thermography verified the historical data and individualized the most important energy problems. IR inspection evidenced the presence of thermal bridges, low U-value of envelope, heat gradient through the walls, internal moisture, mould and air leakage at windows, joints and junctions of the building envelope. Sonic trial proved the presence of some mechanical anomalies and confirmed the real composition of the envelope realized by double masonry in bricks and rubble mix. Heat flowmeter measurement calculated the thermal conductance of the walls (Fig. 2).

2) The European Directive 2006/32/CE related to energy efficiency in final users defines energy audit as a «[…] systematic procedure to obtain adequate knowledge of the energy consumption profile of a building or group of buildings, an activity and/or industrial facility or public or private services, to identify and quantify energy saving opportunities from a cost-effectiveness profile and to report the results».

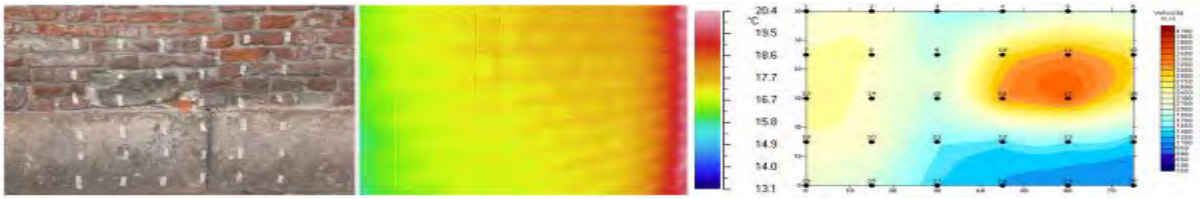

Fig. 2. Confront among visual test, infrared thermography and sonic trial of opaque envelope.

On plants, infrared thermography showed the high temperature of radiators (80°C) and of artificial lighting (60°C) and the functioning of plant in unused ambient. Visual test and environmental monitoring illustrated the low energy performance of HVAC, the incorrect energy management relating to the continual opening of windows and doors, the internal high temperature of air and ignition of lighting during all the day (Fig. 3).

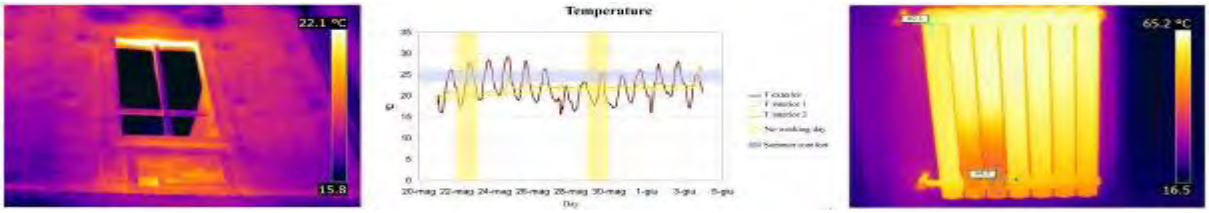

Fig. 3. Environmental monitoring and infrared thermography showed the high temperature of air.

Energy monitoring confirmed the low performance of HVAC and the high fuel bills of the last five years. Energy opportunities of the building regard the thermal mass of envelope, the breathable, and the natural moisture management. Energy performances were evaluated using static and dynamic simulations. The building was in the lower class of energy label with high annual energy consumption.

4.2. Evaluation of environmental performance

Environmental tests verified the presence of damage due to great flux of people and of incompatibility of the protecting policies. Users comfort was appraised with questionnaires and interviews conducted using the Post Occupancy Evaluation method. The analyses were realized on three categories of users: students, teachers and staff. The comparison between discomfort problems and environmental conditions showed the malfunctioning of mechanical systems and the use of incorrect management procedures. Particularly, environmental treats regarded high temperature and heat gain in the attics (mean temperature: 24°C in winter and 33°C in summer), high value of relative humidity in the laid undergrounds (60-65%), temperature fluctuation, low light level (200-300lux), discomfort glare and inadequate lighting (Fig. 4).

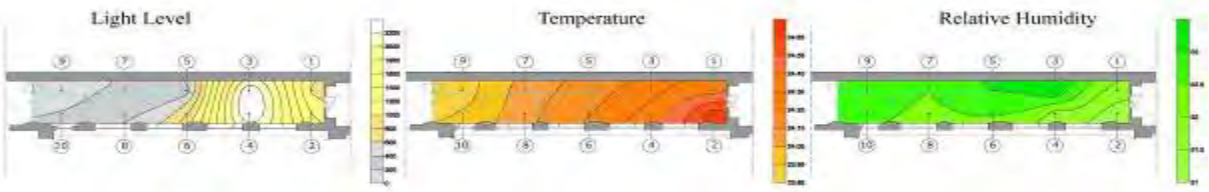

Fig. 4. Monitoring of light level, temperature and relative humidity of air in a room.

Comfort analysis demonstrated the abuse of artificial lighting and the use of wrong light sources (neon light). There is a direct relationship between environmental condition and surface decay. Damage regards cracks, surface breaking, moisture sources, water absorption, and percolation (Fig. 5).

Fig. 5. Decay problems are directly related to environmental condition and regard cracks, surface breaking, moisture sources, water absorption, and percolation.

5. Retrofit actions

The integration of conservation, design and operation is a radical approach to future-proofing historic buildings. Compatibility, integration and reversibility of retrofit actions are the principal items involved in the study of historic buildings. The lack of compatibility may cause serious long term problems of decay, such as bacteriological germination due to air permeability of windows or cracking in masonry due to low mechanical performance, water absorption, percolation and internal moisture. The lack of integration could have a negative effect on the physical composition and static resistance of the structure.

First of all, in Sant'Alessandro University was necessary to understand how traditional buildings behave as environmental systems. Non-destructive testing shows that the envelope didn't require insulation systems because the walls guarantee good thermal and hygrometric performances, both in winter and in summer. However, the invasiveness of internal or External Thermal Insulation Composite Systems (ETICS) or double façades may erase the historical traces and artistic value of the heritage. On the laid undergrounds it is possible to insulate with thermal plaster or internal rigid insulation in transpiring materials, because of the absence of historic traces. The basement and the roof have high energy losses due to the missing of insulation. To insulate the lower insole preserving the original floor, it is possible to add rigid or sprayed foam insulation on the internal surface. To insulate the roof could be installed underside insulation or insulated ceiling characterized by mechanical, chemical and physical compatibility with the original roof. Transparent envelope has high thermal losses and air infiltrations. For this reason, it is necessary to evaluate the replacement of existent glasses and frames with new windows (low-e glasses and wooden frames) having better performances of thermal insulation, air permeability, water resistance and UV protection. The PVC cover on the roof presents convection, air leakage, water adsorption and solar gain. It is necessary to study the replacement with Transparent Insulating Materials, solar control or selective glasses. For protecting the office from solar gain and discomfort glare can be installed internal shading devices and curtain (Table 1).

The main problem is caused by mechanical plants. The existent boilers have very low thermal performance. May be evaluated the replacement with an innovative heat pump, that balances heating and cooling needs. The low performance of radiators and fan-coil get worse by the absence of insulation on thermal distribution, climatic control and heat accounting systems. Furthermore, air-conditioning systems damages the artifacts and the buildings because the movement of air masses soils and dusts the walls, the frescoes, the inlays and the decorations. The intervention requires the evaluation of the insertion of radiant panels on existing floor (not characterized by particular historic value). Instead, it is necessary to insert thermostatic valves on existing radiators and heat accounting systems. The electric system not always is safety from risks. The lighting has discrete energy performances, guaranteed by the integration with daylight, halogen lamps and periodic maintenance on inefficient devices. To increase the level of light can be installed diffusers on existent glasses of the office and high efficiency sources. Solar energy technologies must be integrated within buildings and their

surrounding landscapes, in order to obtain financial support and to increase their efficiency. The use of photovoltaic panels is recommended for decreasing the high electric consumption (Table 2).

Table 1. Definition of possible retrofit actions for the building envelope.

Measurements	Compatibility	Integration	Reversibility
Roofs			
Add rigid insulation on the top surface	■	■■	■
Apply sprayed foam insulation to the top	■	■■	-
Install underside insulation	■	■	■
Install insulated ceiling	■■	■	■
Walls			
Insulate with thermal plaster or wall	■	■	-
Basement			
Install underside insulation	■	■	■
Windows and doors			
Install high-efficiency doors and windows	■	■	-
Install low-e glasses on existing frames	■	■■	-
Transparent Insulating Materials	■	■	-
Install selective materials	■	■	-
Install weather-stripping on windows	■	■■	■■
Shading devices			
Install internal shading devices	■	■	■
Day lighting systems			
Install diffusers on existent glasses	■	■	-
Install interior curtain	■■	■■	■

Incompatible actions: replace with insulated or green roof; insert ETICS or double façades; install storm windows, films or supplemental glazing; add veranda or solar greenhouse; maintain fit, closure and sealing of windows; install external shading devices, skylights, light pipes or light shelves; painting for minimizing the sunlight absorption

Note: ■■ = Yes - = No ■ = Specific project is required

Table 2. Definition of possible retrofitting actions for plants and renewable technologies.

Measurements	Compatibility	Integration	Reversibility
Boiler plants			
Test boiler efficiency	■■	■■	■■
Optimize the air-fuel ratio	■■	■■	■■
Install air conditioning units and heat pumps	■■	■	-
Install an exhaust air heat recovery system	■■	■	■
Clean and repair radiators and convectors	■■	■■	■■
Replace exiting systems with radiant panel	■	■	-
Install single-zone systems	■■	■	■
Install thermostatic controls	■■	■■	■
Optimize the operating temperatures	■■	■■	■■
Electric systems and artificial lighting			
Install the most efficient lamps and ballast	■	■	■■
Install dimmers	■■	■	■
Maintenance of lamps	■■	■■	■■
Solar energy technologies			
Install photovoltaic panels	■	■	■
Install solar heating panels	■	■	■

Incompatible actions: install mechanical ventilation pant; insulate the distribution system; insert wind technology systems

Note: ■■ = Yes - = No ■ = Specific project is required

A software simulation with Design Builder allowed to verify the energy benefit related to various retrofit actions. In this way, the proper interventions have been selected in order to improve energy and environmental efficiency of the building (Table 3).

Table 3. Retrofitting actions to be realized in Sant'Alessandro University .

	Measurements		Reduce of		
			Thermal loss	Thermal gain	Air infiltrations
A	Roofs	Add insulation on the top surface	70-80 %	-	-
		Install insulated ceiling	60-70 %	-	-
B	Walls	Insulate with thermal plaster	30 %	-	-
		Insulate with thermal wall	50 %	-	-
C	Basement	Install underside insulation	50-60 %	-	-
D	Doors	Install high-efficiency	10-20 %	-	70 %
E	Windows	Install high-efficiency windows	50-70 %	25-40 %	90 %
		Install low-e glasses on frames	30-40 %	25-40 %	60 %
		Install weather-stripping	-	-	40 %
F	Curtain Roof	Transparent Insulating Materials	50-80 %	30-40 %	50 %
		Install selective materials	50-60 %	50-60 %	50 %
		Install internal shading devices	-	20-30 %	-
G	Boiler plants	Test boiler efficiency	-	-	-
		Optimize the air-fuel ratio	20 %	-	-
H		Install thermostatic controls	30 %	-	-
I	Electric systems	Install the most efficient lamps	30 %	-	-
L		Maintenance	-	-	-

Note: ■ = Most efficiency action

The most important problem regards the education of staff and stakeholder to a correct thermal and light management of rooms, corridors and foyers. The building can save up to 35% energy, without compromising heritage value and occupancies comfort, by implementing the mentioned ECMs.

6. Conclusion

The objective of energy end environmental quality in historic building can only be achieved by combining a diversification of energy production from various renewable sources together with cutting greenhouse gas emissions. The goal may be obtained only by an integrate analysis of historic, dimensional, functional, energy and environmental matter. A deep knowledge of a real need permits to propose the most appropriate retrofit actions. On the contrary, non-critical application of energy standards and general models disadvantage the existing building or its parts, without getting a real advantage in the overall energy balance.

Abstract: All dwellings in the UK are required to have an Energy Performance Certificate (EPC) when sold or let, giving potential owners or tenants information on the cost and associated CO_2 emissions of heat and power. The Scottish traditional construction of solid stone walls tends to get unfavourable EPC ratings, leading to a perception that 'old is cold': this paper uses alternative calculation methods to question that perception.

The difference in results from steady-state and dynamic energy assessment methods is investigated for a dwelling with high thermal mass. The study focuses on modelled data and concludes that SAP 2009's monthly assessment estimates lower energy use and therefore gives a more favourable EPC rating than the annually based RdSAP 2005; and further that the application of dynamic simulation models may not be the optimum solution to further understanding energy efficiency of this type of dwelling.

Keywords: *Energy assessment, Behaviour, Thermal mass, Heritage, Dynamic simulation*

1. Purpose of the research

1.1. Introduction

In Scotland, nearly 20% of the housing stock was built pre-1919[1], and is considered to be of traditional construction. For the purpose of this research, traditional construction is defined as a dwelling with solid stone walls, although it is worth noting that other construction types were used in this pre-1919 era. For many people there is a perception that these types of dwellings are draughty, cold, and expensive to heat. The introduction of EPCs has tended to affirm that perception, with very low ratings for larger dwellings of this construction. However, work by Historic Scotland, the Government department responsible for the historic environment in Scotland, and others, is starting to question this perception. The perception of "old is cold" can be viewed from many angles, as different variables are important to different groups. For example, a government may look at statistics provided via EPCs, a homeowner may consider fuel bills, a tenant whose rent includes bills (and therefore has little concept of the cost of heating) may purely consider the temperature of surfaces (stone walls feel cooler to the touch) or the feel of draughts. If the relationship between thermal inertia, occupancy and energy use can be better understood, energy modelling can be instrumental in changing people's perceptions of energy use within dwellings, better educating them towards reducing energy use.

This research sets out to compare three energy assessment methods for a case study dwelling – a traditional mid-terrace, mid-floor, tenement flat in Edinburgh. It aimed to investigate how well the models predict energy demand, and how they assimilate the high levels of thermal mass seen in solid wall construction throughout the model, including feedbacks.

2. Approach and methodology

2.1. Dwelling types

The research aimed to be relevant to as many stakeholders as possible. Therefore, the most recent Scottish House Condition Survey (SHCS) report data from 2009 is used to assess the Scottish housing profile. Direct comparison can be made between just the pre-1919 dwellings

using detailed data - Table 1 shows the dwelling types and which are most prevalent within the age band, hence the choice of tenement flat as the case study dwelling, being a considerable proportion of the pre-1919 housing stock[1].

Table 1. Housing split across pre-1919 housing stock in Scotland[1].

House type	Number	Percentage of pre-1919 stock
Detached	109,000	24
Semi-detached	68,000	15
Mid-terrace	53,000	12
Tenement flat	180,000	40
Other flats	39,000	9
Total	*449,000*	*100*

2.2. Models

There are a number of building performance simulation models available globally and in the UK. To maintain relevance for the widest audience, the project uses models that are accredited in the UK to produce energy performance certificates and carry out Building Standards compliance checks.

Standard Assessment Procedure (SAP)[2] is used for new-build dwellings, Reduced Data SAP (RdSAP) is used for existing dwellings[3], and IES<VE> is a dynamic simulation software used for non-domestic buildings. The background to each model used is explained, with a summary of how the model was used and the assumptions made.

2.2.1. SAP 2009

The primary purpose of energy assessment in the UK is producing Energy Performance Certificates (EPCs) for both domestic and non-domestic buildings, at the point of sale or rent.

Standard Assessment Procedure (SAP) began in 1993, with a number of both major and minor alterations to the methodology since[2]. The largest overhaul was following the introduction of the Energy Performance of Buildings Directive (EPBD) in 2002: an update to SAP was needed to ensure it was consistent with energy assessment methods across the EU.

The latest update to SAP came in April 2010, as the Government released SAP 2009, v9.90, to be used from October 2010[2]. This new model has updated carbon emission factors, fuel prices, climate information, and also now includes space cooling. The biggest difference to v9.90 is that it has moved from an annual calculation to a monthly calculation. SAP uses a steady-state calculation, in that it assumes that variables are constant within each time step, implying that the method has become more detailed and aims to be more accurate, however, it does not include feedbacks within the system.

While the technical guide and calculation methodology for SAP are open to anyone to view and download, the majority of software providers allow access to their SAP programmes only to qualified assessors. A minority allow unlimited or academic access. The defined SAP methodology[2] has therefore been put into a bespoke spreadsheet model to enable detailed examination of the calculations and relationship between variables.

2.2.2. RdSAP 2005[3]

The most significant change to SAP has been the introduction of RdSAP in 2007, used solely for predicting the energy demand in existing dwellings. It does this by providing a database of information to be used in the calculation where an assessor finds information unobtainable (such as wall construction, thickness, U-values) as the dwelling is already built. For dwellings built in the 20th century the system is relatively fair, creating age bands of dwellings. For example all housing post-1984 will have the same characteristics. However for dwellings built prior to 1919, the focus of this research, there is a single age band, which may lead to unrepresentative information being used in the model, affecting the modelling result[4].

Figure 1 shows that the frequency of updates to SAP and RdSAP has increased, but also shows that the model used for RdSAP is consistently behind SAP which is used for new-builds. Since October 2010, new-build dwellings are required to use SAP 2009, v9.90, whilst existing buildings continue to use SAP 2005, v9.83, using the previous set of carbon factors and out of date fuel prices.

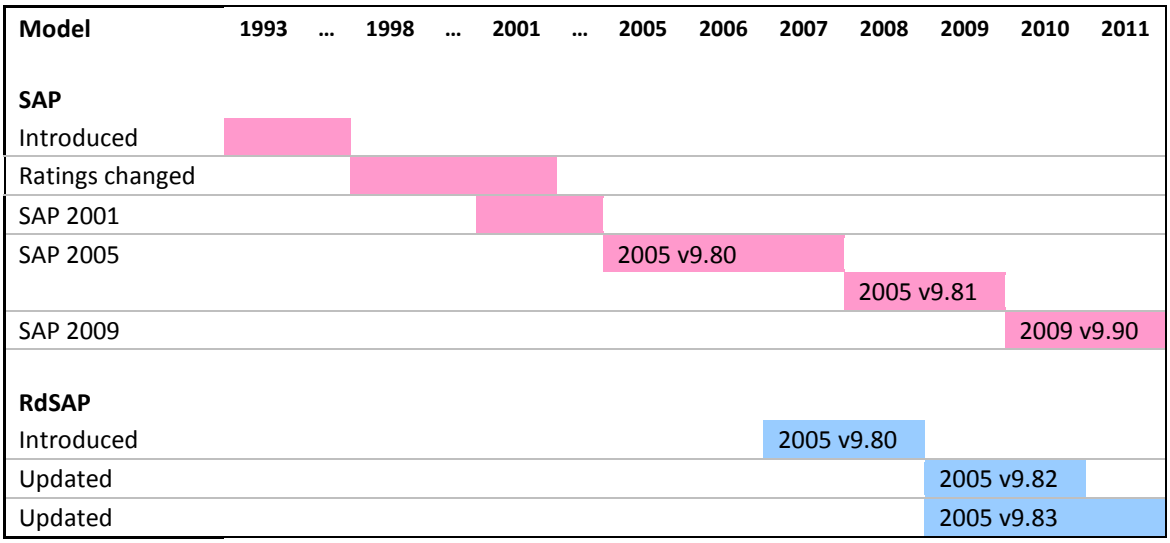

Fig 1. Changes to SAP since its introduction in 1993[2]

Similarly to the method used for SAP, the defined RdSAP methodology[3] has been put into a bespoke spreadsheet model, enabling in-depth examination of the calculations and relationships between variables. This method also allows direct comparison between entering known values and those from the construction database.

2.2.3. Dynamic Simulation Models

There may be scope for non-domestic models, their principles or methods to be included within domestic models, or to replace them. In addition to the standard domestic (SAP and RdSAP) and non-domestic methods, the UK National Calculation Methodology (NCM) includes Dynamic Simulation Models (DSMs). These DSMs look at both high spatial resolution as well as high temporal resolution to model the changes that occur over time using fundamental mathematics of the heat transfer processes that occur both inside and around a building.

As well as the basic heat gains and losses calculations, DSMs also include convection, heat transfer by air movement, thermal radiation transmitted by surfaces, solar transmission, and absorption and reflection by any glazing. The heat gains utilised are both sensible heat (the

temperature change in the air of the room) and latent heat (the change in humidity in the room). Dynamic models require the building to be divided into multiple zones, and use much more detailed weather data than in SAP and RdSAP, from the Chartered Institute of Building Services Engineers (CIBSE)[5].

In the UK, there are two DSMs accredited to produce EPCs for non-domestic buildings: this research uses IES<VE>, or Virtual Environment. IES originated from academic research, but became commercial in 1994 with a user-friendly interface[6], and by using the same user-interface as professionals in the construction sector it is believed that the conclusions of this research will be accessible to a larger number of readers.

2.3. Occupancy

The SHCS provides information on the demographics of occupants in dwelling types within the pre-1919 age band of housing[1]. Using this data three occupancy profiles were produced, summarised in Table 2. These are expanded upon using studies by the Energy Saving Trust and reasonable assumptions (by the authors), to provide a list of appliances used in each occupancy profile, and assumptions are made with respect to use of heating and behaviour towards ventilation and heating where possible within the models used.

Table 2. Summary of occupancy profiles to be assumed in the research.

	Occupancy Profile		
	1	2	3
Description	Single adult	Small family	Older smaller
Number of adults	1	2	2
Age of adults	16-34	45-54	70-80
Number of children	0	2	0
Age of children	-	14-17	-

To assess the effect of occupancy on energy use in dwellings of traditional construction, IES<VE> is used, as neither SAP or RdSAP include appliance use in energy consumption calculations. During the initial model runs when comparing IES<VE> and the two SAP methods, occupancy profiles from the NCM are used, to ensure that as many variables as possible are the same in the DSM as in SAP 2009 and RdSAP 2005. However, to assess occupancy effects, the profiles from Table 2 are used, with tailor-made equipment, lighting, appliances and occupant activity profiles defined within the DSM.

2.4. Data Collection

For any type of building performance simulation, certain basic details are required, such as dimensions, heating system information, and constructions. Depending on the model used and therefore level of information required, additional details are sometimes required. A complete data set for the Case Study dwelling was collected by the author, through consulting with architectural plans and discussions with the homeowner/occupant. Typically, however, assessments of existing dwellings are done by site visits and physical measurements made. For this case study, architectural plans were available following work carried out on the flat in 1992.

By collecting sufficient data for a DSM, certain variables are known in greater detail than are needed for SAP and certainly for RdSAP. The methodology within RdSAP requires that certain variables are entered as defaults, and others are entered in more detail.

3. Results

3.1. SAP 2009 vs RdSAP 2005

When comparing the two domestic energy assessment methods, the variables that differ greatly are solar gains, fuel for space heating, and CO_2 emissions from space heating (see Table 3). The factors contributing to these variables can be traced back through the calculation to further understand the differences.

3.1.1. Solar gains

The method used to calculate solar gains in RdSAP 2005 uses a UK average vertical solar flux for the year, applied to each area of glazing. The SAP 2009 method is far more detailed, doing a monthly calculation using the mean global solar radiation on the horizontal for latitude 53.4° (approximately Manchester, UK), then calculating the vertical solar flux from that using orientation, and then calculating solar gain, again applied to each area of glazing.

3.1.2. Fuel for space heating

The fuel used for space heating is a factor of the heating system *efficiency* (identical in both SAP 2009 and RdSAP 2005 and therefore negligible) and the heating *requirement* – the kWh/year needed to heat the dwelling to the required internal temperature. This heating requirement is where the difference between the methods lies.

In SAP 2009, the heating requirement is a factor of the Heat Loss Coefficient, the total internal gains, the average external temperature, and the average internal temperature. In RdSAP 2005 the heating requirement is a factor of just the internal gains and the Heat Loss Coefficient. The SAP 2009 calculation is therefore more detailed and is also monthly. In both methods, the solar gains are a direct factor towards calculating heating demand, so any errors or differences in calculating solar gains will feed through and enhance the differences in fuel used for space heating.

3.1.3. CO_2 emissions for space heating

These are a direct function of the fuel used for space heating, and will always be different between models where the fuel demand is different. Additionally, the CO_2 emissions are calculated using emission factors ($kgCO_2/kWh$) which were updated in 2009 and for mains gas are now 2% higher.

3.2. SAP 2009 vs IES<VE>

The results that can be analysed from IES<VE> are similar to those from SAP 2009, as they are both in monthly formats. However, IES<VE> allows the user to go into more detail down to hourly level, and view in graphical format the energy use, emissions, and internal variables such as temperature.

Table 3 compares the key variables from SAP 2009 with those from IES<VE>. IES includes equipment in its total electricity figures while SAP and RdSAP do not, therefore only electricity for lighting is shown here for more accurate comparison.

It is obvious from Table 3 that IES<VE> is the most onerous method of assessing energy and emissions from this tenement flat. Additional analysis may assess whether the reason is inaccuracies in the database's default values, the calculation method, or inconsistencies in data entry across all three models due to the inputs required.

Table 3. Summary of key variables across the three models.

Variable	Units	RdSAP 2005	SAP 2009	IES<VE>
Space heating demand	kWh/year	6813	3366	13,067
DHW demand	kWh/year	2791	2371	161
Lighting electricity demand	kWh/year	317	298	1457
Total energy demand	kWh/year	10,052	6165	15,900
Space heating emissions	$kgCO_2$/year	1322	666	} 2566
DHW emissions	$kgCO_2$/year	542	469	}
Lighting emissions	$kgCO_2$/year	134	154	615
Total emissions	$kgCO_2$/year	2052	1357	3674
SAP rating	n/a	78	87	*
EPC rating	n/a	C	B	*

Notes: * = Not calculated within IES<VE> for this dwelling.

3.3. Occupancy effects

Both SAP 2009 and RdSAP 2005 use a standard assumption of the number of occupants in a dwelling. The equations used differ but both are factors of the total floor area. In this case study the results are the same, assuming occupancy of 2.13 people, while in reality the flat is home to 2 adults. Consequently, in this case study it can be suggested that the energy requirements for domestic hot water, heating and lighting may not differ wildly when using the exact figure of 2 people. However, as mentioned in 3.2, SAP does not include the energy for equipment and appliances. By including these, it is suggested that the total energy demand and total emissions will both increase. This case study has two bedrooms, and could potentially also house two young children in the second bedroom, increasing the equipment use with additional televisions etc, but also increasing all other loads within the dwelling, as more showers are taken, more food is prepared, and more rooms require heating and lighting.

4. Discussion

Energy assessment in the domestic sector has one main purpose – the production of EPCs. With new-build dwellings, energy assessment methods can be used during the design phase to reach a particular level of design and CO_2 and energy savings as required by planning conditions, by suggesting constructions, insulation levels, and low or zero carbon technologies. For existing dwellings, energy assessment can also be used for this, but if the assessment is inaccurate, it may result in inadequate, deficient or inefficient retrofits.

While the EPC system is designed to be standardised across the UK, with standardised occupancy and location information used (in RdSAP at least), it only serves its purpose truly for sale and rentals, as it informs the new occupier of suggested costs. The methodology as it is cannot identify areas of high energy use or optimum areas for retrofit for a particular occupancy. For example, in a large house with occupancy profile 3, greater emissions savings may be made with retrofit options that favour reduced heating thereby reducing bills and raising quality of life as the occupants regain use of rooms previously cut off as ‘too cold’. In a small flat with occupancy profile 2 where appliance and equipment use is heavy, it may be wiser to reduce electrical demand through efficient appliances, or introduce renewable electricity supply.

In terms of the human impact on energy assessment and on the occupant's energy use the second biggest factor is the way the assessor carries out the data collection and RdSAP calculation. There are a number of areas within RdSAP where detailed information can be found if the assessor has the time or inclination to find it, but due to time constraints on a project they may use more default information from the database than is ideal. While assessors undergo training and examination, there is currently no quality control stipulated in the Building Standards for Scotland [7]. Only if an assessor is accredited through an English-based company will they undergo recurrent checks on their assessments. It is suggested that these assessor errors could be significant, and further research on this is in progress.

As outlined earlier, energy assessment needs to be as accurate as possible for informed decision making, but there are varying levels of complexity of models, and balance is needed between simplicity and complexity. DSMs use detailed input data and are time intensive, whereas simplified steady state methods use a less accurate approach in a faster time. It remains to be seen whether a single optimal method can be found that combines improved levels of detail with short timescales. To combine accuracy and speed, a statistical approach could be used to define polynomial functions from the DSM to provide statistical methods that in essence are a simplified dynamic approach [8,9]. Table 4 outlines the main differences between the types of model looked at within this research.

Table 4. Summary of main variables and differences between assessment methods

	SAP	**RdSAP**	**Dynamic**
UK Accredited for:	New-build Domestic	Existing Domestic	Non-domestic
Construction details	Exact, from plans	Database unless known	Database unless known
Thermal Mass	Limited	✗	✓
Include heat gains	✗	✗	✓
Overheating risk (as standard)	✗	✗	✓
Climate variables	Monthly	Annual	Hourly
Time to assess	1-2hrs	1-2hrs + site visit	1-2 days + site visit
Cost to assess	££	££	£££ upwards

RdSAP and SAP both require a number of simplifications in the data input. In both methods, a default database U-value for solid sandstone walls was used; however work is ongoing at Historic Scotland to measure U-values in-situ. It may be possible in future to use measured U-values to better represent a particular dwelling's heat loss.

The research in this paper could be compared to real energy bills in an attempt to validate the analysis, but there will still be inconsistencies, as so many aspects of the SAP and RdSAP methodologies are standardised and fail to include equipment and appliances. An energy assessment was carried out on this property in 2009, but comparisons between the assessment here and the EPC are difficult for three main reasons: the EPC assessor assumed no flats on the ground floor, substantially increasing the area of heat loss; the EPC assessor used a different floor area ($75m^2$ to the $65m^2$ used from plans); a new boiler was installed in 2010, improving the space and water heating efficiency and therefore energy demand. The first two points here are indicative of the human error aspect explored in Section 4.

Rapid changes within the construction industry and Building Standards equally past, present and future, combined with updates to the energy assessment methodology, mean that energy assessment stakeholders work in a rapidly changing arena. Updates to Building Standards are expected in 2013 and beyond, and changes in the EPBD cannot be ruled out. Future Standards may require different things of existing buildings, and energy assessment may have a different purpose. Therefore, while the outcomes of this research are relevant in 2011, their relevance in the future cannot be predicted.

5. Conclusions

It can be seen here that the models disagree on key variables. Where SAP 2009 and RdSAP agree quite well as to the energy required for DHW and lighting, IES predicts a far higher lighting demand, but a much lower DHW demand. Similarly to the lighting, IES predicts far higher space heating demand than the domestic models. If comparing just the domestic models, SAP 2009 predicts lower energy use for all variables than RdSAP 2005. Further work will be carried out into the variations in energy demand predicted by the models used.

This work shows there is still potential for improving energy assessment, and the complexity of *precise* energy assessment does not necessarily lead to *accurate* energy assessment.

Abstract: In many historic buildings, conservation heating has been used to control the RH in winter. Heat pumps are much more energy efficient than direct electric heating, so this technology may be adapted for climate control. Dehumidification has not been regarded as appropriate for historic buildings due to poor regulation, but recent development in electronic hygrostats makes this technology an attractive alternative. The annual energy consumption for both control strategies was calculated from statistical meteorological data for Denmark. The most energy efficient control strategy is determined by the U-value of the building, the air exchange rate and the volume. For large buildings conservation heating with heat pump technology seems to be the most energy efficient, unless the thermal insulation is very poor. For small buildings dehumidification is more efficient unless the building is very leaky. The two strategies for climate control were tested in historic houses owned by the National Museum in Denmark and used for exhibition only in the summer season. Kommandørgården has an uncontrolled climate in summer due to open doors in the opening hours. In winter the RH is controlled to 60-70% by hygrostatic heating. Liselund is an 18th century mansion located in a romantic garden on the island Møn at the Baltic Sea. The house is open only for guided tours in the summer, and the RH is controlled all year by dehumidification.

Keywords: *Dehumidification, conservation heating, air infiltration, historic building, climate control*

1. Introduction

Denmark has a mild and humid coastal climate due to the influence of the Atlantic Ocean and the Gulf Stream. The average relative humidity is high, and frequent rainfall and mist from the sea is a source of humidity to any building. An ordinary house usually has a moderate RH inside due to heating and ventilation. But a historic building, which is not used for living or working anymore, has a high RH even if there is no human activity. The humidity comes from the outside air and in some cases also from rising damp or rain penetrating the walls. A permanent high RH has dramatic consequences for preservation of the interiors. Woodworms may eat up the furniture and moth will feed on the textiles if nothing is done to reduce the RH. There are two options for a simple humidity control strategy in historic houses which are not permanently occupied by humans: Conservation heating or mechanical dehumidification. The question is which of the two strategies is the most energy efficient, and how to decide for the one or the other. In the present paper the question is dealt with through energy calculation of a generic building and a case study of two Danish buildings: Kommandørgården is a traditional farmhouse on the island Rømø, and Liselund is a mansion located on the island Møn.

Conservation heating is a well established practice to control the relative humidity for preservation purposes [Staniforth et al 1994]. It is a simple and robust method, but the stability of RH depends on the air infiltration rate and the temperature control. A leaky house with a thermostatic control will experience large variations in RH. Hygrostatic control is more flexible, but may suffer the problem of positive feedback due to evaporation from damp walls or floors. Another peculiar aspect of conservation heating is that heating is required also in summer to maintain a moderate RH. The summer heating may be avoided if the house has large south facing windows [Rademacher 2010]. As energy conservation becomes more and more important, heating all year is less attractive for climate control. The heat loss is much larger from historic buildings than from modern houses due to poor thermal insulation of

walls and ceilings. Leaky doors and windows further increase the heat loss. In a historic house, the potential to improve the thermal performance is limited. Instead, the source of energy must be efficient. Electric heaters are frequently used because they need little installation work. Heat pumps are much more energy efficient, so this technology might be adapted for use in historic buildings [Brostrom and Leijonhuvud, 2008].

Dehumidification has until recently not been regarded as an appropriate control method due to the risk of damage caused by too much drying. Surely old fashioned dehumidifiers without proper RH control used in buildings sites were not suitable for historic houses. But the development of electronic hygrostatic control has made dehumidifiers an attractive alternative for historic buildings, where heating is not needed for human comfort. There are two methods for dehumidification of atmospheric air; absorption and condensing. The condensing dehumidifier contains the same elements as a refrigerator, but in a different combination: A fan drags the air through the cooling unit to extract the moisture, which drips into a bucket or to a drain. The cooled air then passes through the heating unit and back into the room a little warmer than before. This method works well in heated buildings but is less efficient below 8˚C. The absorption dehumidifier passes the air through a desiccant, usually silica gel, which absorbs the water vapour from the air. When the desiccant is full, a supply of warm air removes the moisture to the outside. The advantage of this method is that it works at low temperatures, even below zero degrees. The humidity is not transformed into a liquid, so the device does not need a drain or a bucked to be emptied. However, the device requires ducts for the release of the warm humid air to the outside.

2. Theory

A model building with a total volume of 500 m^3 was used for the calculation of energy efficiency. The building had one level with a rectangular plan of 10 x 17 m^2 and 3 m to the ceiling. The U-value of the ceiling and the walls was 1.0 W/m^2K, which equals 50 cm solid brick masonry or 5 cm wood planks. The model did not take into account heat loss or gain from the floor. Solar radiation to the building and heat radiation to the open sky was not considered. The building was empty and had no internal sources of humidity. The only source of moisture into and out of the building was the outside air, which would enter at a constant rate. If nothing was done, the inside climate of the building would be almost the same as outside. But the RH was to be maintained constant at 60% all year, either by heating or by dehumidification. The calculation used the monthly averages of temperature and relative humidity in Denmark. For every month the appropriate temperature for conservation heating and the excess moisture to be removed by a dehumidifier was determined. These data are presented in table 1.

The energy needed for conservation heating and dehumidification as a function of the Air Exchange Rate (AER) is shown in Fig. 1. In the case of dehumidification (blue line) the energy demand depends only on the AER. It was assumed that an absorption dehumidifier would use 1 kWh to remove one kg of water from the air. The energy was used to heat up the air stream that evaporated the moisture from the adsorbent. In the case of conservation heating (red line) the energy needed to achieve the target RH depends on the temperature difference between inside and outside. It is assumed that the heat pump gives of 3 kWh of heat for each kWh of electric power (COP = 3). As for dehumidification, the energy demand increases proportional to the AER. But even an airtight structure needs heating due to the heat loss by transmission thought the walls and ceiling. This depends on the U-value and defines the intersection with the Y-axis. The crossing point of the two straight lines divides the diagram into two segments. Dehumidification is more energy efficient than heating with a heat pump if

the air exchange rate is lower than 1 per hour. At higher air exchange rates heating becomes more favorable. The heat loss from a highly insulated building (U = 0.1 W/m^{2}K) and a very lightly build house (U = 2.0 W/m^{2}K) is shown for comparison. A heat pump is more energy efficient for climate control in a well insulated building if the AER is higher than 0.1 per hour, whereas dehumidification is favorable in a building with little thermal insulation if the AER is below 2 times per hour.

Table 1. Monthly average for outside temperature (Out T), relative humidity (Out RH) and outside absolute humidity (Out AH) for Denmark. Estimated inside temperature (In T) and temperature difference (T dif) for conservation heating to a constant RH at 60%. Estimated inside absolute humidity (In AH) and difference in absolute humidity (AH dif) for dehumidification to a constant 60% RH.

	Meteorological data			Conservation heat		Dehumidification	
Month	Out T (°C)	Out RH (%)	Out AH (g/m^3)	In T (°C)	T dif (°C)	In AH (g/m^3)	AH dif (g/m^3)
Jan	0	87	4.2	5.5	5.5	2.9	1.3
Feb	0	85	4.1	5.0	5.0	2.9	1.2
Mar	2	83	4.6	7.0	5.0	3.4	1.2
Apr	7	76	5.9	10.5	3.5	4.7	1.2
May	12	68	7.2	14.0	2.0	6.4	0.8
Jun	16	68	9.2	18.0	2.0	8.2	1.0
Jul	18	71	10.8	21.0	3.0	9.1	1.7
Aug	17	74	12,0	22.5	5.5	8.7	3.3
Sep	14	78	9.4	18.5	4.5	7.2	2.2

Nov	5	87	5.9	11.0	6.0	4.1	1.8
Dec	3	88	5.2	9.0	6.0	3.6	1.6

For every U-value there is an AER, at which heating and dehumidification is equally efficient. The relation between AER and U-value is linear as shown in Fig. 2. If a building with 500 m^3 volume has a combination of AER and U-value above the blue line, then dehumidification is the most efficient way to control the RH to 60% over the year. This is typical for historic buildings which are not used for living or working. If the combination of AER and U-value is below the blue line, then a heat pump is more efficient for climate control. Modern buildings which are ventilated for human comfort are in this segment. Similar lines for equal energy efficiency is shown for a large building (2000 m^3) and a small building (100 m^3). Heating is favorable for most combinations in a large building, whereas dehumidification is more efficient in small buildings for most combinations of AER and U-value.

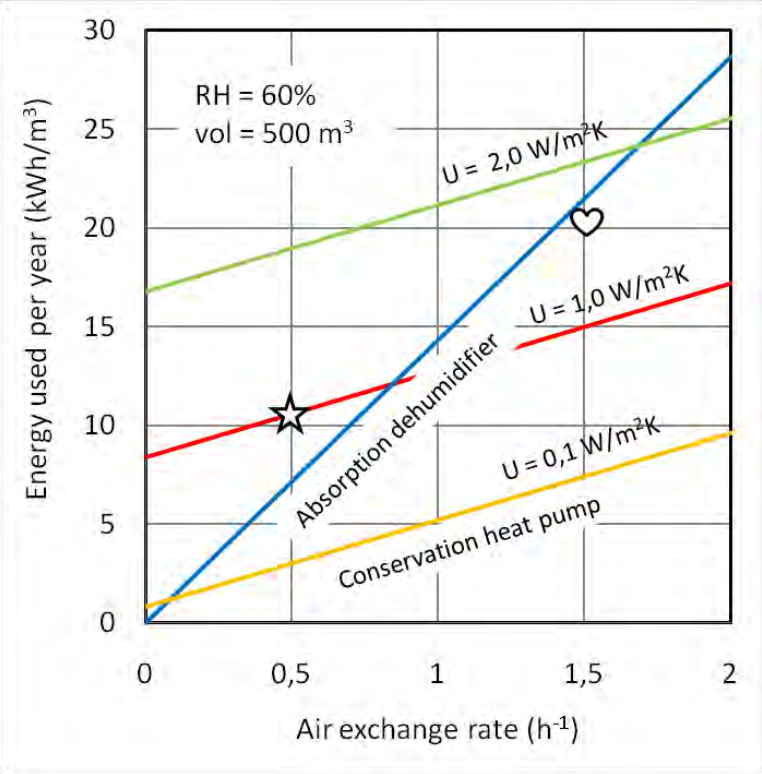

Fig. 1. The energy used per year by two different strategies to control the relative humidity to 60% in a 500m³ building. The calculations were based on monthly statistic data presented in tab. 1. The star represents Kommandørgården and the heart represents Liselund.

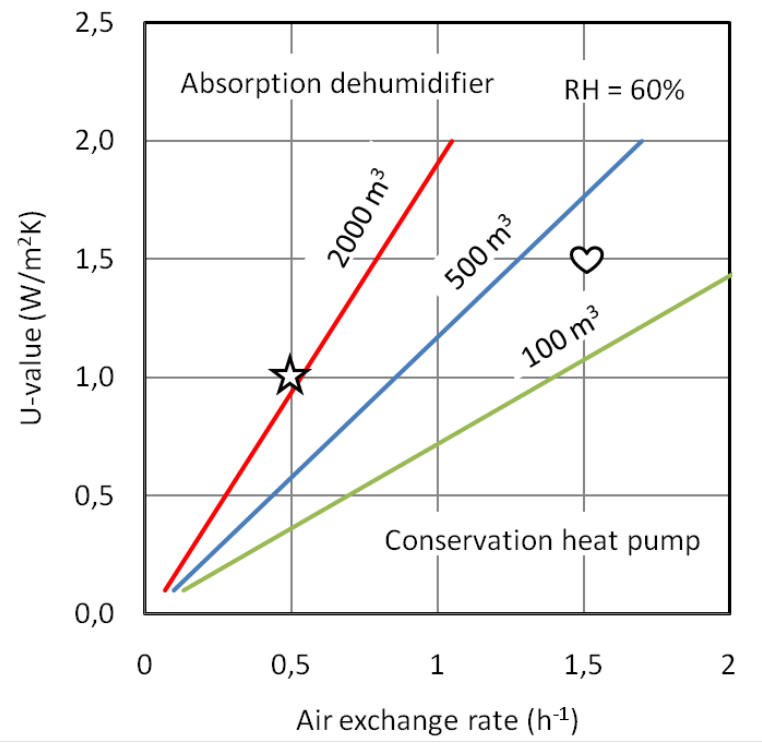

Fig. 2. Lines of equal energy efficiency with dehumidification and heating by a heat pump for controlling the RH to 60%. The size of the building is indicated for each line. The star represents Kommandørgården and the heart represents Liselund.

3. Conservation heating at Kommandørgården

The concept of conservation heating was implemented in Kommandørgården (Fig.3). The traditional farmhouse is located on the island Rømø at the west coast of Jylland, exposed to the strong winds from the North Sea. The building has solid walls of brick masonry with wooden panels or glazed tiles on the inside. The floors and ceilings are wooden planks and the roof is thatched. The average U-value of the walls and ceiling is 1.0 W/m^2K. The volume of the ground floor is 250 m^3. It is used as an open air museum in summer, and climate control is not possible due to the many visitors during the day. In the winter 2006 conservation heating was introduced with portable heating fans in the three main rooms. Each heater was controlled by a hygrostatic switch placed in some distance from the warm air stream. Climate records for 1 January to 1 July 2006 shows that the temperature was raised from 2-3 ˚C to 8-12 ˚C, and the RH dropped from 90% to 65 – 55 % (Fig. 4). The heating was stopped when the museum opened at the end of March, and the RH soon rose back above 80%. The RH dropped to 60-70% again in the two first weeks of May, when the house was heated due to conservation works. This episode shows that conservation heating would be feasible also in the spring.

The air exchange rate in winter was measured by the PerFlour-Tracergas method (PFT) in collaboration with the Building Research Institute (Bergsøe). An inert fluorcarbon gas was emitted at a constant rate to the interior from metal tubes distributed in the rooms. The gas was collected by glass tube samplers mounted in distance from the emission tubes. The amount of gas collected over a 4 weeks period was a measure of the average concentration, which depended on the infiltration of outside air. Usually the procedure should be repeated both in summer and winter to account for the different outside conditions, but in this case the measurement was done only in February, where the AER was 0.5 h^{-1}. This result is plotted with a star in the diagrams in Fig. 1 and 2. From Fig. 2 it seems that dehumidification would be more energy efficient for controlling the RH in winter, and perhaps also in summer if an air lock was installed at the entrance.

4. Dehumidification at Liselund Mansion

Dehumidification has been used for climate control in Liselund mansion, which dates back to 1800. The building is situated at a small pond in a romantic park on the island Møn at the Baltic Sea (Fig. 5). The walls are 50 cm solid masonry and the roof is thatched. The floors are wooden planks and the ceiling is gypsum plaster. The building has large single glazed windows and doors, which take up 25% of the wall surface area. The volume of the basement and the ground floor is 650 m^3 and the average U-value is 1.5 W/m^2K. In summer there are guided tours, but apart from that it remains closed all year.

The RH is controlled by an absorption dehumidifier (Munters) located in the basement. The dry air is distributed with ducts into each room through small grills in the floor. The air is returned though the staircase to the basement. The desiccant is embedded in a revolving unit, which enables the dehumidifier to work continuously. Absorption and evaporation takes place simultaneously from separate segments of the unit. The RH was 55-65% all year, whereas the temperature was drifting from around 0 ˚C in winter to 20 ˚C in summer (Fig. 6). The annual energy consumption for dehumidification was 13 MWH or 20 kWh per m^3 per year. The Air Exchange Rate was not measured, but can be estimated to 1.5 h^{-1} from Fig. 1. The doors and windows are indeed rather leaky, and much energy would be saved by improving the air tightness of these components.

Fig. 3. View of Kommandørgården from the southeast. The traditional farmhouse is located on the island Rømø at the West coast of Jylland close to the North Sea.

.

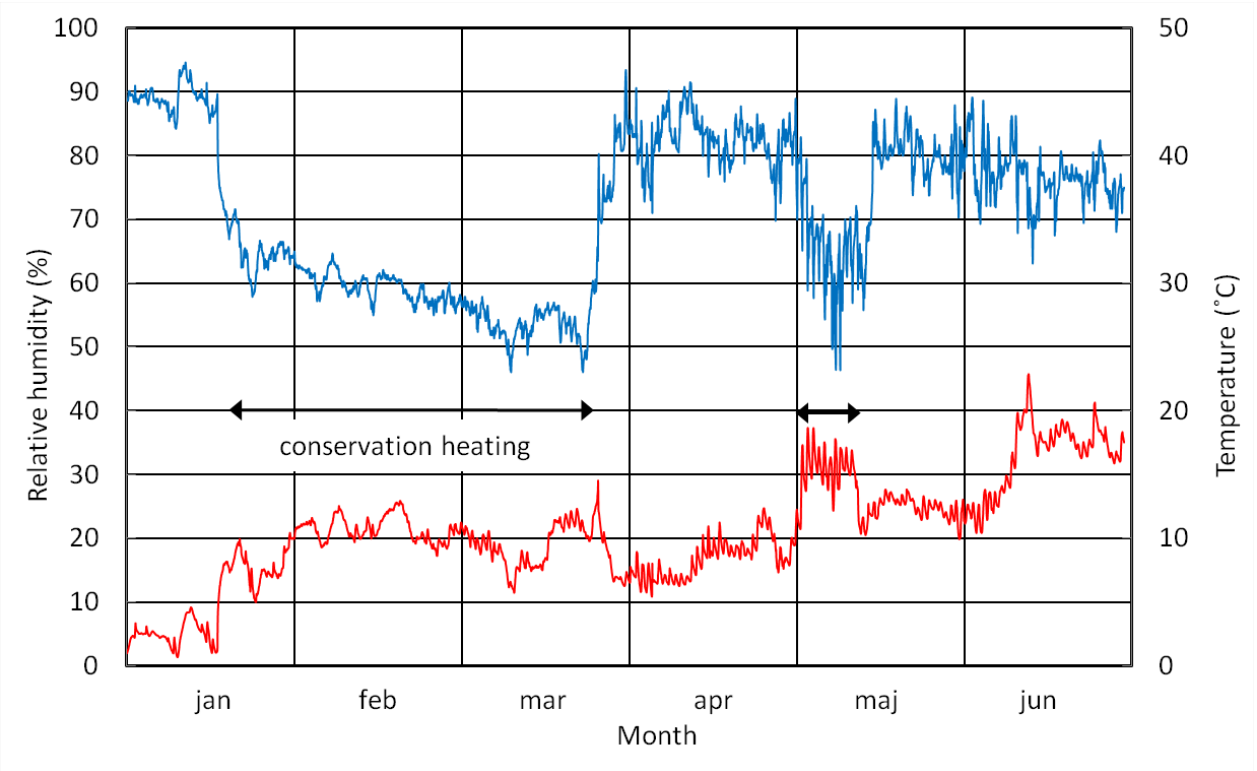

Fig. 4. Indoor climate records from Kommandørgården over six months in the winter and spring 2006. Conservation heating with hygrostatic control to 60% was started in mid January and terminated at the end of March when the museum opened for the Easter holidays.

Fig. 5. View of Liselund Mansion from the southwest. The building is located in a romantic garden on the island Møn close to the Baltic Sea.

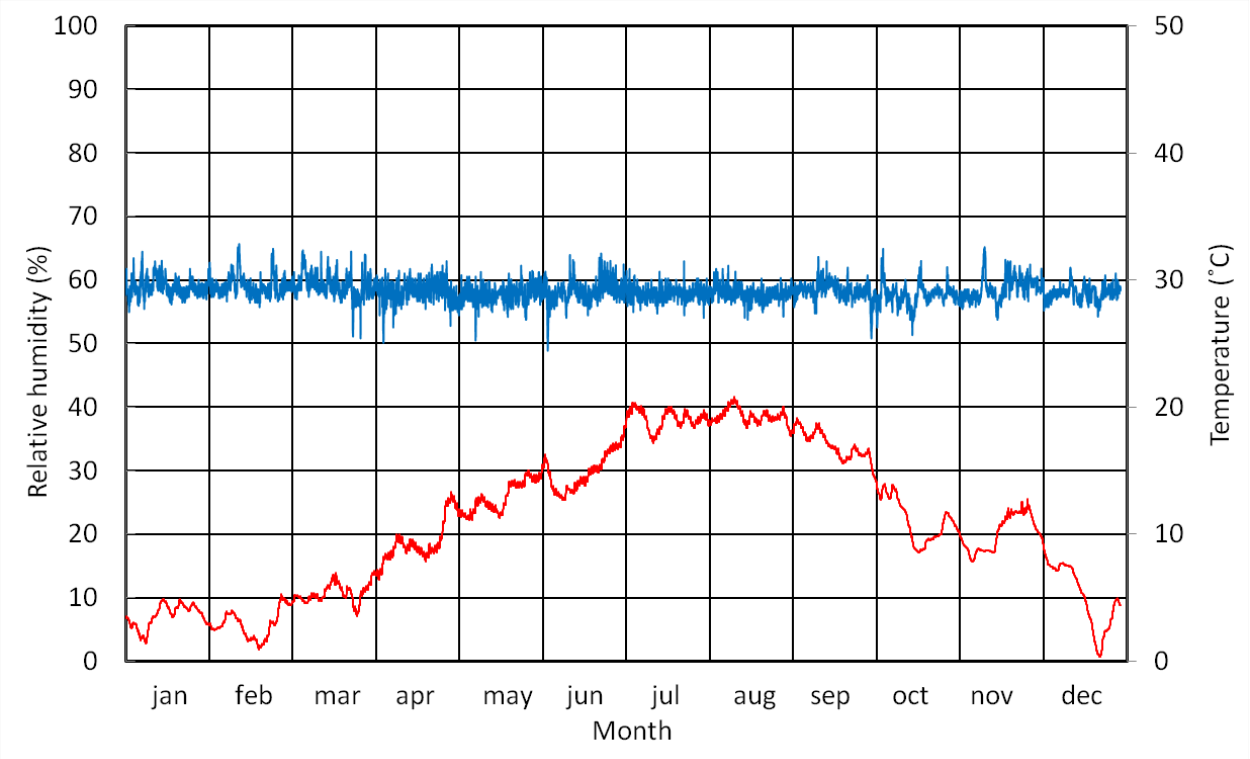

Fig. 6. Indoor climate records from Liselund Mansion in 2009. The relative humidity (RH) was controlled to 55- 65 %RH by dehumidification. The indoor natural temperature variation was 0 – 20 °C due to the influence of the outside temperature.

The combination of U-value and estimated AER is plotted in Fig. 2 with a heart. According to this, conservation heating with a heat pump would be more energy efficient if nothing is done to reduce air infiltration. Another reason for the high energy consumption could be evaporation of moisture from the ground. The basement floor is only slightly above the water level of the pond outside. Such external sources of moisture are not included in the calculations and are a potential source of error.

5. Conclusion

The strategy for climate control in historic buildings depends on whether the house is occupied by humans or not. In many historic buildings, conservation heating has been used to control the RH in winter. But the heat loss is usually large, because historic buildings are leaky and have poor thermal insulation. It is difficult to improve the performance of the building envelope, so the energy source must be efficient. Heat pumps are much more energy efficient than direct electric heating, so this technology may be adapted for climate control. Dehumidification has not been regarded as appropriate for historic building, but better regulation makes this technology an attractive alternative. The paper gives a general method to determine the most energy efficient strategy for humidity control in relation to buildings characteristics. The most energy efficient control strategy is determined by the U-value of the building, the air exchange rate (AER) and the volume. For large buildings, conservation heating with heat pump technology seems to be the most energy efficient, unless the thermal insulation is very poor. For small buildings dehumidification is more efficient unless the building is very leaky. The results are only valid for locations with natural climatic conditions similar to Denmark. Further research will generalize the method and also take into account internal moisture sources as well as other types of dehumidifiers.

Abstract: The use of solar energy in a building of cultural-heritage value is an issue that brings the trade-off between aspects of use and preservation to a head. A sustainable use and preservation of historic buildings requires broad and long term compromises between social, economic and environmental aspects. The objective of the present paper is to present and discuss a decision framework for such compromises regarding the use of solar energy in historic buildings.

Keywords: *Solar energy, Renewable energy, Historic buildings, Cultural heritage*

1. Introduction

The heavier demands that society now places on the efficient management of finite resources in general and energy in particular is bound to have consequences for our ability to use and thus preserve the built cultural heritage. When rising energy prices coincide with people's greater insistence on indoor comfort, all the more historically valuable buildings stand the risk of being insufficiently heated and, ultimately, either abandoned or vulnerable to damp, mould and vermin. Such a trend runs diametrically counter to the goal of long-term use and preservation of these buildings.

The use of solar energy in a building of cultural-heritage value is an issue that brings the trade-off between aspects of use and preservation to a head. On the one hand, solar energy facilitates long-term use as it makes it possible for buildings to be heated with renewable energy at a lower running cost; on the other hand, the visible installations – the solar collectors or solar cells – have a marked impact on their appearance and cultural heritage value. Conversely, while non-installation protects the buildings' cultural-heritage values, in the short term, there is a danger that such a decision will make them less attractive for long-term use and thus limit opportunities for their preservation. Economically and ecologically sustainable heating solutions must therefore be found that make it possible to use the buildings without jeopardising their cultural heritage value.

There is a general agreement that the use of solar energy in historic buildings must be considered carefully. The problem today is that decisions too often are based on relatively short term techno-economic and ecological considerations on one hand and considerations of vaguely defined cultural heritage values, with a focus on aesthetics, on the other hand.

A sustainable use and preservation of historic buildings requires broad and long term compromises between social, economic and environmental aspects. The decision context is multi-disciplinary and decisions are elaborated on the basis of both qualitative and quantitative data. There is therefore clearly a need for a structured approach to the decision-making which minimizes the risk for arbitrary and ad-hoc decisions which will have negative long-term impact on energy use, preservation or, in the worst case, both. The objective of the present paper is to present and discuss a simple decision framework for such compromises regarding the use of solar energy in historic buildings.

The cultural heritage can be seen as a cultural capital not unlike other forms of capital, with the important differences that it is possibly irreplaceable and its societal value is likely to be

higher than its market value[1]. Given this irreplacability, the cultural heritage should be considered a non-renewable national resource that demands efficient and careful management with a long time perspective.

A fundamental consideration when taking a decision on energy saving or energy transition, such as the introduction of solar energy, should thus be whether it will facilitate the sustainable management of the building, taking into account both long-term use and preservation. To achieve this, as with all other aspects of sustainable development, one must act from a perspective that aims to satisfy today's needs without it compromising the opportunities for future generations to satisfy theirs.

This fundamental tenet of the sustainability discourse is, not new. A similar philosophy was espoused by John Ruskin back in 1849 in his *The Seven Lamps of Architecture*, in which he describes older buildings thus: *"They are not ours. They belong partly to those who built them and partly to all the generations of mankind who are to follow us."*[2]

2. Sustainability in cultural heritage buildings

2.1. A model

The following is a development of Kohler's[3] model for sustainability in the built environment, based on the three general dimensions of sustainability. *Ecological values* comprise embedded energy and the resource use of the building. *Economic values* are market value, running costs and revenues. *Social values* are functional values and cultural values. Cultural values are referred to as *cultural heritage values* which in turn are divided into documentary values and experiential values. The objective is not to add to the scientific discussion of these value categories, but rather position them in the overall context of the present paper.

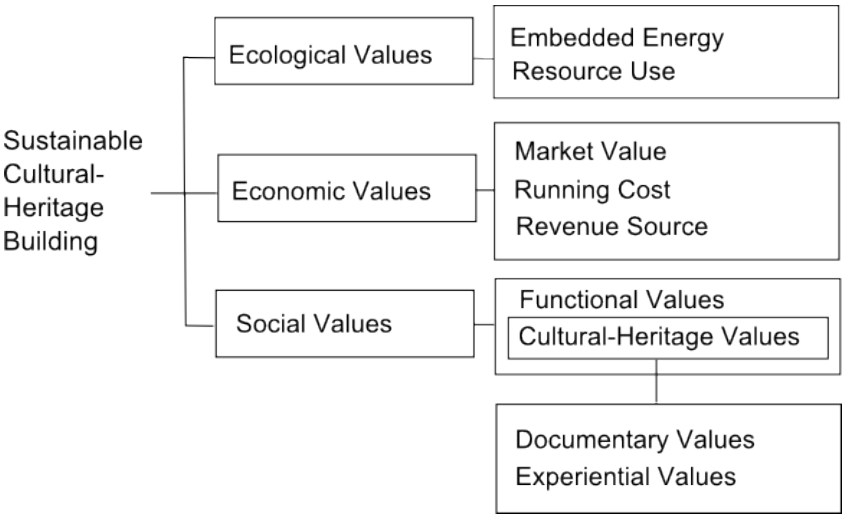

Fig 1: Conditions for sustainable cultural heritage buildings

If we are to achieve a truly sustainable management of buildings, we must take all three categories of values into account. A sustainable approach to the built heritage thus requires showing far-sighted consideration for all value categories, seeking balance between them, and understanding that they are mutually dependent rather than isolated quantities.[1] Such management demands the identification of the built environment's values in order to ascertain how they are affected by change. In the following section the three value categories are discussed in a generic way, with a focus on the dependency between cultural heritage values and the two other value categories.

2.2. Social values

Social values help to promote human wellbeing and can be broken down into functional and cultural-heritage values. All building types embody functional values, which is to say values that help to fulfil people's practical, aesthetic and symbolic needs.

The built heritage also contains cultural values, which, like their functional counterparts, contribute to human wellbeing. However, these latter values can also be of more overarching significance to sustainable development. The Faro Convention defines European cultural heritage as a resource for memory, understanding and identity.

The functional value of a building would generally increase with the use of solar energy. In some building where there are no viable options, for example unheated buildings with moisture problems, the use of solar energy can have a strong positive effect.

Cultural-heritage values can be divided into *documentary* and *experiential* values. The documentary value is associated with the building's function as source material – which on examination and analysis can yield information about the past – and chiefly comprises traditional value criteria based on historical knowledge (e.g. architectural-historical and personal-historical value). Estimating the documentary value of a building or built environment requires a degree of prior knowledge of the observer.

Experiential values are, by definition, more subjective than documentary values, and focus on the architectonic and aesthetic expression of a building or built environment. Experiential values are based mainly on immediately perceivable properties and qualities that thus require no prior knowledge to appreciate. Experiential values include architectonic value, artistic value, patina, environmental value and continuity value.

In the short term, the use of solar energy would have a negative effect on cultural heritage values. It is important to differentiate between irreversible effects on documentary values and reversible effects on experiential values. Ultimately, the fundamental cultural heritage values are dependent on the long term use and preservation of the building and thus on all other values.

2.3. Economic values

The economic aspects that are to be considered for a sustainable building management are market value, running cost and revenue. In addition to that we need to consider communal values related to the building in its context.

The market value of the building depends, of course, on running costs and revenues. Culture heritage values generally have a positive effect on the market value, even though this relation hardly lends itself to be quantified.

Revenue values, through direct utilisation (e.g. entrance fees) or indirect utilisation (restaurants, hotels and dwelling), are affected by culture heritage value in the same way as market values are.

Running costs are usually the main driving force when it comes to energy efficiency measures. High running costs can jeopardise the building's use or maintenance, which can lead to disrepair and dilapidation. This can reduce its value as a building as both its functional and market value are brought down, which, in the long run, will impact on its cultural-heritage value.

On being classified as "cultural heritage", a building undergoes a process of commoditisation to become a product, by which is meant an item or phenomenon possessing economic value. The "cultural capital" of a town or region has become an important resource in the scramble to attract desirable businesses and consumers with purchasing power, competition in which cultural heritage is exploited as a product around which the image and character of the area can be assembled. Such marketing also enables a property owner to use a building's cultural-heritage values in order to offer business and residential space that appear more attractive than offices and houses lacking such value.[4] Cultural-heritage values can thus be a factor that boosts the market value of a building, but if the building, by virtue of such a classification, is granted legal protection, the effect can be the opposite in that its market value drops.[5] It is not only the owner of such a building who can profit from its cultural heritage status; since property prices are location-bound and thus determined, for example, by the qualities of the cultural heritage environment, neighbouring buildings can also benefit. A change in the qualities that characterise an environment can thus impact upon the market value of other buildings in the vicinity.

That the market value of a built environment increases by virtue of the experiential values to which other buildings of cultural-heritage value give rise can therefore be seen as an externality, i.e. a side-effect that is of benefit to a third party. The built heritage can also generate other kinds of externalities, such as tourism, jobs and regional development[5], and in so doing contribute to national economic growth. In this way, the building, even if privately owned, can serve as a kind of collective utility and thus as something that benefits the wider community.[6]

2.4. Ecological values

Part of the ecological value is the embedded energy. The building is a non-renewable resource that, like other non-renewable resources, should be managed efficiently and carefully. Existing buildings can be seen as ecological capital comprising different type of construction materials, the consumption needs of which can be limited by their preservation, maintenance and continuing use. This also reduces the need for energy-demanding newbuilds.

The other part of the ecological values is related to the use of energy and other resources. Prudent energy efficiency measures can make this kind of building more energy efficient as well, and thus increase its value as a resource for sustainable development.

The use of non-renewable resources would in most cases decrease with use of solar energy, adding to the ecological value. More importantly, a sustained use of the building would make a continued use of the energy embedded in the building.

3. The impact of solar energy installations on a buildings values

A decision to introduce solar energy is usually motivated with an expected increase in the building's economical, ecological or functional value. At the same time, the installations risk damaging the cultural-heritage value of the building and/or its surroundings which in turn could have an effect on the other values.

A decision not to introduce solar energy has the least impact on the cultural heritage value, in the short term. However it will reduce the ecological values. More important is that a non-decision in the long term may reduce economic and functional values even to the point where it might eventually threaten the use and condition of the building and thus also more fundamental cultural-heritage value.

This line of reasoning sheds light on two aspects of the point at issue: firstly, the various value categories are, in different ways and to different degrees, interdependent, which means that the preservation or reinforcement of all value categories is a decisive factor in achieving the goal of long-term use and preservation of the built heritage. Secondly, it shows how vulnerable the value categories are to mutual conflict. The decision-making process therefore demands of the various actors involved an ability to take judicious decisions that can help to optimise the preservation of the different values of the building or the built environment. Looking solely to the cultural-heritage values in such a situation, for example, can ultimately damage opportunities for a building's long-term use and preservation, which can have a knock-back effect on its cultural-heritage value. Decisions on energy measures for buildings of cultural-heritage value therefore require a conscious and insightful balance of priorities between the various value categories of the building in question.

4. Risk assessment

Having identified the various values of a building, a risk analysis can be made in order to assess the short and long-term effects of a proposed change on all the value categories. A similar analysis should also be conducted on the basis of a no-installation scenario in which no change is made.

A simple risk-benefit matrix, see Fig 2, can be used to identify different types of problems. In cases with a low benefit or a high risk, marked in red, one should be restrictive. Low risk and high benefit, marked in green, is generally a win-win situation. Cases involving medium risk and medium to high benefit, marked in yellow, would probably need more attention.

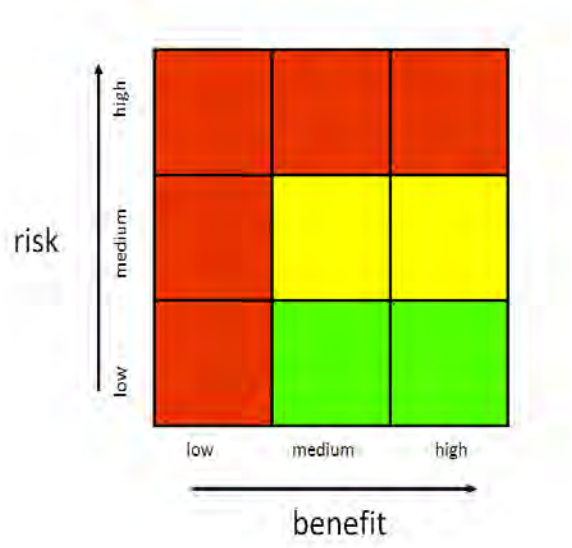

Fig 2: A matrix for a risk – benefit analysis

5. Two generic examples

5.1. A medieval church.

From a technical point of view, the steep and large south facing roof are a good place for solar collectors or solar cells, see fig 3. Depending in the alternatives, the use of solar energy adds to the ecological value in most cases. Depending on the investment, there might also be an economic value added in a lower energy cost. The visible impact would be considerable

and, for most people, have a negative effect on the experiential cultural heritage value of the church as well as its surroundings. The document value of the building need not necessarily be affected, if installations are made in a careful and reversible manner.

If solar cells are used to produce electricity for the grid, one should consider the option of producing electricity somewhere else. If this is an option, the only benefit of installing solar cells on the church roof would be an added symbolic value, allowing the church to make a green statement. Thus there is a low or medium risk and small benefit.

In the case of a church with moisture problems, mould is a common, solar panels could be used for conservation heating. This would add to, or at least secure, the functional value as mould may render a building unfit for use. In the long term, the use of the building is the most important factor for a sustained preservation of the building and it's cultural heritage values. Here, the use of solar heating would have a positive and maybe decisive effect on the functional and cultural heritage values of the building. Thus there would a high benefit, and a low to medium risk.

Fig 3 An illustration of the examples, a medieval church and the roofscape of Visby

5.2. A hotel in a World Heritage town.

The Hanseatic town of Visby on the island of Gotland is a world heritage site:

> "A former Viking site on the island of Gotland, Visby was the main centre of the Hanseatic League in the Baltic from the 12th to the 14th century. Its 13th-century ramparts and more than 200 warehouses and wealthy merchants' dwellings from the same period make it the best-preserved fortified commercial city in northern Europe."[7]

A small family hotel situated in the Visby wants to use solar energy to produce hot water in the tourist season. The main building has a large south facing roof well suited for solar collectors, but it is also well visible to the public. The use of solar energy would add to the ecological value in most cases. The added economic value is significant since any other option would give a high investment in relation to the short period of use. The building itself is ordinary, the risk is associated with the visible impact on the roofscape of the city, se fig 3. As the installation would be visible Visby has a lot of visitors, the overall effect on the experiential value would be high. In the long term, extensive solar energy installation could have a negative effect on tourism, thus reducing the economic viability of both the hotel and the city. Thus we have both a high risk and high benefit. A more depth investigation of this case should focus on optional solutions, either finding a less visible location for the solar collectors or another source of energy.

6. Closing discussion

The management of the built cultural heritage should strive to ensure its posterity to future generations. Since the value categories of buildings are mutually dependent, long-term use and preservation require a management process that takes their economic, ecological and social values into consideration.

It is thus impossible to provide a general answer to the question of whether the installation of solar energy technology should be considered a measure that contributes to the long-term use and preservation of a building of cultural-heritage value, or whether it constitutes a threat to the cultural-heritage values that make the building or the built environment worth preserving in the first place. This is a judgement call that must be made on a case-by-case basis by weighing the potential risks and benefits (fig. 4). Should the risks be deemed relatively high, installation should not proceed. Conversely, if the benefits are relatively high, installation can be considered appropriate. However, the most problematic cases arise when both the risks and benefits of solar energy are equally high. These cases require a thorough impact analysis to ascertain the best action to take in the interests of long-term use and preservation.

Much of the debate around solar energy and built heritage concerns individual cases. A challenge for the future is to seek a more coordinated, inter-sector planning and decision-making process based on a holistic view of the built environment. Such a process should take account of all the value categories represented in the building in question and the environment in which it stands. Involving all concerned parties at an early stage of the process and identifying all values makes it possible to create a planning and decision-making process with clear allocations of rights and responsibilities. This, in its turn, will enable an assessment of the positive and negative consequences an installation might have for the various value categories, and thus of which decision creates the most favourable opportunities for the sustained use and preservation of the building and the built environment.

Abstract: Energy use in the building stock represents a major contribution to the total energy use in developed countries. Increasing limitations to the energy demand of the new buildings have been imposed by the building codes in the last decades, which resulted in improved building envelopes.
Yet, in many cases it is not either technically or economically feasible to improve the existing building shells. A typical example is represented by historical buildings, such churches and old buildings, which often may not be improved for aesthetical or economic reasons. Often poorly insulated, such buildings would require a high energy demand to keep them at the preferable hygro-thermal conditions. As a consequence they are often left unheated, which also affects the usability of these buildings. However, the risk of moisture damage often requires them to be slightly heated to a certain temperature.
As the energy demand is linked to the possibility of improving the building shell, for instance by adding insulation or making it more airtight, the exergy approach gives interesting insights on the problem. Exergy analysis emphasizes the thermodynamic valuable part of the energy demand in the building and straightforwardly defines the minimum energy demand for a certain process. The energy demand being equal, it is still possible to lower the exergy demand and consumption. A lower exergy demand paves the way to the exploitation of renewable sources, such as solar power.
Often the main task is to keep the RH humidity within a certain range. Aim of this paper is to perform a theoretical exergy analysis of three different solutions for lowering the RH in the building. The basic approach keeps the temperature of the indoor space at a constant level. A second approach-the so-called conservation heating- consists in letting the temperature vary according to the maximum allowed indoor relative humidity. In the third case the target is reached by means of a dehumidification process. Advantages and disadvantages of the different approaches are shown under the energy and exergy points of view.
The present research is done within the framework of the "Spara och bevara" project, which targets cost-efficient solutions for the conservation and the use of heritage buildings in Sweden and the IEA Annex49 and ESF COSTexergy projects, which aim at energy-efficient buildings and communities through the application of the low-exergy approach.

1. Introduction

In European countries, residential and commercial buildings are the sector with the largest share of primary energy use, 25% (1) and a relevant share of that is supplied by fossil fuels. The reduction of the energy demand and the exploitation of renewable energy sources has then become a priority in the EU political agenda. A widely used approach to reduce the energy demand in buildings is to improve their thermal insulation. While cost-effective during the construction phase of the building, this approach is expensive in existing buildings and alternative strategies should then be applied. The reduction of the quality of the energy supply in buildings is recognized as beneficial to reduce the environmental impact due to the energy use in buildings. An effective tool to quantify the quality of energy is exergy.

The IEA ECBCS Annex 37 (2) and the IEA ECBCS Annex 49 (3) showed that a great potential for improving the energy use in buildings resides in lowering the energy quality, i.e. the exergy, in buildings. A relevant share of the energy demand is represented by space heating and domestic hot water, (4) and (5), which is energy with low quality; buildings have a high energy demand but a low exergy demand. In contrast to this they are often supplied with valuable energy sources, such as direct electricity heating and gas. The exergy analysis applied to buildings explains how to use the energy in a more rational way by reducing the exergy losses, i.e. the energy quality mismatch between sources and end-use energy. This reduction can be obtained by supplying the building demand with degraded forms of energy, such as waste and low-temperature heat, that would be unsuitable for high-exergy processes, which occur for example in industry and transportation.

The application of the low exergy approach benefits also the exploitation of renewable sources. Renewable energy supplies have often low specific power. So-called low-exergy systems are systems with low temperatures and therefore low specific power. A floor heating, for instance, has low emission temperatures and lower emission power per unit area than radiators. It is therefore suitable for low supply temperatures, i.e. low exergy supply, such as energy from ground heat storages or from solar panels.

Optimized low-exergy systems need to be integrated and require a holistic approach. A prerequisite to an improved use of energy is to perform an exergy analysis of the system demand to highlight what is the potential for improving the overall system. In the present paper, exergy analysis was applied to the specific case of the historical buildings.

In such buildings the control of the relative humidity, RH, is important to decrease the risk of formation of mould and condensation. The lowering of RH can be obtained by heating, i.e. increasing the temperature of the air, or by dehumidifying, i.e. decreasing the water vapor contained in the unit mass of air. A common process in dehumidification consists in decreasing the air temperature needs below the dew-point, to condense the water vapor, and then to reheat it, thus making the process energy demanding.

Aim of this paper is to explore the potential for the reduction of the relative humidity. Three different approaches have been chosen and analyzed exergy-wise in two different Swedish locations.

2. Methodology

Exergy is defined as the maximum work that can theoretically be extracted by a device working between two states in non-equilibrium. When temperature, pressure and chemical composition are the same as the surroundings, thermodynamic equilibrium is reached and no more work can be extracted. These conditions are called dead-state. For buildings, the surroundings are represented by the environment and the dead-state conditions, often called reference conditions, are represented by environment temperature, pressure and chemical composition. In buildings exergy analysis the chemical composition regards the moisture content of the air, which some studies have shown to affect in a relevant way the exergy calculation, especially in warm and humid climates, (6) and(7).

In the present paper, exergy analysis has been applied to the three strategies for reducing the risks of condensation in historical buildings. An upper limit of 70% RH has been considered safe in this paper, following the approach used in (8). The building has been modeled into indoor room space and outdoor environment, whose conditions represent the so-called reference state.

To reach certain set-point conditions of the indoor air, a flow of exergy has to be supplied. The minimum flow needed is determined by the physical conditions of the unit air, i.e. the exergy content per unit mass. The minimization of the exergy content is the necessary prerequisite to the decrease of the exergy demand. The air exergy content resulting from the different strategies to lower the RH has then been compared. This approach allows to keep a general approach that can be applied to several types of buildings and also to benchmark the expected performance of the different strategies in terms of exergy.

Two different Swedish locations have been simulated, Gothenburg and Östersund. Gothenburg is located on the southwest coast of Sweden (latitude 57º43´) and it has a coastal climate with high RH most of the year. Östersund is located in the middle of Sweden (latitude 63º) and it has an inland climate, considerably colder than Gothenburg.

The first strategy is the background heating, which consists in keeping the indoor temperature at 12 ˚C by providing heat to the room. If the ambient temperature is higher than this set-point temperature, the building is left unheated.

The second strategy is the so-called conservation heating, which consists in the use of heating to keep the internal humidity under a certain level above which the risk of mould formation is considered to increase consistently. This target relative humidity, which in this paper is set to 70% (8), is kept by raising the indoor temperature. As the temperature increases, the saturation pressure of the water vapor decreases, i.e. the air is capable to dilute more vapor, and so does the relative humidity decreases. When the indoor RH was higher than the 70% set-point, then the indoor temperature was set to the value corresponding to this RH set-point, by calculating the saturation pressure of the vapor. When the RH was lower than the RH set-point, no change in the indoor temperature took place.

In the third case, the target relative humidity is kept to 70% by dehumidification. This process is usually done by decreasing the temperature of the air under the dew-point, condition at which the water contained in the air starts to condense. By removing it and post-reheating it the air becomes drier. The exergy content in an ideal dehumidification process (9) was calculated when the RH was higher than the 70% set-point.

In the second and the third strategy, indoor thermo-hygrometric conditions have also been investigated for two different levels of internal moisture generation, $\Delta v=1$ g/m^3 and $\Delta v=2$ g/m^3, with Δv (g_{vapor}/m^3_{air}) being the humidity added from the building structure.

In the Table 1 a summary of the set-points for RH and temperatures are shown for the different strategies.

Table 1: Summary of temperature and RH set-points in the different strategies. The temperature in the constant temperature heating is kept at 12˚C or higher in warmer seasons. In the conservation heating strategy, the values of the internal temperature depends on the relative humidity. In the dehumidification strategy, the temperature in the room is the same as the environment.

Strategy	Room set-point temperature [˚C]	Room set-point RH [%]
Constant temperature heating	12	-
Conservation heating	Dependent on RH	70
Dehumidification	-	70

The expressions for the calculations of the specific exergy have been derived from (7) and (9):

$$Ex_{s,th} = \left(c_{p_a} + \omega_i c_{pv}\right) T_0 \left(\frac{T_i}{T_0} - 1 - \ln\left(\frac{T_i}{T_0}\right)\right) \quad (1)$$

$$Ex_{s,ch} = R_a T_0 \left(\left(1 + 1.608\omega_i\right) \ln\left(\frac{1 + 1.608\omega_0}{1 + 1.608\omega_i}\right) + 1.608\omega_i \ln\left(\frac{\omega_i}{\omega_0}\right)\right) \quad (2)$$

In the equation (1) $Ex_{s,th}$ is the thermal specific exergy, T_i is the ambient temperature, T_0 is the environment temperature and c_p is the specific heat capacity of the air. In the equation (2) $Ex_{s,ch}$ is the chemical specific exergy, R_a is the ideal gas constant for air, T_0 is the environment temperature, 1.608 represents the molar mass of air to that of water vapor, ω_i is the humidity ratio of the room and ω_0 is the humidity ratio of the environment. The air exergy content of the three different strategies have been calculated with time-steps of 1 hour for a whole year. This simplified model doesn't take into account the moisture storage in the structure; the structure itself acts as a constant moisture generator (Δv=1 and Δv=2 g/m^3). The exergy calculated in each time-step is then the exergy needed to keep the air in conditions of temperature and humidity considered safe to avoid condensation and mould growth.

3. Results

In Figure 1, the average monthly values of the temperature and the relative humidity, derived from the hourly calculations, are displayed. The temperatures are plotted for all the analyzed cases; the simulations of the conservation heating strategy are shown for the different Δv (cases 2a, 2b and 2c). The RH is the same in all the simulations of the case 2 due to the RH control strategy. The environment RH is above the 70% limit for most of the year. The constant temperature heating strategy (Case 1) has an indoor temperature constantly set to 12 ˚C, except in summertime, when it is higher. This strategy decreases the moisture to very low levels in winter time, which is not a favorable condition for artworks possibly present in this type of buildings. In the conservation heating strategy (Case 2) and dehumidification (Case 3) the RH indoors is in the range between 60 and 70% during the whole year, due to the control of the humidity. The indoor temperature of the dehumidifying case is the same as the outdoor temperature, while the case of the conservation heating case it is slightly higher when a decrease of the RH is needed.

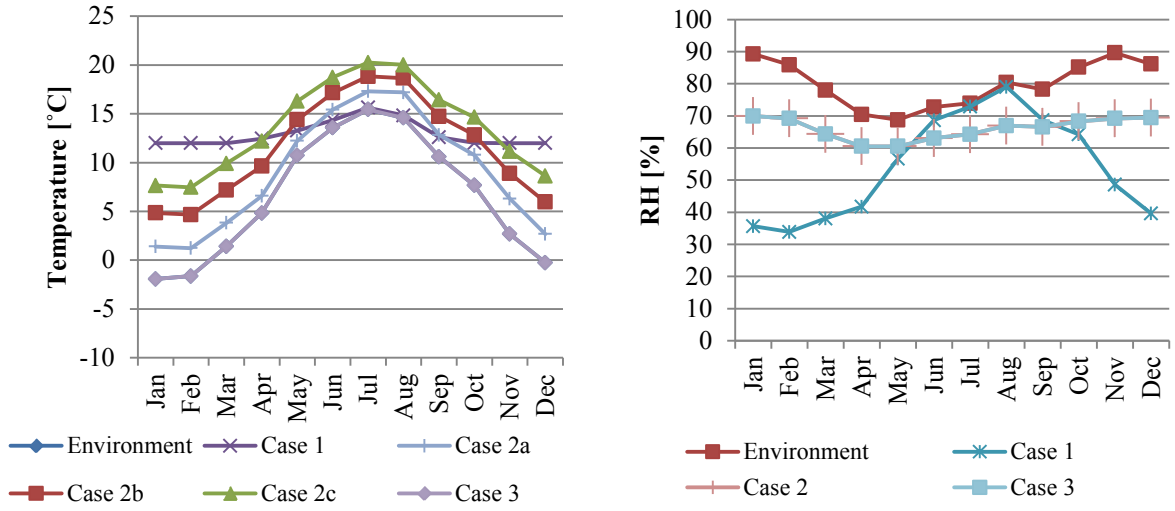

Figure 1: Monthly temperature distribution (left) and relative humidity RH (right) in the three cases in the Gothenburg simulations. Case 1 is the constant temperature heating, Case 2a is the conservation heating for Δv=0 g/m³, Case 2b for Δv=1 g/m³, Case 2c for Δv=2 g/m³ and Case 3 i s the dehumidification.

In the Figure 2 results from the calculations for Gothenburg are presented. The exergy content for three different cases, sum of the time-steps for εαch month, iσ σhown. For Δv=0 g/m^3, the exergy content in the air is significantly lower for the conservation heating and dehumidification strategies in the cold period of the year, when compared to the constant temperature strategy. In fact, in the January average conditions with an environment temperature of -1.9 ˚C and RH of 89 %, the temperature necessary to keep the RH under 70% is 1.5 ˚C. By hεαting up to 12 ˚C the RH falls to 34%, which is a low level of moisture in the air at the expense of a great exergy content.

The exergy content increases for both constant heating and dehumidification strategies αsΔv increases, due to the higher temperatures that must be reached in the room to decrease the relative humidity for the conservation heating and to the greater potential of chemical exergy in the dehumidification case. Yet, in the period between December and February the exergy content of the constant temperature heating is the double of the conservation heating with Δv=2 g/m^3.

In the warm season, i.e. from May until September, the exergy content of the constant heating gradually decreases, due to the increasing environment temperatures, but the relative humidity of the room in these conditions is higher than the limit value of 70%.

In the warm season the exergy content of the conservation heating and the dehumidification αpproach iσ comparαblε for the diffεrεnt valueσ of Δv. Howεver, the εxεrgy contεnt of the αir in the conservation heating cases becomes remarkably higher in the cold months, from December to March, when the environment relative humidity has the highest yearly peaks.

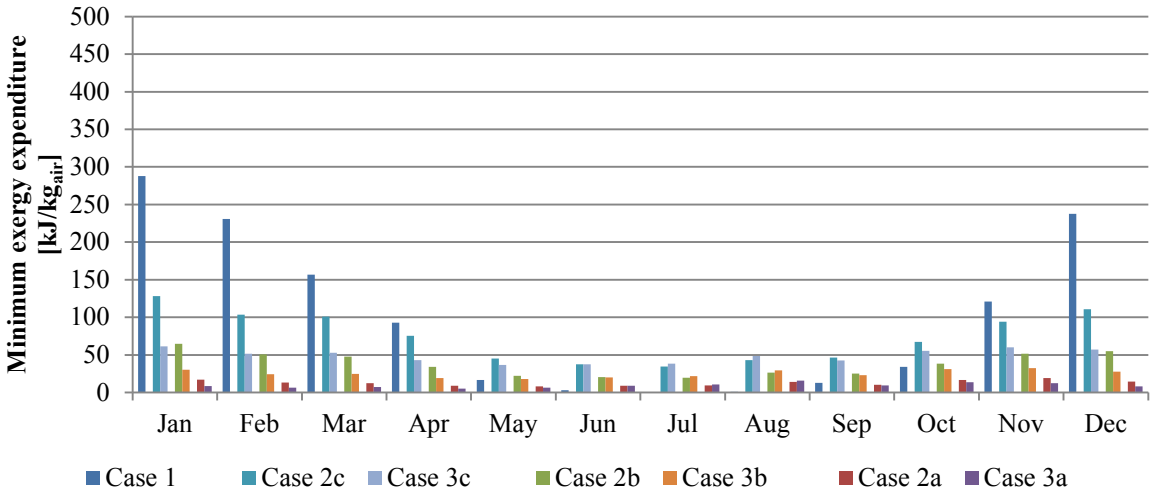

Figure 2: Comparison of the minimum exergy expenditure per kg of indoor air, in the Gothenburg climate. The air exergy content is the sum of the values calculated for each time-step. Case 1 is the constant temperature heating, Case 2a is the conservation heating for Δv=0 g/m^3, Case 2b for Δv=1 g/m^3, Case 2c for Δv=2 g/m^3, Case 3a is the dehumidification for Δv=0 g/m^3, Case 3b for Δv=1 g/m^3, and Case 3c for Δv=2 g/m^3.

In Figure 3, average monthly temperatures are shown for Östersund, together with the average values for the monthly temperatures for RH. The temperature patterns are similar to the ones obtained for the Gothenburg climate, but the minimum average temperature is lower (-5.9 in February) than in Gothenburg (-1.9 in January). The relative humidity is also lower: the yearly average RH in Östersund is 74.8% while in Gothenburg is 79.9%. This makes it possible that all the three approaches keep the average value of the RH under the 70% limit value. The temperature difference between environment and room in the cold period is greater than 15 ˚C in four months for the constant temperature heating case, causing the RH of the room to drop down to values in the range of 20-30%. The range of RH for the conservation heating and the dehumidification are within 60% and 70% during the whole year, which is an ideal condition.

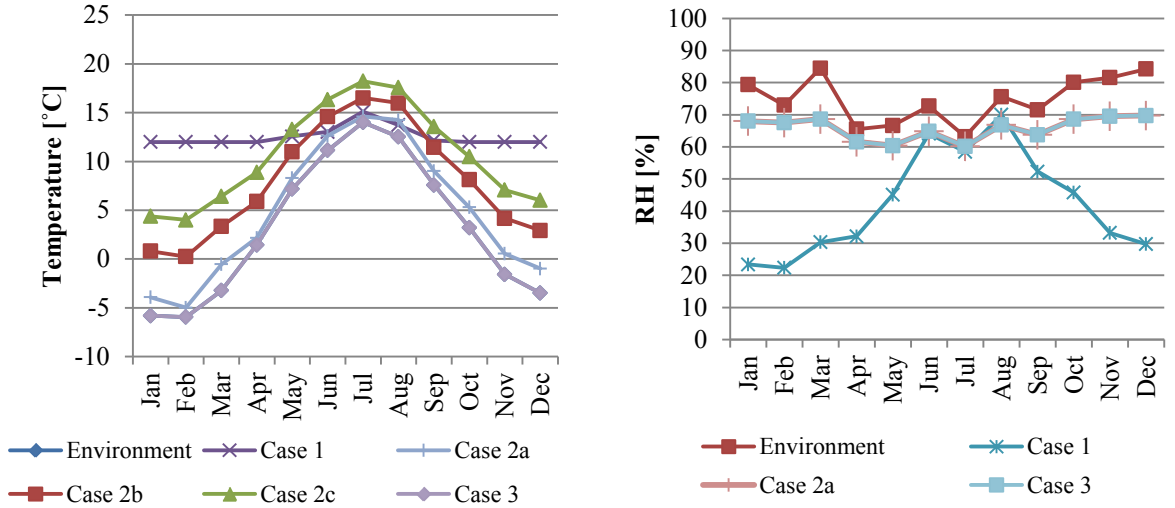

Figure 3: Monthly temperature distribution (left) and relative humidity RH (right) in the three cases in the Östersund simulations. Case 1 is the constant temperature heating, Case 2a is the conservation heating for Δv=0 g/m3, Case 2b for Δv=1 g/m3, Case 2c for Δv=2 g/m3 and Case 3 is the dehumidification.

In Figure 4, the exergy content of the room air in the different cases is shown for Östersund. In the cold season from October to March, the constant temperature heating approach has an exergy content three times higher than the conservation heating and ten times higher than the dehumidification with $\Delta v=2$ g/m^3. The increase of Δv has a relevant effect on the increment of exergy content both for the conservation heating and dehumidification strategies. Similarly to the Figure 2, the exergy content is significantly lower in the cold season in the dehumidification when compared to the conservation heating, while in warmer season there is little difference between the two strategies.

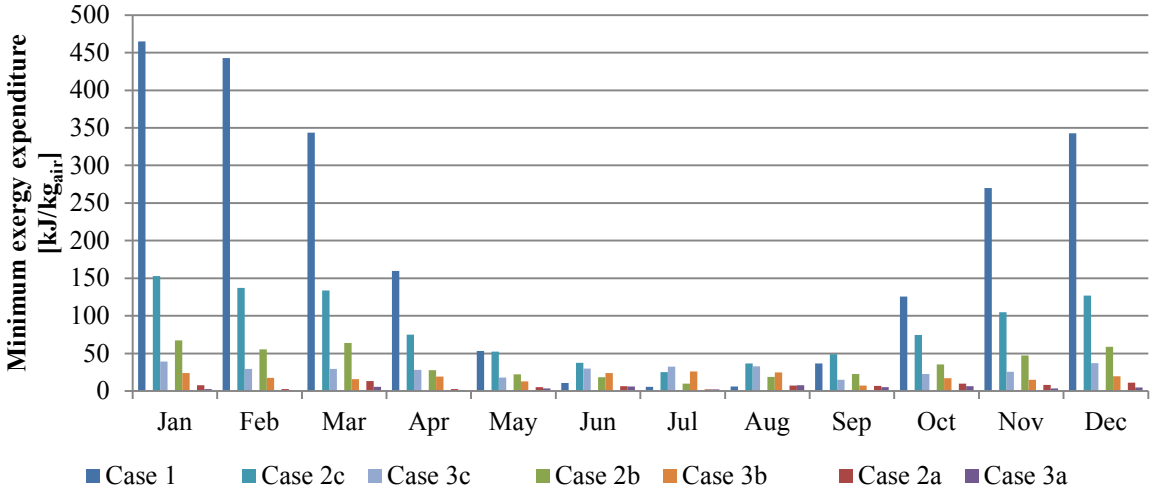

Figure 4: Comparison of the minimum exergy expenditure per kg of indoor air, in the Östersund climate simulation. The air exergy content is the sum of the values calculated for each time-step. Case 1 is the constant temperature heating, Case 2a is the conservation heating for $\Delta v=0$ g/m^3, Case 2b for $\Delta v=1$ g/m^3, Case 2c for $\Delta v=2$ g/m^3, Case 3a is the dehumidification for $\Delta v=0$ g/m^3, Case 3b for $\Delta v=1$ g/m^3, and Case 3c for $\Delta v=2$ g/m^3.

4. Discussion

For both Gothenburg and Östersund, some general trends can be highlighted.

- In the cold season the temperatures reached in the constant temperature approach are too high, causing both the RH to decrease too much, and at the same time the exergy content to increase significantly. In the warmer period it is ineffective in maintaining the RH under the 70% limit in one of the two cases analyzed (Gothenburg).

- The increase of the internal moisture generation Δv decreases the advantage of the conservation heating and dehumidification strategies on the constant temperature heating, due to the higher temperatures that must be reached in the room to decrease the RH and the higher moisture exergy content.

- The dehumidification approach has a significantly lower exergy content in the cold months, when compared to the constant temperature and the conservation heating approach.

- In warmer months, the difference of the exergy content between conservation heating and dehumidification is minimal

5. Conclusions

In the present paper the exergy concept has been applied to explore the potential energy savings to limit th e relative humidity of the air, which plays an important role in the preservation of historical buildings. Three different strategies have been simulated in two different locations in Sweden, Gothenburg and Östersund.

Constant temperature heating has proved to be inefficient and not efficacious at the same time. This strategy is not able to limit the RH under the target values and it consumes unnecessary exergy in cold periods due to the large temperature difference between the environment and the room.

In the conservation heating approach, the temperature differences between environment and room are approximately constant during the year, also with increasing Δv. This feature is very important when a heat pump is used. The coefficient of performance (COP) of a heat pump is highly dependent on the difference of temperature between condenser and evaporator, $\Delta T_{c\text{-}ev}$. The smaller the $\Delta T_{c\text{-}ev,}$ the higher is the COP of the heat pump, which makes this strategy attractive for the building heritage.

Abstract: The correct selecting of typical meteorological year is an important factor for accurate building energy simulation. In this study, the Sandia method has been applied to prepare the new TmyCreator software for selecting the proper data as the typical meteorological year (Tmy2). Also, the results of this new software have been compared with the available Tmy2 weather data file for two cities. It is found that, the results of TmyCreator software have good agreement with the old created Tmy2 weather data file for these cities.

Keywords: Typical meteorological year; Building energy simulations; Finkelstein–Schafer statistics

1. Introduction

The weather data is the most important factor for building energy simulation software. The hourly data of meteorological parameters such as solar radiation, dry bulb temperature, relative humidity, wind speed, atmospheric pressure and etc are usually needed to simulate building energy.

Many methods have been suggested to provide the typical meteorological year. Typical meteorological year has been presented in different types for examples Tmy2 (NREL 1995) and WYEC2 (ASHRAE 1997) in the United States and Canada and TRY (CEC 1985) in the Europe. The Tmy2 and WYEC2 typical weather years contain more solar radiation and illumination data than older formats such as Tmy (NCDC 1983), WYEC (ASHRAE 1985) and TRY (NCDC 1981).

From 1970 to 1983, Ashrae commissioned three research projects to represent weather year data for energy calculations (WYEC), which used the TRY format but included solar data (measured data, if available or calculated based on cloud cover and type). In the early 1990s, Ashrae began to update the WYEC data set. New WYEC data sets were listed in Tmy format, and calculated hourly illuminance data, data quality as well as source flags, were included [1].

Typical meteorological year has been obtained in various types and for different cities in the earth's surface. Apple L.S. Chan [2] reviewed various types of typical weather data sets in a paper and then the Finkelstein–Schafer statistical method applied to analyze the hourly measured weather data of a 25-year period (1979–2003) in Hong Kong. A. Kalogirou [3] presented the generation of a type 2 typical meteorological year (Tmy2) for Nicosia, Cyprus. Also, Joseph. C. Lam [4], Zhang Qingyuan[5] and T. N. Anderson[6] in the different researches, provided the various typical meteorological years based on different year periods and in many places of the Earth's surface. The author (A. Ebrahimpour[7]) in previous research, created the typical meteorological year data from the measured weather data of a 14-year period (1992–2005) in Bandarabass using Sandia method [8].

In spite of this fact, the majority energy simulation softwares use typical Meteorological Year, so the exact values are necessary in order to correct estimation of the building energy consumption

at the year. In this study, the Sandia method [8] has been used to create the TmyCreator software. Using the TmyCreator software, the typical meteorological year can be select from the measured weather data of a available year period (such as 1961–2010) in a city. The result of TmyCreator software has been compared with the available Tmy2 weather data file for various cities such as Salt Lake City.

2. Sandia method

The Sandia method is an empirical approach that selects individual months from different years of the period of record. For example, in the case that contains 30 years of data, all 30 Januarys are examined and the one judged most typical is selected to be included in the Tmy. The other months of the year are treated in a similar manner, and then the 12 selected typical months are concatenated to form a complete year. Because adjacent months in the Tmy may be selected from different years, discontinuities at the month interfaces are smoothed for 6 hours on each side. The Sandia method selects a typical month based on nine daily indices consisting of the maximum, minimum, and means dry bulb and dew point temperatures; the maximum and mean wind velocity; and the total global horizontal solar radiation. For each month of the calendar year, five candidate months with cumulative distribution functions (CDFs) for the daily indices that are the closest to the long-term CDFs are selected. The CDF gives the proportion of values that are less than or equal to a specified value of an index. Candidate monthly CDFs are compared to the long-term CDFs by using the following Finkelstein-Schafer (FS) statistics for each index.

$$FS = (1/n)\sum_{i=1}^{n} \delta_i \qquad (1)$$

Where, δ_i is absolute difference between the long-term CDF and the candidate month CDF at xi and n is the number of daily readings in a month.

Because some of the indices are judged more important than others, a weighted sum (WS) of the FS statistics is used to select the 5 candidate months that have the lowest weighted sums. The weighting factors listed in Table 1 for Tmy type.

$$WS = \sum w_i FS_i \qquad (2)$$

Where, w_i is weighting for index and Fs_i is *FS* statistic for index.

All individual months are ranked in ascending order of the WS values. A typical month is then selected by choosing from among the five months with the lowest WS values the one with the smallest deviation from the long-term CDF. In Hall's original method, persistence structures characterized by frequency and run length of days are included. The persistence of mean dry bulb temperature and daily global horizontal radiation are evaluated by determining the frequency and run length above and below fixed long-term percentiles. For mean daily dry bulb temperature, the frequency and run length above the 67th percentile and below the 33rd percentile are determined. For global horizontal radiation, the frequency and run length below the 33rd percentile are also determined. The persistence data are used to select, from the five candidate months, the month to be used in the Tmy. The highest ranked candidate month in ascending order of the WS values that meet the persistence criterion is used in the TMY. Then, the 12 selected months were

concatenated to make a complete year and smooth discontinuities at the month interfaces for 6 hours each side using curve-fitting techniques. [9 & 10]

Table 1: The weighting factors in Sandia method

Wearher index	**weighting factor**
Maximum dry bulb temperature	1/24
Minimum dry bulb temperature	1/24
Mean dry bulb temperature	2/24
Maximum dew bulb temperature	1/24
Minimum dew bulb temperature	1/24
Mean dew bulb temperature	2/24
Maximum wind speed	2/24
Mean wind speed	2/24
Total horizontal solar radiation	12/24
Direct normal solar radiation	--

3. Tmy2 selection procedure in TmyCreator software

For using the TmyCreator software, The hourly measured weather data of Dry Bulb Temperature {C}, Dew Point Temperature {C}, Relative Humidity {%}, Atmospheric Pressure {Pa}, Wind Direction {deg}, Wind Speed {m/s}, Global Horizontal Radiation {Wh/m2},Direct Normal Radiation {Wh/m2} and Diffuse Horizontal Radiation {Wh/m2} have been prepared.

In Sandia method, the hourly measured data of dry bulb temperature, dew point temperature and wind speed have been used to select the Tmy2. So, calculating the maximum, minimum, and mean dry bulb and dew point temperatures and the maximum and mean wind velocity during a day and total global horizontal solar radiation during a day have been based on hourly measured data in TmyCreator software.

Other remained data in the Tmy2 weather file has not been calculated and the default values of Energyplus document software have been used [11].

4. The TmyCreator software

To use the TmyCreator software (Figure 1) the hourly measured weather data must be prepared for the desired period (such as 1990-2010). Also, the hourly measured weather data are the Dry Bulb Temperature {C},Dew Point Temperature{C}, Relative Humidity{%}, Atmospheric Pressure{Pa}, Wind Direction {deg},Wind Speed {m/s}, Global Horizontal Radiation{Wh/m2},Direct Normal Radiation{Wh/m2} and Diffuse Horizontal Radiation{Wh/m2}.

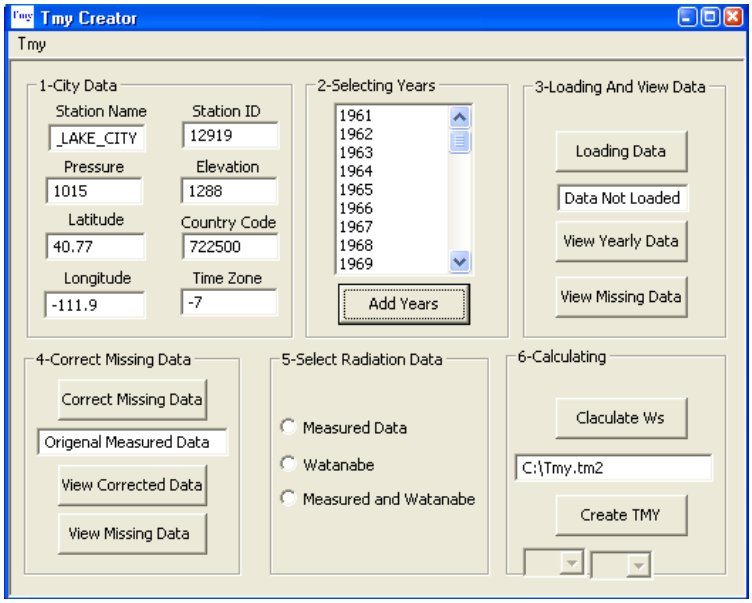

Figure 1: The TmyCreator software

4.1. Correct Missing Data

The TmyCreator software corrects the missing data using other available data as following method:

The missed data = (the amount of after three hour+ the amount of before three hour)/2

5. Validating the TmyCreator software

To validating of the TmyCreator software two methods have been used. In the first method, the Tmy2 weather data for the two city of the USA have been created by TmyCreator software from hourly weather data and the created Tmy2 file have been compared with the created Tmy2 weather data by NREL[1].

5.1. Comparing the Tmy2 Weather file

In the first stage, the 30 year period (1961-1990) hourly weather data for two city of the USA have been provided from the NCDC[2] and NSRDB[3] (for solar radiation data) and using this data the Tmy2 weather file have been created by TmyCreator software . Then the information about of selected year in the Tmy2 weather file created by TmyCreator software and NREL has been compared.

The Table 2 and 3 shows the number of not available hourly weather data for Abilene and Salt Lake City in USA in the year. It can be seen that the missing data for Abilene City is more than Salt Lake City.

The result of running the TmyCreator software using this hourly weather data for mentioned cities have been displayed in the Table 4 and 5.

Table 4: Compared result of TmyCreator software and available Tmy2 data by NREL for Salt Lake City

	City Name	Salt Lake	
		Name of years used by NREL	Name of years used by TmyCreator software
1	JANUARY	1976	1976
2	FEBRUARY	1971	1973
3	MARCH	1967	1987
4	APRIL	1976	1976
5	MAY	1989	1988
6	JUNE	1968	1968
7	JULY	1976	1976
8	AUGUST	1973	1989
9	SEPTEMBER	1972	1972
10	OCTOBER	1967	1968
11	NOVEMBER	1962	1962
12	DECEMBER	1965	1965

Table 5: Compared result of TmyCreator software and available Tmy2 data by NREL for Abilene City

	City Name	Abilene TX	
		Name of years used by NREL	Name of years used by TmyCreator software
1	JANUARY	1974	1974
2	FEBRUARY	1980	1961
3	MARCH	1961	1961
4	APRIL	1969	1969
5	MAY	1981	1981
6	JUNE	1979	1979
7	JULY	1974	1988
8	AUGUST	1981	1970
9	SEPTEMBER	1962	1970
10	OCTOBER	1980	1980
11	NOVEMBER	1977	1971
12	DECEMBER	1967	1979

In these tables the selected year for each month of the year by TmyCreator software and NREL have been showed. It can be seen that the TmyCreator software selected the years for 7 month like as selected year in NREL weather data for Salt Lake City and also selected the years for 6 month like as selected year in NREL weather data for Abilene City. Complete dissimilarity years selected for each month in the NREL file and the file produced by TmyCreator software is the following reasons:

1- As shows in Table 2 and 3, the missing data for these cities is more and not known that NREL How corrected the missing data when created the Tmy2 weather data file. The TmyCreator software corrects the missing data using other available data as following method :

The missed data = (the amount of after three hour+ the amount of before three hour)/2

2- Because the solar radiation data have important role in selecting the year of the Sandia method, it not known that NREL used of hourly measured radiation data or predicted data.

So, we can say that the TmyCreator software is acceptable.

6. Conclusions

In this study, the Sandia method has been applied to prepare the new TmyCreator software for selecting the proper data as the typical meteorological year (Tmy2). Also, the results of this new

software have been compared and it is found that, the results of TmyCreator software have good agreement with the old created Tmy2 weather data file. Using this software the Tmy2 weather file can be prepared for anywhere of the earth. The Tmy2 weather data file have been prepared for 6 city of IRAN (Tehran, Tabriz, Esfahan, BandarAbass, Shiraz, Boshehr and Yazd).

Use of stochastic weather generators in the projection of building energy demand in a changing climate

Abstract: Compliance with building codes in many countries requires energy simulation of designs in local climate conditions. However, over a building's lifespan, weather conditions may alter considerably due to climate change. There is a risk therefore that a future climate may alter lifecycle heating and cooling demands from those experienced today. The development of 'stochastic weather generators' provides an opportunity to produce synthetic weather data representative of a future climate. These models are calibrated against observed data, before being refitted to the climate change projections of global circulation models. The generator's output is thousands of years of weather data for a particular future time period. Theoretically these outputs would be appropriate for building energy demand simulation, although analysis of such a high number of projected years would be impractical. This research has developed a method whereby a unique energy "fingerprint" is created for a building and used to estimate heating and cooling demands without the requirement for hours of computation. Energy demand estimates from the fingerprint have been crosschecked with dynamic simulation, indicating a high degree of correlation. The weather generator utilised in this study has been produced by the UK Climate Impact Programme (UKCIP) and is freely available on-line.

Keywords: *Climate change, building energy demand*

1. Introduction

The 2008 Climate Change Act commits the UK to a challenging 80% reduction in greenhouse gas (GHG) emissions from a 1990 baseline by 2050 [1]. With buildings responsible for almost half of UK emissions [2], the construction industry will play a significant role in achieving this aim.

To drive reductions in GHG emissions, many countries have adopted energy benchmarking processes that require calculation of building energy demand over a single year [3]. For example, the Energy Performance of Buildings Directive (EPBD) in Europe requires member states to develop calculation methodologies to allow building energy demand to be determined [4]. These calculations are required to account for the fabric and systems proposed within a design, as well as the outdoor climate conditions typically found at the location of the building.

Measures such as the EPBD may be effective in reducing GHG emissions assuming steady climate conditions. However, evidence suggests that significant changes to the climate in recent years have already altered the energy performance of buildings. Wright [5] was able to demonstrate changes in heating degree-days over the period 1976-2000 consistent with a warming climate. Similarly Jenkins *et al*. [6] indicated an 18% reduction in heating degree-days, along with a 32% increase in cooling degree-days in London over the period 1961-2006.

Given the long lifespan of many buildings, it is reasonable to assume the climate a building is exposed to over its life could be different to that assumed during the design stage. This could influence the heating and cooling loads of the building, and potentially increase the GHG emissions beyond those expected. To ensure GHG emissions resulting from energy demand

are limited across the lifecycle, a method of analysing the possible influences of climate change is required. This paper describes how hourly weather sequences representative of a range of possible future climate alternatives may be produced in a format suitable for routine building energy analysis. The following section outlines work previously completed by others in this field.

1.1. Background

Hundreds of software applications have been developed for the estimation of building energy demands [7]. The most advanced of these tools simulate the performance of designs against hourly (or even sub-hourly) inputs. Weather sequences representative of the proposed building site are therefore required at this hourly resolution. However, there is a lack of data at this level of detail that accounts of the influence of climate change in the future.

1.1.1. Building analysis and climate change

Cole and Kernan [8] first identified the need to consider the influence of a changing climate on building lifecycle energy demands in 1996. However, at the time no suitable weather data were available to undertake such a study. Since then various methods have been developed to address the problem. The most simplistic approach has been to substitute weather data local to the site for that of a remote location that may be representative of a changed future climate. Gatrell and McEvoy [9] used this approach by using weather data from Rome and Milan as an approximation of London's possible future climate. The drawback of this method is that the relative humidity and diurnal temperature range of the substitute location may be quite different to that of the present site, even if the temperatures are similar to those expected for the future. In addition, the hours of sunlight and solar inclination may be unrealistic and would clearly not be subject to variation, even considering climate change.

1.1.2. Morphed weather data

In an effort to produce more suitable weather data accounting for future climate change, Belcher [10] developed an approach whereby the weather conditions of a given site are "morphed" inline with the projections of large scale climate models. In this work, Belcher used the Global Circulation Models completed by the United Kingdom Meteorological Office Hadley Centre and presented by the UK Climate Impacts Programme (UKCIP) in 2002 [11]. The process provided an estimate of possible future conditions by "shifting and stretching" hourly recorded weather data. This created a new annual sequence with monthly average conditions equal to those projected by climate models. The morphed data produced by this process have been applied by many researchers [12] [13] [14], although it does suffer from two potential drawbacks. Firstly, only one year of data can be produced for a given time period in the future, so the uncertainty in the projection cannot be satisfactorily addressed. Secondly, the morphing technique relies on the baseline recorded weather being from the same time period as the baseline in the climate model. This is not always possible.

1.1.3. Weather generators

More recently a new method has been made generally available that offers an alternative form of 'future' hourly climate data – stochastic weather generators. In 2009 the UKCIP produced an on-line user interface that allows generation of hourly synthesised weather data for any decade up to 2080 at any location following a 5km grid [15]. A full technical description of the weather generator and reference to the underlying scientific papers is provided by Murphy and Jones [16] [17]. A simplified description of the workings of the weather generator is however now provided by way of introduction.

The main difference between the 2002 and 2009 projections presented by the UKCIP is that a spread of probabilistic climate change is presented rather than one prediction. UKCIP have achieved this by simulating a number of subtly different, but equally plausible, models that all represent the climate in a slightly different way. From each of these models, "change factors" are produced that provide an indication of possible variation in weather variables at a monthly time scale. The weather generator is then used to downscale the monthly projections into a synthesised daily, and finally hourly, time step. Jones *et al*. [17] describe that like most weather generators a stochastic rainfall model is used to synthesise other weather variables based on the rainfall state. To achieve this, the weather generator is first calibrated using observed rainfall data and other weather conditions to produce relationships between the variables. The monthly change factors from the probabilistic models are then used to produce a future rainfall condition, which in turn is used to generate other future weather variables including temperature, humidity and cloud cover. To ensure that a wide range of plausible climate models are applied, a minimum of 100 sequences of data are produced by the weather generator. In addition to this, to ensure that a future climate can be well defined from the synthesised weather, each sequence is 30 years in length. This means that the weather generator produces at least 3,000 years of possible future weather data for any future decade.

The challenge for building energy modelling is how to apply such a vast quantity of data to assess the probabilistic performance of buildings in the future. Some progress has been made by Smith *et al*. [18] in the application of the new data. However in this study all 3,000 years were applied to a specific case study requiring specialised batch simulation and advanced processor power. The work discussed here aims to simplify the process so that analysis can be completed quickly as a routine activity within building design.

2. Methodology

The objective of simulating building energy performance against future weather conditions is to determine the sensitivity of the design against a range of future scenarios. In doing so, the energy required over a lifecycle may be reduced. However, the energy required by one building in the future may be different to that of another. For example, a heated and naturally ventilated building may use less energy in a 'warm future', as no air-conditioning system is present. Conversely, a building with high casual heat gains and a full air-conditioning system may require much more energy in a warmer climate. Many buildings may fall between these extremes. The method adopted therefore first tests a building's response to different weather conditions to define a unique 'fingerprint'. The fingerprint is then used to estimate energy demand (in the form of equivalent carbon dioxide, CO_2eq, emissions) from all 3,000 years of data. The following sections outline how this has been achieved.

2.1. Selection of example weather years

To understand how a building responds to differing climate conditions, a range of example years are required to define a suitable profile. In this analysis, dry-bulb temperature is used to differentiate between the years and indicate the potential energy demand of the building. However, taking a simple average of annual temperature does not indicate how much energy a building may require for heating and cooling. This is because it is the variation of hour-by-hour temperature either side of the average that indicates energy demand. For example, if an annual average temperature is 14°C, it is not known if the temperature spends a long time around this value, therefore requiring little heating or cooling energy in the building, or if wide extremes are experienced over the course of the year leading to high energy loads. Therefore, to indicate the amount of time in a year when temperature is at a particular value, a Cumulative Distribution Function (CDF) is produced for each of the 3,000 years.

When these CDFs are plotted and overlaid, a complete 'envelope' is created. Fig. 1 shows a hypothetical example of CDF plots of temperature. Example years are then chosen from across the full range of the envelope to test the building against a wide range of conditions. These are selected by plotting percentile positions across the envelope, then selecting the year which has the closest fit to the percentile points. To achieve this, a "goodness of fit" test is applied in a similar way to that used in the development of Test Reference Years (TRYs) for the UK Chartered Institute of Building Services Engineers (CIBSE) [19] [20].

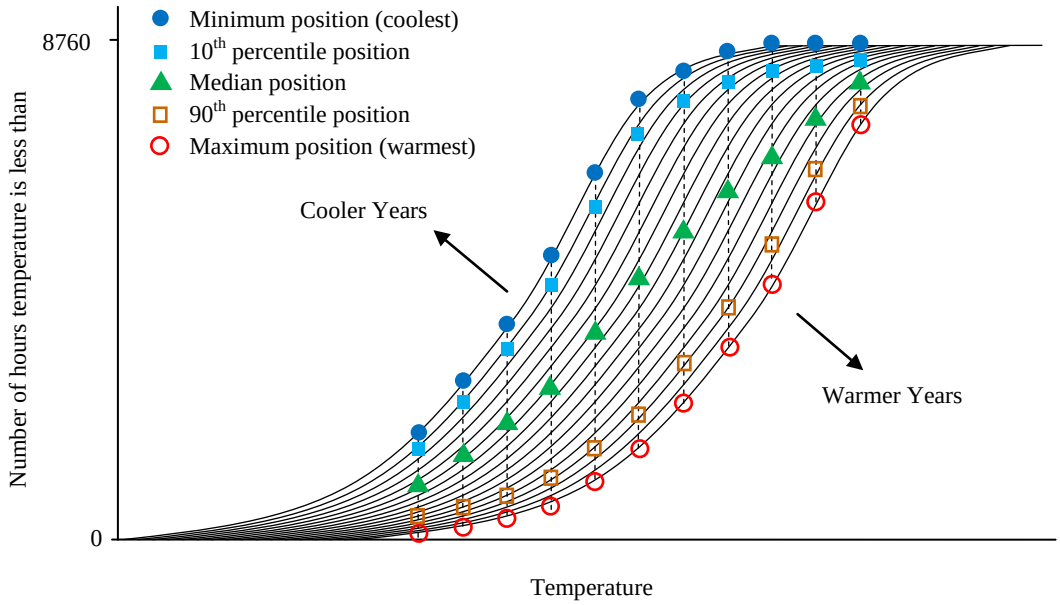

Fig. 1. Hypothetical example of Cumulative Distribution plots from UKCIP Weather Generator output. Each line represents a single synthesised year. In practice the generator would produce at least 3,000 years, each with equal probability of occurring.

In total, nine years are selected from the envelope at a spread of 10 percentile intervals. These years are then used as the external weather conditions in a thermal simulation of a building. To illustrate the process, an example building is described in the next section.

2.2. Testing of building performance

The building used to create an example fingerprint is a small Police Station in the south of the UK. It consists mainly of offices and meeting rooms, but also includes a relatively large computer server room. To complete the dynamic thermal simulation of the nine weather years, Integrated Environmental Solutions[1] (IES) v5.9 has been used. The outputs of heating and cooling energy demand are converted to CO_2eq values using a conversion factor typical to the UK [22] (0.198 kgCO_2eq/kWh for natural gas and 0.517 kgCO_2eq/kWh for grid supplied electricity). The hourly values are then aggregated into daily totals and a corresponding average daily temperature is calculated.

A binned frequency approach is then applied, where frequency of occurrence of daily average temperature in 1°C bins is determined. Using the same bins, the corresponding heating and

[1] The IES software determines annual building energy demands by modelling heat transfer processes at an hourly, or sub-hourly, time step. It is approved for use in building regulations compliance in the UK [21].

cooling energy demand (in CO_2eq) is summated. An example of the output of this process is shown in Fig. 2. Unsurprisingly, most building heating load occurs at low external temperatures and more cooling demand is found at higher temperatures. In addition to this, it is seen that of temperature frequency shows some correlation with the emissions, particularly cooling. This indicates some consistency between average daily dry bulb temperature and total heating and cooling load. The final stage is to use this profile to define a unique building energy fingerprint.

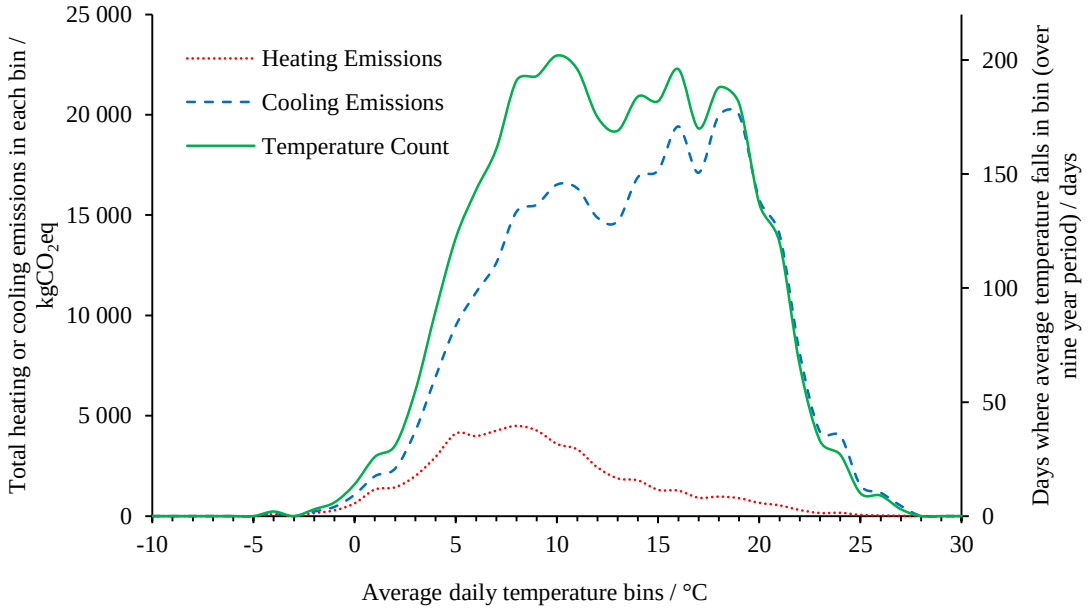

Fig. 2. Total CO_2eq emissions from example building heating and cooling demands and temperature frequency of occurrence in daily average temperature bins of 1°C

2.3. Production of unique fingerprint

To produce the fingerprint, the heating and cooling emissions are simply divided by the frequency of temperature occurrence. This gives a varying heating and cooling coefficient at each of the temperature bins with units of kgCO_2eq/day. Fig. 3 shows the unique fingerprint for the example police station building. In this particular case a minimal year round heating demand can be seen regardless of external temperature. This is due to a continual requirement for domestic hot water. Similarly a continual baseline load is also present for cooling as a result of the computer server room air conditioning equipment. In this case CO_2eq emissions are clearly dominated by cooling demand.

Once the fingerprint is created, annual CO_2eq emissions can be determined for any year with no need for further dynamic thermal simulation. This is achieved by simply multiplying the coefficient by the frequency of temperature occurrence for a given year, which can be readily achieved using a spreadsheet application.

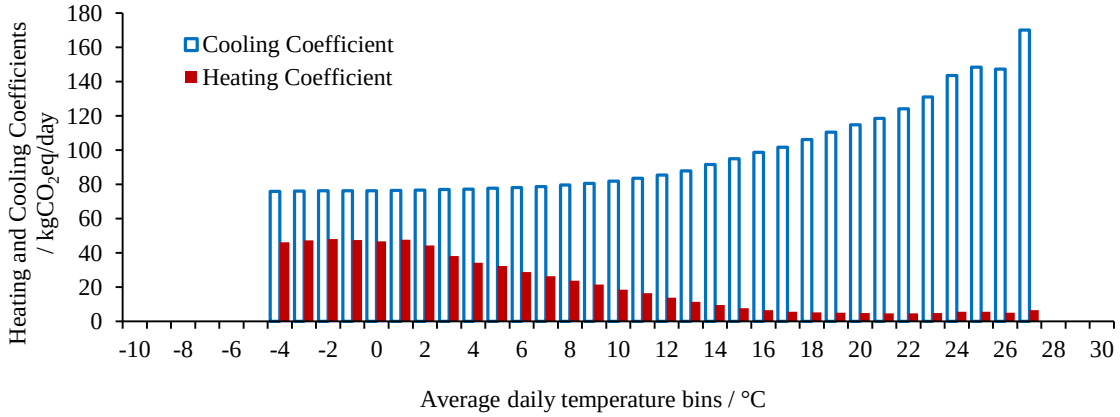

Fig. 3. Unique fingerprint of example building built from heating and cooling coefficients

3. Results of validation

To check the validity of the developed approach, the accuracy of the fingerprint at estimating building energy demand has been crosschecked using dynamic thermal simulation. To complete this, a number of years have been selected from the UKCIP weather generator and energy demand for heating and cooling has been determined in the example building using both methods. The years chosen for this process did not include those used to produce the fingerprint. Figure 4 shows the correlation between total (heating plus cooling) CO_2eq emissions for the example building against fourteen different years of weather.

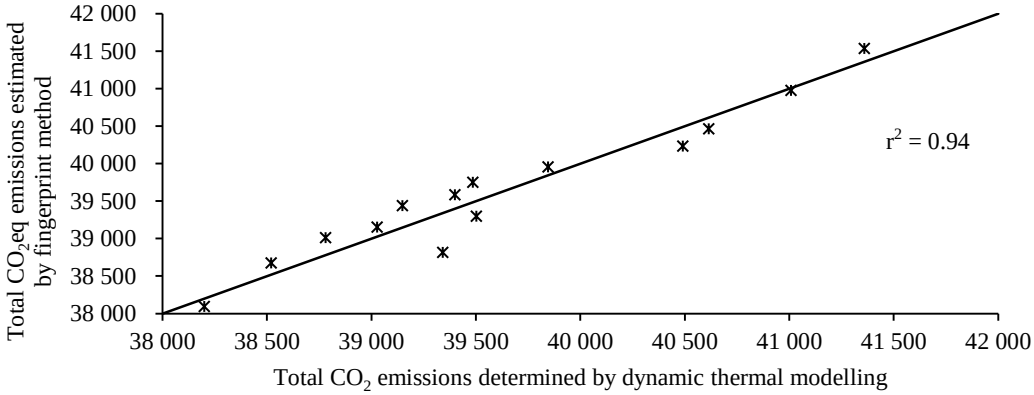

Fig. 4. Comparison of CO_2eq emissions between estimated figures using fingerprint method and dynamic thermal simulation

An r^2 value of 0.94 has been found between the two methods, indicating a high degree of correlation. This would suggest that for the case study examined, the fingerprint method is an acceptable way of estimating building energy demand for multiple years of data without requiring thermal simulation of each year.

4. Discussion and conclusions

The process developed here allows building CO_2eq emissions to be estimated directly from probabilistic climate change projections with minimal computation. The degree of correlation of the 'fingerprint' estimate to that determined by dynamic thermal simulation is very high, and greater than anticipated. It was previously assumed that a lower correlation may have been found, as the fingerprint method does not consider varying solar radiation and

(de)humidification requirements, focusing instead only on external dry-bulb temperature. It is however well known that these weather variables may affect building energy demand separately form dry-bulb temperature. It is assumed that as the weather data are produced by a 'generator', there may be a stronger link between the variables than experienced in reality. For example, in the generator it may be that warm days are generally also sunny and that cool days are frequently cloudy. This is not always true in reality. It may therefore be that the Weather Generator produces weather sequences where the variables are more correlated than reality (due to the known link to the stochastic rainfall state) and therefore particularly suitable for building energy estimation. However, as the method described in this paper is only applicable to generated weather sequences, this limitation is not a primary concern. Despite this, the issue is recommended for investigation in future work.

The method developed in this study allows any building design to be tested against possible future climate conditions. The advantage of using a weather generator as the basis of this work is that a wider range of climate conditions can be investigated than previous methods allowed. This will allow a design to be checked in multiple scenarios, allowing poor performing systems to be focused on for improvement. The main benefit of the approach is that a wide range of weather conditions can be explored without excessive levels of thermal simulation. It is hoped that this approach will be applicable to the routine thermal analysis of buildings. Further work is however required to investigate the accuracy of the fingerprint method in different building types in different locations to fully validate the method.

Ultimately, by investigating building energy demand performance over a range of possible weather conditions a better insight is provided into possible CO_2eq emissions that may be released as a result of heating and cooling a building over its operational lifecycle. The situation to be avoided is one where emissions in the future increase as a result of increases in cooling demand due to a warmer climate. This would be counterproductive to the UK achieving its target reduction of 80%.

5. Acknowledgements

The authors gratefully acknowledge the support of the UK Engineering and Physical Sciences Research Council (EPSRC) for this research, which forms part of the University of Surrey / Brunel University Engineering Doctorate Programme in Environmental Technology. They would also like to thank Parsons Brinckerhoff for their continued support of the programme.

Abstract: *Indoor Ecology* (IE) is an emerging research field that aims to develop new approaches and technologies which allow indoor environments and occupants to dynamically co-adapt to each other in order to enhance human wellbeing and productivity while simultaneously optimizing energy efficiency. The central idea in IE is that humans, building systems and the interior environment form a single, integrated complex 'ecosystem'. One way to IE optimization is though lighting, especially daylighting and daylight simulation. Current approaches to energy-efficient buildings emphasize only limited aspects of interior lighting, such as the carbon footprint, without regard to the multiple effects lighting has on human health, wellbeing and productivity which must be considered if truly sustainable interior spaces are to be designed. This paper documents five on-going investigations which study various aspects of the lighting-human interaction in a variety of circumstances. For example, students in the classroom setting are exposed to wide changes in lighting as well as inadequate light during early classes, likely affecting attention, retention and performance. Subjects displayed a marked preference for natural lighting when given the option; supporting a general hypothesis that daylighting might be a solution to the twin problems of promoting health and productivity while decreasing energy use.

Keywords: *Daylighting, Low-energy lighting, Visual acuity, Health, Wellbeing*

1. Introduction

The emerging discipline of Indoor Ecology seeks to develop the theories, methodologies and technologies needed to recast building design and architectural space in terms of flexible, sustainable and evolving human-building ecosystems. As part of this larger initiative, the effects of environmental lighting on human physiology and behavior must be investigated alongside the physical parameters of architectural space. The objective of the current research initiative into the effects of lighting on vision/visual acuity and health/wellbeing is to establish guidelines that can assist in the development of sustainable lighting solutions to promote the health and wellbeing of building occupants. This process-based research investigation looks to nature as a way of remodeling the built environment by considering the human-building relationship as a complex, evolving ecological network. Such an approach requires that environmental lighting be viewed from multiple perspectives – visual acuity, mood, chronobiology, health, energy efficiency, etc. – in order to inform the technological development of sustainable interior lighting systems [1]. Sustainable in this sense is broader that typically used in architectural design and includes the effects of light on human health and productivity as well as energy-efficient lighting design. The overall on-going research objective is to develop design criteria, guidelines and parameters to support the development of low-energy sustainable architecture at the nexus of health, energy and technology.

1.1. Background

Recent research indicates that lighting has increasingly become a public health issue [2]. These studies have shown that individuals working in natural sunlight are more productive, more effective, and happier than those who work under traditional artificial light. In addition, several studies have demonstrated a connection between environmental lighting levels and higher productivity and better performance from building occupants [6, 7]. Natural changes in

daylight balance the body's circadian rhythm, which determines sleeping and eating patterns, cognitive activity, heart rate, hormone levels – in fact, virtually all physiological and behavioral parameters. Circadian phase shift and transmeridian travel have been shown to contribute to jetlag, seasonal affective disorder (SAD), delayed sleep phase syndrome (DSPS), and is implicated in more various diseases and disorders, including cancer [3]. In industrialized nations it is estimated that up to 20% of the workforce are involved in some kind of shift work [4] which is associated with exposure to unusual or abnormal levels and/or patterns of light and dark. Studies have associated these unusual levels and patterns with higher incidences of breast cancer and colorectal cancers [1]. Thus, the sustainability of human productivity and well-being, even life itself, is directly tied to environmental lighting.

Lighting is also a sustainability issue in terms of energy use. Buildings consume 39% of the primary energy in the United States—on average 18% is used by lighting systems alone [5]. Also, the heat produced by a lighting system can generate up to 24% of the total building cooling load [6]. Proper lighting utilization using low-energy systems that generate little heat could result in significant cooling energy savings for buildings and a smaller carbon footprint.

The twin requirements of promoting human health and productivity and designing energy efficient lighting systems appear to be at odds. How can lighting be designed sufficiently bright enough to sustain human health and productivity while suitably energy efficient enough to sustain the planet? One possibility is the creative use of natural daylight. Daylight brings enough light to meet lighting needs of 50 to 70% of the occupancy period in the temperate zone of the earth while saving energy up to 50% of the gross full yearly use of light [8, 9].

For proper health and energy savings it is important to understand how light affects physiology and behavior. Ocular light, or light reaching the eye, serves two major functions: vision and control of circadian rhythm [10]. Daylighting provides the quality light necessary for maximum vision and visual acuity [11] and provides the full spectrum of light needed for health and wellbeing [3]. Circadian rhythm is regulated by changes in visible light from the sun throughout the day [12] and is controlled daily by the full spectrum of natural light together with darkness in the environment [10].

1.2. Physiology and Daylight

Natural daylight is crucial to promote productivity, health and wellbeing due to light's visual and non-visual effects. In addition to object recognition or visual information, light provides data on the timing and intensity of light and dark to synchronize the body's biological rhythms. Photonic information (non-visual effects of light) is transmitted from the eye to the suprachiasmatic nucleus (SCN) located in the hypothalamic region in the center of the brain, leading to a cascade of hormonal changes in the pituitary, pineal, adrenal and thyroid glands.

The SCN serves as master pacemaker or biological clock in humans, synchronizing the circadian rhythms that regulate and modify virtually every physiological and behavioral process in the human body. The human SCN displays a natural period slightly longer than 24 hours and must be reset by light of the appropriate spectrum and intensity, at the proper time, to provide a consistent temporal order. When this temporal order is significantly disrupted – through inappropriate interior lighting, for example – it can lead to damaging emotional and physiological effects such as those associated with seasonal affective disorder, jet lag, delayed sleep phase syndrome, and may exacerbate serious conditions such as cancer. These effects are especially evidenced by people involved in shift work [13, 14, 15], such as the doctors and staff working in the Emergency Department at Hahnemann who are part of this research.

The hominid ancestors of humans did not live in buildings and evolved their circadian system – which present humans have inherited – exposed to the natural day/night cycle. The full spectrum of light available in this cycle includes UVA, UVB and visible light: at noon there is high intensity in the *blue light* region, in the late afternoon blue light is preferentially scattered out of (removed from) incoming sunlight so that the late afternoon sun provides red and orange light, and when the sun sets it becomes dark. Circadian rhythms are controlled primarily by daily exposure to levels of light in the blue-green spectrum together with alternating darkness in the environment. Blue light triggers the production of serotonin in the body, which enhances alertness and cognitive performance, while red or amber light signals the onset of dusk; the absence of light encourages melatonin secretion [16, 17]. Returning buildings to a natural light environment through the use of daylighting or mimicking the full spectrum of natural light using energy-efficient artificial lighting would both conserve energy and promote the wellbeing of building occupants [18].

2. Methodology

There are five on-going investigations to determine the effects of a variety of lighting options in different architectural settings. These studies are designed to test environmental preference for natural light, artificial light effects on human health and productivity, different artificial light sources effects on vision and visual acuity with respect to energy use, and the effects of light shelves on indoor illumination levels. Preliminary results are documented in this paper.

3. Results

3.1. Hahnemann Hospital Emergency Department Waiting Room Daylighting Study

The waiting room of the Hahnemann Hospital Emergency Department is a poorly monitored space: patients suffering from an accident, illness or even fear, are also unsure as to how long they may be waiting or what will happen once they see the doctor. After the recent death of a Philadelphia man waiting for care, attention has been refocused to emergency department waiting rooms. While it is not clear what led to his death, the event does suggest that health care providers should know more about what is happening to patients, both in the short and long term, while they are in the waiting room of emergency departments.

Although the effects of the environmental lighting should influence designs for healthcare spaces, this is rarely the case. Light exposure of specific frequencies and intensities has been shown to affect mood and performance [20, 21, 22] and even treat certain aspects of depression [23]. Not known is whether lighting can affect a person's health and wellbeing over short and irregular time periods such as while waiting for care at emergency departments. Waiting durations vary from less than a minute to as much as 12 hours – longer wait times are associated with increasing levels of impatience and agitation.

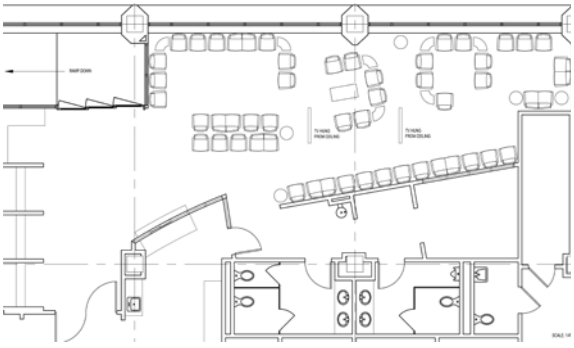

Fig. 1. Plan of the Hahnemann Emergency Department Waiting Room (north side top of drawing).

In addition to effects of lighting on patient attitude and mood, lighting may also affect the underlying health problem that brought the patient to the hospital in the first place. The current lighting of the Emergency Department waiting room at Hahnemann Medical Center was analyzed as a first step in assessing effects of lighting on waiting patients (Fig. 1).

The next step is to determine the effects of the current lighting on patients. The initial hypothesis is that patients will aggregate in areas of high light intensity or natural lighting. In the daytime, the seats adjacent to the north windows receive the most natural daylight. The prediction is there will be a natural gradient of persons within the waiting room tending to sit near the windows. However, at night there is little difference in lighting (all artificial lighting) and no gradient of persons is expected as a result of lighting conditions. The artificially-lit waiting room of the evening hours will be used as a control to determine if there is a preference to sit near the windows. Other factors must be considered such as location relative to televisions, where other persons have already occupied a seat or even proximity to bathrooms or vending machines. The lighting measurements will be correlated to seat positions in another series of measurements. Data is presently being gathered; initial results support the hypothesis suggesting a trend to prefer sitting near the windows in daylight hours.

3.2. Hahnemann Emergency Department Baseline Staff Productivity Study

Another aspect of patient care is the performance of the health care providers. Given the well known performance deficits associated with circadian disruption and sleep deprivation, is it possible for environmental lighting to act as a counter agent to these effects? Current practice for emergency room service delivery involves doctors participating in schedules that involve 8- or 10-hour shifts of two days of daytime, two days of afternoon/evening, two days of overnight and two days off. An initial staff productivity study will serve as a baseline inventory of sleep, self reported quality of wellbeing, burnout, sleepiness and preferred phase of circadian activity as well as the Emergency Department (ED) lighting environment. In this second ED study, resident physicians will wear light sensing wrist actigraphs that measure movement to assess objective sleep-wake activity patterns in different lighting conditions for one work cycle. Within the ED, lighting apparently varies little and there is no natural lighting once inside the patient treatment areas. However, lighting conditions may change based upon specific tasks being undertaken and/or the influence of lighting on performance may be task dependent. Lighting levels will be measured and correlated to tasks to assess how the Emergency Department lighting could be better designed to support ED staff performance.

3.3. Lighting and the Educational Environment

It is well known that time of day affects performance and learning. Sleep deprivation and fatigue are detrimental to an array of neurocognitive functions and, by extension, decrease learning. However, these observations have not been systematically applied to scheduling classes with the goal of enhancing a student's learning experience.

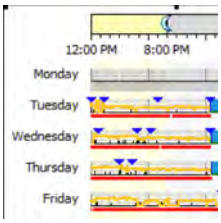

Fig. 2. Actogram from wrist actigraph demonstrating ambient light exposure, sleep, rest, and activity periods for an average subject over 21 days.

Lighting levels are being documented in several Drexel University classrooms and show significant variation from room to room and at different times of day in the same room. In fact, the lighting levels have been found to vary significantly from desk to desk within a single room even when the room is artificially illuminated. The discrepancy in lighting levels is even more pronounced when the room also has access to natural daylight, compounded with orientation to the sun (whether east, west, north or south orientation). To determine how these varying lighting conditions effect learning, students are being monitored for activity and light exposure using wrist actigraphy (Fig. 2). The data will be

cross-referenced with the student's performance to determine the effects of lighting and sleep/wake cycles on academic achievement. Further studies will evaluate classroom seating position with respect to lighting and effects of lighting on mood, sleepiness and performance.

Preliminary investigations consist of data collection using wrist actigraphy for 2 weeks during a school term. Weekdays were analyzed to determine the average light exposure students received during the day. Light was recorded in 60 second epochs. 180 epochs were averaged to create six, 3 hour bins from 06:00-24:00. Average light exposure (lux) was compared across the bins. While previous analysis failed to reveal a significant exposure to ambient light during the night (24:00-06:00), daytime exposure was shown to vary significantly by time of day. A one-way ANOVA was used to test for differences in average light exposure in 3 hour bins from 06:00-24:00. Exposure differed significantly across the six time bins, $F(5, 102) = 3.78$, $p = .003$. Also, a trend toward increasing light exposure was seen as a result of time of day with the hours of 12:00-14:00 showing the highest average lux per subject. Additionally, during students' earliest waking hours, from 06:00-09:00, analysis revealed significantly reduced light levels, equivalent to the sleeping environment, despite student's schedules and activity measurements correlating this time period as active class time.

3.4. Light Source, Vision and Visual Acuity

Not only are lighting levels, light with respect to time of day, and physiologically experiencing the full spectrum of natural daylight important for the work environment, but also the *quality* of the light can be crucial—especially in an emergency medicine situation when the attending physician may be tired and yet responsible for completing tasks that require precise visual acuity, such as making incisions and stitching wounds.

During the summer 2010, five lighting experiments were set up to compare and contrast five different light sources for visual acuity and comfort, which were cross-referenced with age, gender and whether or not corrective lenses were used. Each lighting experiment had an eye chart with verse from Ralph Waldo Emerson's *The Conduct of Life*, with point sizes varying from 1pt to 7pt, each illuminated by a different light source. The test subject looked through goggles to ensure the same focal distance from the eye chart and selected the smallest point size that could be read. The lighting level was been set at +/- 530-650 lux for each of the four artificial light sources: LED, Phillips incandescent, compact fluorescent and GE incandescent (Fig. 3). The fifth lighting experiment used available natural daylight and the test subject noted the lighting level at the time of the test; daylighting levels tended to vary within the range set up for the artificial lighting sources at +/- 530-650 lux. The test subject was requested to indicate which one of the light sources was the most comfortable (Fig. 4). Sixty-five people were surveyed with ages ranging from 9 to 77 years. While the use of corrective lenses did not seem to affect the study, the daylight source was overwhelmingly preferred. However, this was not the case during the spring when daylighting levels varied 200-500 lux.

Fig. 3. Light Boxes, from left to right: LED, Phillips incandescent, CFL, GE incandescent

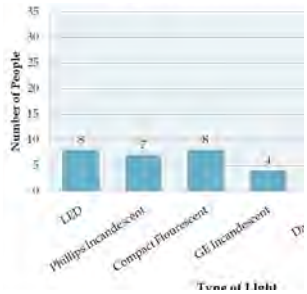

Fig. 4. Light Source Preference

Determining quality of light with respect to light source and energy consumption is critical to meet today's energy conservation needs. Daylighting is ideal because it consumes no energy and is cost-free. On the other hand, radiant energy from light results in heat gain; potentially in the winter a reduction in heating costs, while in the summer an increase in cooling loads. Indirect daylight is ideal because of lowered radiant heat gains. A comparison of the artificial light sources used in this experiment reveals that although users indicated little preference between the artificial light sources, while the LED (light emitting diode) light source is considerably more sustainable, it costs nearly double the CFL (compact Fluorescent); however, both use considerably less energy than either incandescent (Table 1). Additionally, while not measured in this study, both the LED and CFL also generate less heat.

Table 1. Artificial light sources.

LED: Pharox 40 Warm White Light	Incandescent: Philips Duramax R20	Compact Fluorescent: Ecosmart Soft White Cold Cathode	Incandescent: GE Soft White 25

cost over 36,500 hours = $76.38	Cost over 36,500 hours = $219.15	Cost over 36,500 hours = $39.35	Cost over 36,500 hours = $159.15

3.5. Natural Daylighting and Light Shelf Efficacy

Lighting energy accounts for a large portion (30-50%) of total energy consumption of typical commercial buildings [l9], and about 15% percent of residential consumption in the U.S. [5]. Daylight generates enough light to meet lighting requirements of 50 to 70% of the occupancy period in the temperate zone of the earth. Energy savings by using daylighting can be up to 50% of the gross full yearly use of light for interior conditions [8, 9]. For these reasons, techniques that can maximize daylight use in indoor spaces while minimizing heat gain would be useful to ensure both quality light and energy savings in buildings.

A south-facing room was used as a test site. It is a typical office plan illuminated by windows all along the south wall from about 42" above the floor to the ceiling at ten feet above the floor. The orientation is skewed from true south as indicated in the plan (Fig. 5). Light shelves were installed along the central horizontal dividing mullion at approximately six feet above the floor level. A 99.7% reflective coating provided by 3M Corporation was installed on the top surface of the light shelf and on the ceiling above to redirect the reflected sunlight back down into the room. Lighting levels were documented at one hour intervals from 10:00-15:00. It was noted whether or not it was Sunny (Clear Sky), Partly Cloudy, Cloudy, or Rainy. Three separate readings were taken each hour: no light shelf, light shelf horizontal to the floor, and light shelf inclined at 10^{o} below the horizontal. Readings were taken on twenty separate days over a period of six weeks at three locations as indicated on the plan (Fig. 6).

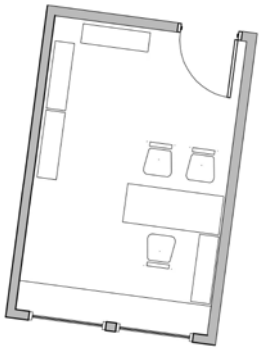

Fig. 5. Office (oriented north up).

Preliminary results suggest that light shelves help to evenly distribute interior lighting levels across the room when located on south-facing windows; glare is reduced at the window due to

the shelf shading adjacent work surfaces while lighting levels are increased at work surfaces within five to eight feet from the window (Fig. 7). Surfaces beyond eight feet receive much less benefit. Daylighting is most effective when the sun is perpendicular to the window, explaining why illumination levels for this test location were highest at 14:00 instead of noon.

4. Conclusions

While human behavior is occasionally considered in the design of low-energy architecture, energy use and efficiency can often take precedence over human comfort, performance and/or wellbeing. Buildings have been designed to efficiently use energy while illuminating building interiors. However, rarely is visual acuity a consideration in lighting design nor are the effects of lighting on physiology and behavior. As a result, lighting is often energy-efficient while building occupants have difficulty succeeding in tasks requiring keen vision, such as suturing a wound or reading fine-print text. Additionally, buildings with 24 hour illumination generally produce the same intensity and wavelengths throughout the period, increasing chances for circadian disruptions with consequent health and performance decrements. The quality and timing of light should be controlled to ensure the physical and mental wellbeing of building occupants. Future areas for research include: 1) evaluating the feasibility of artificially mimicking the full spectrum of light by phase-shifting the day of night-shift workers to reset their biological clocks to be in sync with their natural circadian rhythms; 2) optimizing the educational environment by coordinating course schedules with time of day and classroom lighting levels to enhance student academic performance and alertness; and 3) developing criteria for sustainable architectural design at the nexus of health, energy and technology.

Abstract: Passive Houses have gained popularity the last ten years as a way of improving the energy efficiency in the housing stock. The challenge of avoiding external heating during the cold winter climate in Sweden has pushed the design of a Passive House in a direction where problems with excessive temperatures might occur summertime. The aim of this paper is to evaluate comfort cooling strategies for attaining good indoor climate summertime while maintaining good energy efficiency. Also, to add knowledge of comfort cooling strategies for Swedish conditions as the summer season is short and comfort cooling is normally not installed. The studied strategies include: airing, shading, increased ventilation, cooling machine and evaporative cooling. Additionally, combinations of these methods are studied. To evaluate the cooling strategies and their impact on the indoor temperature and the amount of electricity needed for their operation, computer simulations have been made using the simulation tool *IDA Indoor climate and energy*. The building model is based on an existing Passive House in the district Lambohov in Linköping, Sweden, where continuous logging of temperatures are available. Without comfort cooling the simulations show excessive temperatures summertime which is consistent with the field measurements from the real house. The overall judgement is that passive cooling strategies can provide sufficient cooling during the hottest part of the summer and that both shading and airing strategies should be used for a maximum cooling effect.

Keywords: *Building simulation, Comfort Cooling, Passive House*

1. Introduction

Passive Houses have gained popularity the last ten years as a way of improving the energy efficiency in the housing stock. A Passive House uses only the internal heat gains from lighting, equipment, humans and the incoming solar radiation to heat the building. This is possible through a combination of a highly insulated building envelope and a heat exchanger that heats the incoming air with the exhaust air. A Passive House has therefore no need for a traditional heating system, but occasionally, when the temperature drops fast during a cold period, there might still be a need for additional heating. The challenge of avoiding external heating during the cold winter climate in Sweden has pushed the design of a Passive House in a direction where problems with excessive temperatures might occur summertime.

The aim of this paper is to evaluate comfort cooling strategies in order to attain good indoor climate summertime while maintaining good energy efficiency. Can a clever use of shading, airing and ventilation provide enough cooling to avoid an installation of comfort cooling equipment. Moreover, the use of a cooling machine as well as evaporative cooling is also evaluated.

Socialstyrelsen (The Swedish National Board of Health and Welfare) recommends that the indoor temperature does not exceed 24 and 26 °C wintertime and summertime respectively (Socialstyrelsen 2005). Further, Boverket (The Swedish National Board of Housing Building and Planning) recommends an indoor temperature between 23 and 25 °C summertime (Boverket 2007) and FEBY(Forum for Energy Efficient Buildings) recommends that the indoor temperature does not exceed 26 °C more than 10 % of the time summertime in the hottest part of the building (FEBY 2009).

A study by SP (Technical Research Institute of Sweden) with temperature loggings from 20 terraced house apartments in 4 Passive Houses in Lindås, Sweden, show a mean indoor temperature of 25.2 °C summertime (Ruud and Lundin 2004). Some of these apartments have temperatures within good levels throughout the summer but others have periods with temperatures between 25 and 30 °C and there are occasions when the indoor temperature reaches 30 °C. Dwellers in Passive Houses in the districts of Oxtorget, Glumslöv and Frillesås responded to a questionnaire study about their indoor temperature summertime. The outcome of the questionnaire gave the result that in Oxtorget 31 %, in Glumslöv 56 % and in Frillesås 11 %, respectively, claimed it was too warm during this period (Samuelsson and Lüddeckens 2009). More reports of excessive temperatures summertime have been made from dwellers in a two-storey Passive House in Lidköping and from dwellers living on the top floor in a three-storey apartment building in Brogården, Alingsås (Janson 2010). In Lambohov, Linköping, temperature measurements from two Passive Houses also show excessive temperatures summertime. During the month of July 2010, the mean value of the exhaust air temperatures from these two apartments were 27.3 °C. Further, the exhaust air temperatures from these two apartments were 26 °C or higher during 60 % of this time (KTC 2010).

In contrast to warmer countries, comfort cooling equipment is normally not installed in Swedish dwellings. However, the combination of the isolating capacity of a Passive House and the large solar gains summertime could result in excessive temperatures even in this cold climate. Methods for comfort cooling in warmer countries are normally: shading, ventilation, cooling machines, evaporative cooling, solar chimneys, earth tubes, reflectors and night-time radiation cooling.

2. Methodology

With the use of computer simulations this paper investigates strategies for comfort cooling for a Passive House in a Swedish climate. The simulations have been carried out using the software *IDA Indoor climate and energy (ICE)*, a software that since its release in 1998 has grown to become one of the leading international tools (U.S. Department of Energy 2009). The input data representing the human presence, the use of electricity and domestic hot water are based on a collection of user related data from Boverket (2007). Applied to this household it results in the internal gains of 4.6 W/m^2. The building model in the IDA ICE-simulations is based on an existing Passive House apartment in Lambohov, Linköping, Sweden, where continuous logging of temperatures are available, see Fig. 1. It is one of two 4-room apartments in a Passive House building, both with two floors and an area of 105 m^2. The ground floor has a ceiling height of 2.5 meters and the second floor has a ceiling height of 2.4 meters. The apartment is equipped with an FTX-system that recovers the heat in the exhaust air to heat the incoming air and a constant air volume (CAV) ventilation system with two temperature meters controlling the ventilation. Further, a climate file from Meteonorm is used in IDA ICE to simulate the climate in Linköping. More details are presented in Appendix.

In order to evaluate the different comfort cooling strategies, the first ten days in the month of July, a period with excessive temperatures in the real Passive House are simulated. The reference case without different measures to cool the apartment is compared with implementations of different strategies for comfort cooling. Their individual cooling performances as well as the combinations of these are then evaluated.

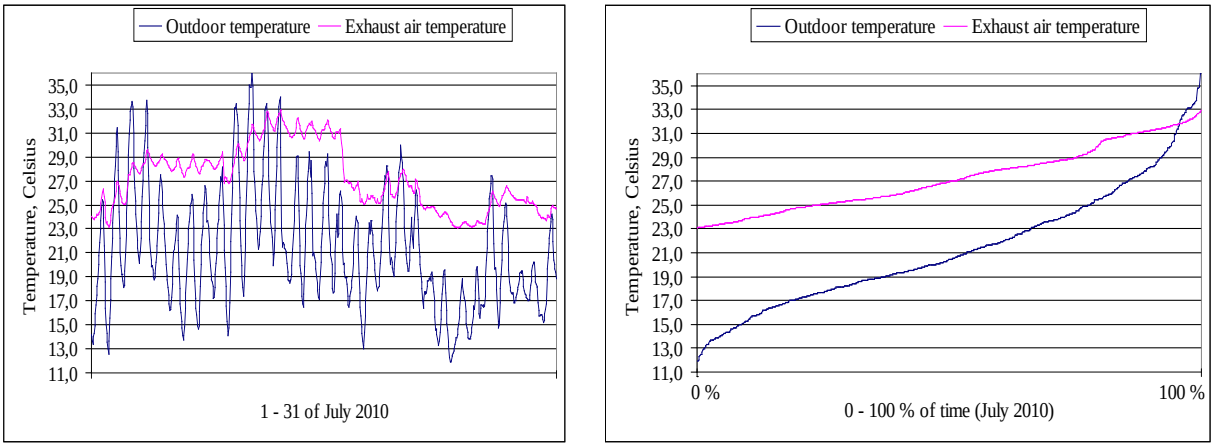

Fig. 1. Temperature loggings during July 2010 from the real Passive House in Lambohov, to the right presented in a duration diagram.

3. Comfort cooling strategies

The simulated comfort cooling strategies and their implementations in IDA ICE are here presented.

3.1. Integrated and external window shading

Integrated and external window shadings of separate types are used. In the simulations the integrated window shading is controlled by the solar radiation, the time of the day and the indoor temperature. It is activated if the direct normal radiation exceeds 100 W/m^2 and if the room temperature is higher than 22 °C. For the integrated shading the solar gains factor (g-value) equals 0.14, the short-wave shading coefficient (T-value) equals 0.09 and the U-value equals 1.0. Moreover, the integrated window shading is not used on the east façade since it could make the apartment too dark inside. This restriction is not made on the use of the external window shading, where an awning is implemented on every window at all times of the day.

3.2. Airing with windows

In contrast to shading, airing with windows is due to safety reasons only allowed certain hours of the day and only with the windows on the second floor. The hours for airing are set to 18:00-22:00 but only if the room temperature is higher than 22 °C and higher than the outdoor temperature. In that case the windows will be 25 % opened.

3.3. Increased ventilation

When the ventilation system is used as a mean to remove excess heat, the ground state of the CAV-ventilation and its airflow of 45 l/s is increased to 90 l/s.

3.4. Airing with a roof hatch

As an option for airing with windows which is only allowed daytime, a roof hatch is implemented in order to investigate how much night-time airing can lower the temperature. It is assumed that security measures are taken in order to keep it open night-time. The roof hatch has an area of 0.7 m^2 and is located in the upper hall. It is intended to be open between 18:00–08:00 but only if the indoor temperature in the room is higher than 22 °C and higher than the outdoor temperature.

3.5. Cooling machine

The cooling machine is connected to the FTX-system which distributes the cooling to the building. The set-point for the exhaust air temperature is 24 °C and the minimum allowed supply air temperature is set to 15 °C.

3.6. Evaporative cooling

Evaporative cooling is investigated as an alternative to the cooling machine. It is connected to the FTX-system and has an efficiency of 80 %. The set-point for the exhaust air temperature is 24 °C and the minimum allowed supply air temperature is set to 15 °C.

4. Results

The simulation results in Fig. 2 show that passive cooling can provide sufficient cooling during the hottest part of the summer. The best cooling result is obtained when both shading and airing strategies are used. Here, the most effective strategy is the combination of the external window shading and the roof hatch. The roof hatch proves to be the best single way to lower the temperature in the apartment. Fig. 3 shows that the combination of the increased ventilation with window shading also can provide a satisfactory cooling result. If the cooling machine or the evaporative cooling is used, the best combination are in both cases either with the external window shading or with the increased ventilation as can be seen in Fig. 4 and Fig. 5. The cooling machine has a better cooling performance than the evaporative cooling but with the standard ventilation airflow none of them can lower the temperature to a comfortable level. Higher ventilation or lower supply temperature than 15 °C is required.

The electricity use of the fans during the ten simulated days is 14.4 kWh/10 days with the standard flow of 45 l/s. The extra power demand for the doubled ventilation is 100 kWh/10 days. In comparison the power demand of the cooling machine for reducing the supply air temperature to 15 °C is about 30 kWh/10 days (cooling demand 100 kWh /10 days) but the temperature reduction is less.

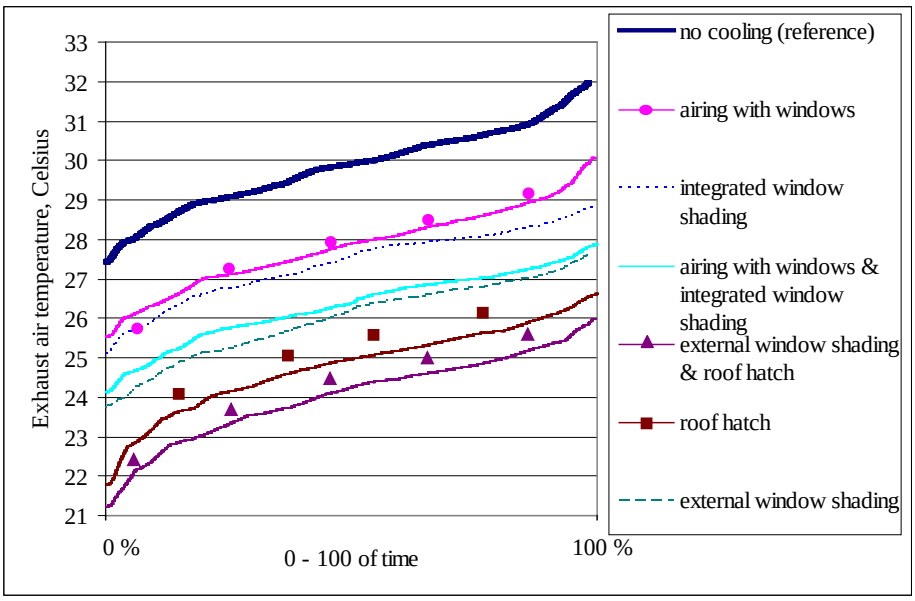

Fig. 2. Simulation results with passive cooling methods. The period is 1 – 10 of July.

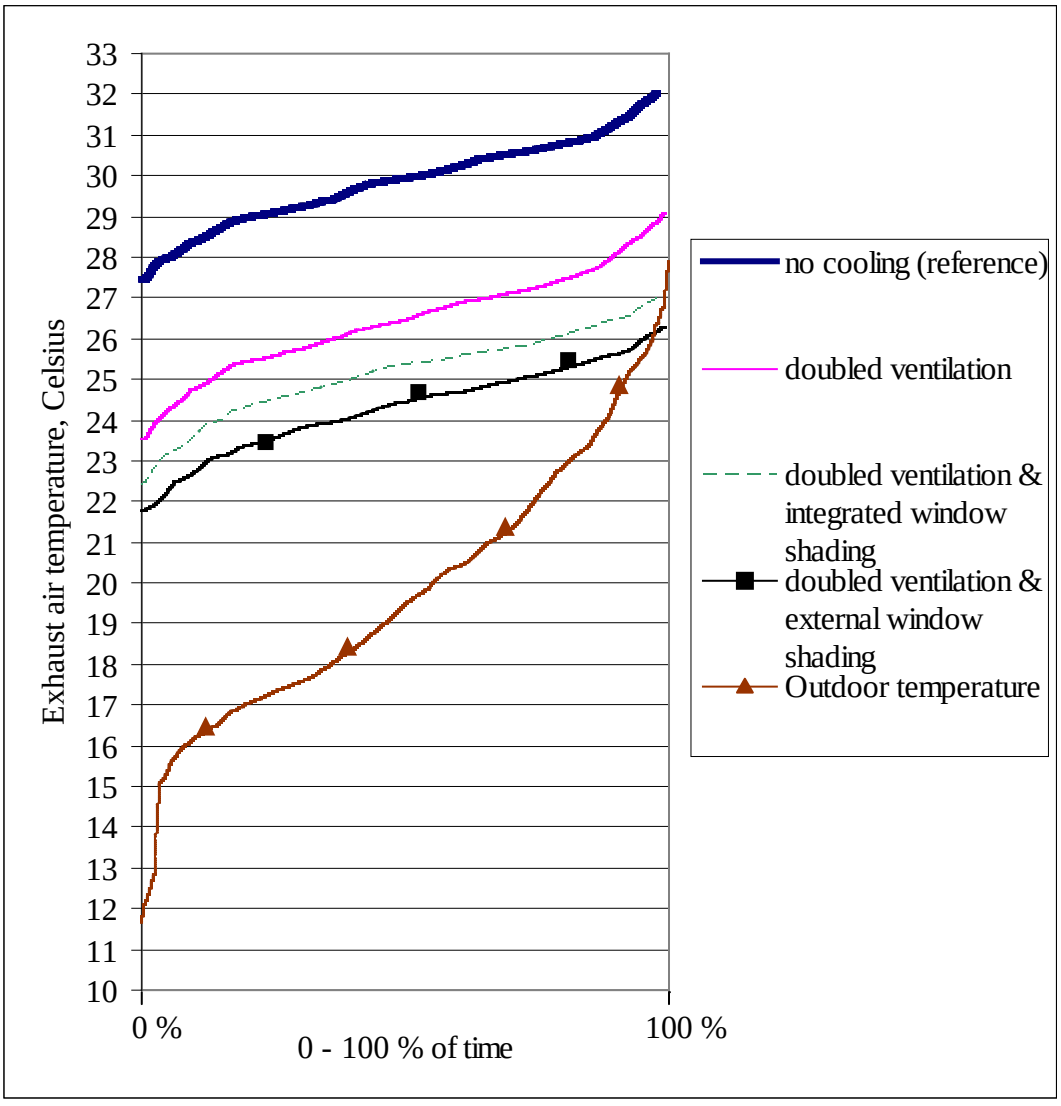

Fig. 3. Simulation results with an increased airflow in the ventilation system, with and without window shading. The period is 1 – 10 of July.

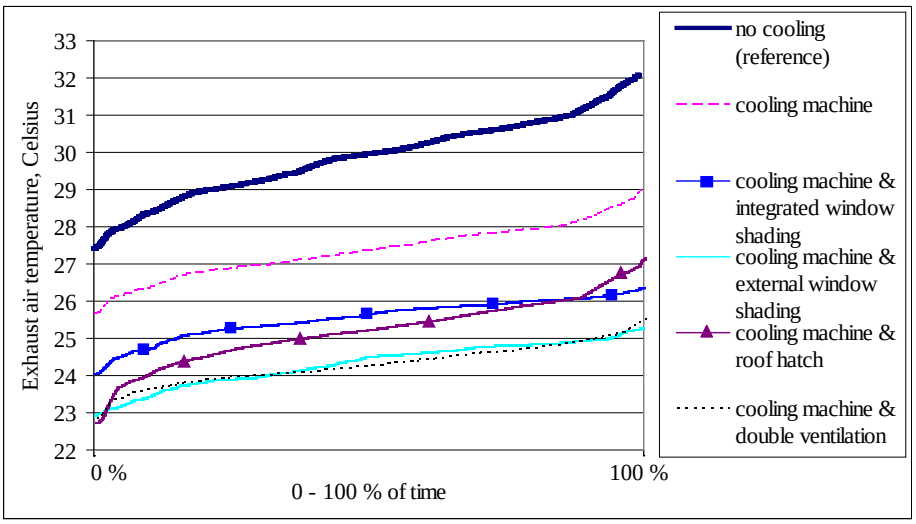

Fig. 4. Simulation results with the cooling machine, with and without passive cooling methods or an increased airflow in the ventilation system. The period is 1 – 10 of July.

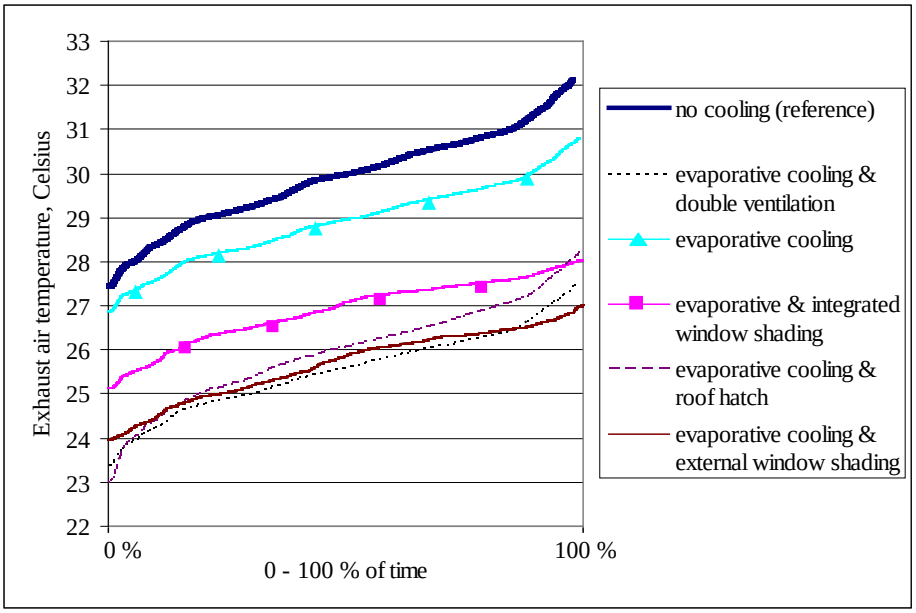

Fig. 5. Simulation results with evaporative cooling, with and without passive cooling methods or an increased airflow in the ventilation system. The period is 1 – 10 of July.

5. Conclusions

The simulation for the reference case agrees well with the practical experiences of excessive summer temperatures in Passive Houses. It seems likely that passive cooling strategies can provide sufficient cooling during the warmest part of the summer. A combination of shading and airing strategies should be used for the maximum cooling effect. However, in these simulations it is assumed that sophisticated devices are controlling the airing and shading based on the indoor and outdoor temperature and the solar radiation. Such devices are normally not yet installed in Passive Houses but nevertheless, the results demonstrate the potential with the use of passive cooling. On the other hand Fig. 2 illustrates that the best result of the passive cooling strategies is obtained with the roof hatch and the external window shading, two strategies that necessarily do not need any controlling devices. Instead of using a roof hatch, an already existing window could be kept open night-time, this would also require that security measures are taken but the installation of a roof hatch would

not be needed. In addition, since an increased airflow in the ventilation system appears as an effective tool for lowering the indoor temperature, it should be made possible for the dwellers to control the airflow after their needs. Neither the cooling machine nor the evaporative cooling can by itself lower the temperature to a comfortable level, it has to be combined with higher ventilation or the supply temperature must be allowed to be lower than 15 °C.

The outcome of these results shows that options for passive cooling should be applied before any cooling machine or such equipment is installed. Since Passive Houses can contribute to increased energy efficiency in the housing stock, it is of great importance that they are well adapted to the summer climate, ensuring a comfortable living.

The outcome of simulations of this sort is highly depending on the implementation of the internal gains and the compilation of user related data used for this in this paper only offers an indication of these amounts. Furthermore, the amount of solar gains summertime is responsible for the excessive temperatures and different simulation software will differ in this result (Lundh and Wäckelgård 2009). Other sources of error come from the software's limitation in computational accuracy. Additionally, a more exact study of the ventilating capacity of a single roof hatch or window could be made using CFD-tools (Computational Fluid Dynamics). In our case the simulated reference case agrees very well with the actual temperature loggings in the house as can be seen by comparing Fig. 1 and 2.

Abstract: Climate change made governments introduce energy performance regulations like the Energy Performance of Buildings Directive (EPBD) and these regulations will be tightened in the future. However, the real performance of current low energy dwellings does not always match the theoretical expected performance and therefore lessons can be learned from the real performance of these houses for future low energy houses.
For four low energy houses, energy consumption and indoor climate have been analyzed through calculations, monitoring and occupant surveys. All houses appeared to be more energy saving in theory and practice than the current Flemish building standard, but with large differences between the houses and with still a large potential for improvement, especially the heating systems. Also the measured CO_2 concentrations in winter strongly differed between the houses and the occupants' perception of indoor air quality did not always match the measured quality. The weakest point according to the surveys was summer comfort, especially in the sleeping rooms, but this was not always confirmed by measurements and calculations. This shows that common comfort theories are not adapted to dwellings and that summer comfort should be evaluated in detail during design. These lessons should be taken into account when designing and evaluating future low energy houses.

Keywords: *Post-occupancy evaluation, Energy, Thermal comfort, Indoor air quality, Occupant behavior*

1. Introduction

The challenges of climate change and the exhaustibility of natural resources made governments all over the world introduce energy performance regulations in order to avoid the construction of energy devouring buildings. These regulations will be tightened in the future, as is already the case with the recent recast of the EU EPBD. Architects and building occupants however do not wait for the tightening to build dwellings that performa better than the legal standard. In Flanders, Belgium, in 2006 at the introduction of the Flemish EPBD version (called EPB), only 2.5% of all new dwellings performed at least 40% better than the legal standard (according to the theoretical calculated energy performance level) whereas in 2009 already 11% of all new dwellings performed at least 40% better than the legal standard [1]. Weak point is that these are theoretical performances and that there often is a discrepancy between theory and practice [2,3]. In order to improve the real performance of future low energy houses, the knowledge of real energy and comfort performance of present low energy houses should be increased. In this research the post-occupancy performance of four low energy houses has been analyzed for the aspects of energy consumption and indoor climate (thermal comfort and relative humidity (RH) in winter and summer, and indoor air quality (IAQ) in winter). Underlying to the analysis were following questions: (1) are these houses as energy saving in practice as calculated in theory? and (2) is the indoor climate satisfactory in these houses, both in winter and summer? In this paper, first, the methodology is presented with a description of the four houses and the calculation method for energy consumption and summer comfort. Also the monitoring campaign is described as well as the survey and the evaluation criteria for energy and indoor climate. Then, the main results of this evaluation are presented and discussed. Finally conclusions are formulated on lessons to learn from this post-occupancy evaluation for the design of future low energy houses.

2. Methodology

2.1. Description of the low energy houses

The dwellings are all located in the province of Limburg, Flanders, near the border with The Netherlands and Germany. Three dwellings are newly constructed and one old dwelling is thoroughly renovated. House 1, 2 and 3 are designed (or renovated) by the same architect, chosen by the occupants for her expertise with energy saving dwellings, whereas for the architect of house 4, it was his first low energy house and also the occupants were not familiar with low energy concepts. The main characteristics of the dwellings are given in Table 1.

Table 1. Characteristics of the dwellings

	House 1	House 2	House 3	House 4
				
Construction year	2005	2004	1830, renovated in 2002	2007
Typology	Detached	Detached	Detached	Semi-detached
# occupants	6	5	5	3
Volume	687 m³	952 m³	770 m³	629 m³
Floor area	294 m²	333 m²	278 m²	252 m²
Heat loss area	549 m²	549 m²	530 m²	419 m²
U_{mean}	0.30 W/m²K	0.28 W/m²K	0.50 W/m²K	0.30 W/m²K
Glass to floor ratio	24%	18%	28%	14%
Heat production system	Soapstone wood stove + backup boiler on gas	Condensing boiler on gas + wood stove	Soapstone wood stove + electrical heater in bathroom	Condensing boiler on gas
Domestic hot water system	Storage tank connected to wood stove + boiler backup	Storage tank connected to boiler on gas	Storage tank connected to wood stove + electrical backup	Storage tank connected to boiler on gas
Heat emission system	Floor and wall heating	Floor heating and radiators	Stove	Floor heating
Ventilation system	Balanced ventilation with ground pipe and heat recovery, summer bypass	Balanced ventilation with ground pipe and heat recovery, no summer bypass	Mechanical supply, connected to ground pipe, natural exhaust	Balanced ventilation with ground pipe (not yet installed)
Renewable solar energy	10m² thermal collectors	4.7m² thermal collectors	4.14m² thermal collectors	4.8m² thermal collectors

2.2. Calculation of energy consumption and summer comfort

Both the calculation method for energy consumption and the assessment method for summer comfort, applied in this research, form part of the Flemish version of the EPBD (further called EPB). The main principles of these calculation procedures are described below.

2.2.1. Calculated energy consumption

The end energy and primary energy consumption for heating and domestic hot water are calculated with the calculation procedure for the EPB. The procedure is mainly based on the EN ISO 13790(2004). It is a steady state monthly based one-zone model, taking into account the insulation quality of the building envelope, useful internal and solar heat gains, performance of ventilation system and heating system and presence of renewable energy systems. Despite the simplifications, the energy consumption calculated with a monthly based steady state one-zone model is very comparable with the energy consumption calculated with a dynamic multi-zone model [5]. The average indoor temperature is 18°C for heating. The outdoor climate is the Test Reference Year of Brussels, Belgium. In the calculation procedure, the volume of domestic hot water used depends on the building volume and the energy consumption for domestic hot water depends on the performance of the heat production system, presence of a storage tank and a solar collector and length of pipes. Also the auxiliary electricity consumption for pumps and fans is calculated. The EPB considers a primary energy conversion factor for electricity of 2.5.

2.2.2. Calculated risk for summery overheating

In the EPB for dwellings, also the risk for summery overheating is assessed, through the overheating indicator. The indicator is calculated based on the yearly surplus heat gains compared to the set point temperature of 18°C. The surplus gains depend on the overall monthly heat gains (internal and solar), the thermal capacity of the building and the proportion of heat losses to heat gains. For the overheating indicator a threshold value of 8000Kh and a maximum value of 17500Kh is set. Below the threshold value, no risk for summery overheating is expected, above the maximum value the summer comfort is totally unacceptable and the designer is obliged to take measures to improve the summer comfort. Between threshold and maximum value, a real risk for summery overheating is assumed, linearly depending on the distance to the threshold value. This means that it is assumed that in practice, there is a real risk that the occupant will install an active cooling system after the house is built, thus increasing his energy consumption significantly. Weakness of this steady state one-zone model is that summer comfort is evaluated at the level of the overall building, whereas overheating typically is a local and dynamic problem that not necessarily occurs in all rooms of a dwelling. But since this method, as part of the EPB method, is used in Flanders to enhance the awareness of architects for summery overheating, it also has been used within this research to roughly assess the summer comfort.

2.3. Monitoring of energy consumption and indoor climate

In the dwellings, indoor climate and energy consumption are monitored from March 2009 until February 2010. The indoor temperature and RH are measured every 15 minutes with an ONSET HOBO H8 logger in the living room and in a north oriented and a south oriented sleeping room. During the winter (November 2009 till January 2010) also the CO_2 concentration in the living room is measured every 5 minutes with a Telaire 7001, coupled with a HOBO H8 logger. With a maximum distance of 30km between the dwellings, the outdoor temperature and RH are only measured at one location. The energy consumption of natural gas, electricity and wood have been noted by the occupants on at least a weekly basis.

2.4. Survey of the building occupants

Apart from calculations and monitoring, also the occupants are surveyed. Their behavior as well as their perception of the indoor climate is analyzed through a survey on the winter and summer situation. Questions are asked on their presence in the house during daytime, on their

habits of opening windows, setting off the heating system during absence and taking measures against summery overheating during absence. Also occupants have to evaluate their perception of thermal comfort, draft and IAQ through a scale of [-3,-2,-1,0,1,2,3] for thermal comfort, a scale of [0,1,2,3] for draft and [-3,-2,-1,0] for IAQ, for winter and summer for the rooms that are monitored. Also questions are asked on the adaptation of the heating system to fluctuating indoor temperatures (eg. due to change in solar irradiation) and whether any room is uncomfortably warm or cold at a certain time of the day.

2.5. Evaluation criteria for energy consumption and indoor climate

To assess the real performance of the low energy houses and to compare the theoretical performance with the real performance, the following evaluation criteria have been used.

For energy consumption, the monitored consumption of all energy carriers (gas, electricity, wood) in each house is normalized into an end energy consumption in kWh/year per m² floor area and a primary energy consumption in kWh/(m².year). Gas and wood consumption are first normalized for a standard year by means of the degree day method (1800 degree days during monitoring and 2087 degree days in a standard year in Brussels). This is compared with the theoretical energy consumption according to the EPB. Since electricity for household appliances and lighting is included in the monitored electricity consumption, but not in the EPB, both the primary energy consumption with and without electricity is given as a result. However, by excluding the electricity consumption, also the electricity for pumps, fans and eventually electrical backup for domestic hot water is excluded. As the results will show, this makes it difficult to mutually compare the houses.

For thermal comfort, the mean indoor temperature and standard deviation are calculated from the monitored data for winter and summer for the different rooms. Also the percentage of time, the temperature in the different rooms is below, in or above the comfort zone is calculated. For the winter situation a comfort zone of 20°C - 24°C is set for the living room and 18°C - 22°C for the sleeping rooms; for the summer a comfort zone of 23°C - 26°C is set for all rooms. This is based on ISO 7730:1994 [4] for a maximum PPD (Predicted percentage of dissatisfied) of 20%. Weak point is that this comfort theory is developed for office buildings. In fact, none of the current comfort theories (Fanger, adaptive model, weighted temperature exceedings,…) is adapted to assess thermal comfort in dwellings and certainly not in sleeping rooms. The measured results for thermal comfort are compared with the perceived thermal comfort by the occupants and with the calculated overheating indicator.

The IAQ is assessed by means of the RH and the CO_2 concentration. The comfort zone for RH is 30-70%. For CO_2 concentration, four IAQ-levels are considered: IDA1 (< 400ppm above outdoor level), IDA2 (400-600ppm above outdoor level), IDA3 (600-1000ppm above outdoor level) and IDA4 (> 1000ppm above outdoor level). An outdoor level of 400ppm is assumed. For a good IAQ normally at least an IDA2 level has to be aimed for. The results are compared with the perceived IAQ by the occupants.

3. Results

3.1. Energy consumption

Table 2 presents the monitored energy consumption for the four houses, with a distinction between yearly consumption of gas and wood for space heating and domestic hot water (row 1 and 2) and yearly electricity consumption for household, lighting, fans and pumps (row 3). In case of house 3, this includes also backup heating for domestic hot water.

Table 2. Monitored yearly energy consumption in all four houses, normalized for outdoor climate

	House 1	House 2	House 3	House 4
Gas [kWh/yr]	3.201	5.577	-	9.301
Wood [kWh/yr]	16.036	1.053	8.992	-
Electricity [kWh/yr]	3.881	5.768	10.188	2.970
Total end energy [kWh/yr]	23.118	12.398	19.180	12.271

Based on these data, the total end energy consumption per year and per m² floor area is calculated, as well as the total primary energy consumption, including and excluding the electricity consumption. Also the energy consumption according to the EPB is calculated, representing the energy consumption for space heating, domestic hot water and auxiliary electrical energy for pumps and fans. Also here the total end energy consumption per year and per m² floor area is calculated, as well as the total primary energy consumption, including and excluding the electricity consumption (here for fans and pumps). These results are shown in figure 1, with the light grey bars representing the monitoring results and the dark grey bars the theoretical consumption. The black bar represents the maximum allowable energy consumption for these houses (in kWh/m²) according to the current Flemish regulation for new dwellings. Although house 3 is renovated and not obliged to meet the regulation for new dwellings, here it is treated as if it were a new dwelling. Results are discussed in section 4.

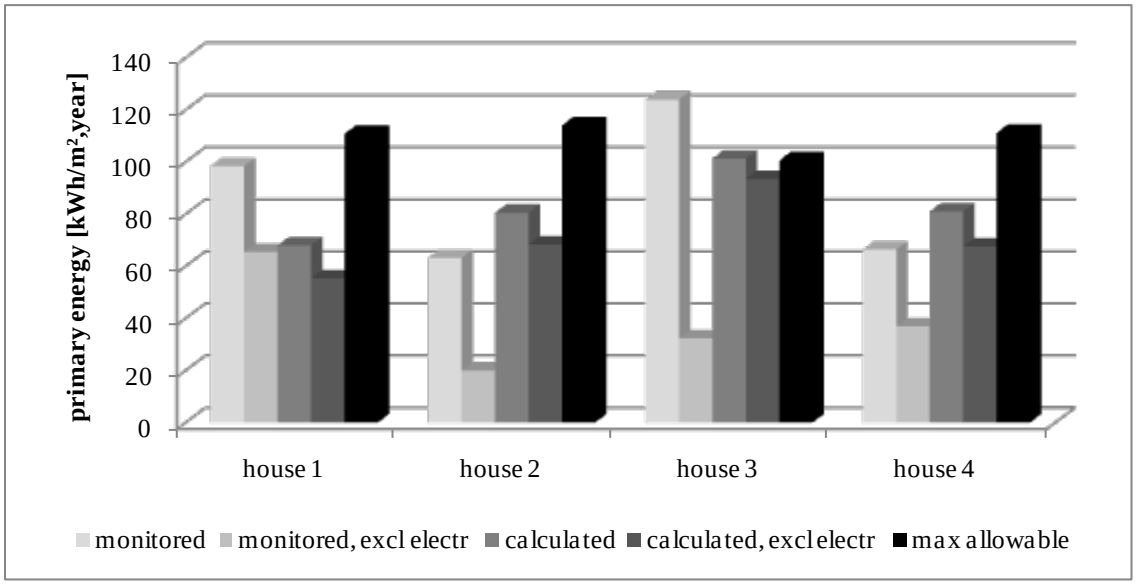

Fig. 1. Comparison of monitored and calculated primary energy consumption (in kWh/m²,year) for all four houses, with distinction between energy consumption with and without electricity consumption.

3.2. Indoor temperature and thermal comfort

Table 3 gives for each house the mean temperature ± standard deviation in the three monitored rooms during the months November 2009 till January 2010 and during the months June till August 2009. For each room also the percentage of time that the indoor temperature lies in the comfort zone is given. For the remaining time in winter, the temperature is nearly always below the comfort zone. For the summer also the percentage of time the temperature is above the comfort zone is presented, as it is an indication for summery overheating.

Table 4 presents the overheating indicator for all houses, calculated as described in section 2.2.2. Based on the threshold and maximum allowable value also the risk that an active cooling installation will be installed afterwards is calculated and presented in table 4.

Table 3. Indoor temperature in winter and summer in living room, sleeping room north and south in all houses

November 2009 – January 2010	House 1	House 2	House 3	House 4
Living room				
Mean temp ± stand.deviation [°C]	22,2 ± 0,7	21,4 ± 0,6	20,2 ± 2,1	20,7 ± 0,5
% time in comfort zone	100%	98%	72%	91%
Sleeping room north				
Mean temp ± stand.deviation [°C]	18,0 ± 1,3	14,8 ± 2,0	18,6 ± 1,7	19,3 ± 0,6
% time in comfort zone	41%	13%	68%	99%
Sleeping room south				
Mean temp ± stand.deviation [°C]	17,3 ± 1,3	15,7 ± 1,7	17,7 ± 1,6	20,3 ± 0,5
% time in comfort zone	25%	8%	31%	100%
June 2009 – August 2009	House 1	House 2	House 3	House 4
Living room				
Mean temp ± stand.deviation [°C]	24,9 ± 1,0	24,0 ± 1,0	24,3 ± 1,8	24,1 ± 1,1
% time in comfort zone	88%	78%	80%	81%
% time above comfort zone	11%	1%	5%	6%
Sleeping room north				
Mean temp ± stand.deviation [°C]	24,6 ± 1,2	23,9 ± 1,2	24,4 ± 1,1	24,5 ± 1,0
% time in comfort zone	81%	72%	82%	87%
% time above comfort zone	10%	3%	4%	8%
Sleeping room south				
Mean temp ± stand.deviation [°C]	24,3 ± 1,4	24,1 ± 1,1	24,8 ± 1,6	24,8 ± 1,3
% time in comfort zone	70%	77%	63%	78%
% time above comfort zone	15%	2%	22%	16%

Table 4.Overheating indicator and risk for active cooling for all houses

	House 1	House 2	House 3	House 4
Overheating indicator [Kh]	13.494	11.548	6.118	8.945
Risk for active cooling system [%]	58%	37%	0%	10%

3.3. Relative humidity, CO_2 concentration and indoor air quality

The RH was within the comfort zone of 30-70% for most of the time. In winter in house 1 and 3, the RH was below 30% during 1% of the time and in house 2 during 5% of the time, but only 0,5% of the time below 25%. In summer only in house 3, the RH was above 70% during 1% of the time. Since human beings are very insensitive for RH and problems with RH are more related to high RH levels (due to risk for moisture damage), these results are very satisfactory, there will be no further discussion on the RH.

Figure 2 shows for each house the percentage of time the different IAQ levels were reached in the living room during the months November 2009 till January 2010.

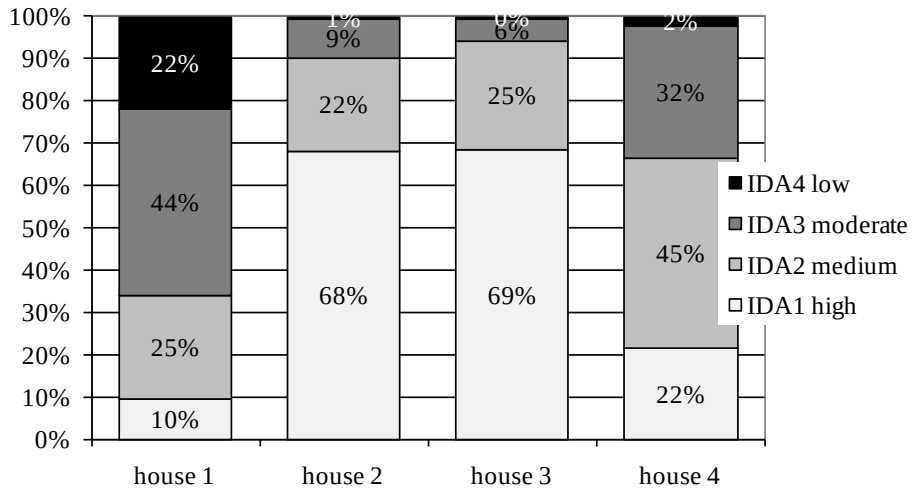

Fig. 2. Percentage of time IAQ levels are reached in each living room during Nov. 2009 till Jan. 2010.

4. Discussion

4.1. Energy consumption

As figure 1 shows, the monitored primary energy consumption is lower than the maximum allowable for all houses, except for the renovated house 3. However, the monitored consumption includes also the electricity for household and lighting, which is not included in the maximum allowable value. Furthermore, the calculated energy consumption assumes a mean indoor temperature of 18°C, whereas the monitored rooms in house 1, 3 and 4 have an overall mean indoor temperature higher than 18°C, except for house 2. This way, it can be concluded that all houses perform better than the current legal standard. The results also show that the houses with condensing boiler (house 2 and 4) perform best and better than calculated in theory. In house 1 the wood consumption is very high, with an energy consumption for heating, higher than the calculated energy consumption (bar 2 vs. bar 4 in figure 1), whereas in house 3 the electricity consumption is very high. For house 1 this might be explained by the higher indoor temperature in the living room, and for house 3 by the electrical backup heating of domestic hot water and the electrical heater in the bathroom. Remarkably, none of the houses has temperature setback during night or absence, probably due to the high inertia of the installed system (soapstone wood stoves and/or floor heating). The occupants with soapstone stove slightly complain about the fact that the massive heating system is not easily adaptable to changing temperatures, thus causing overheating in winter at some moments.

4.2. Thermal comfort

The measured temperature in winter in the living room remains in the comfort zone for all houses, except for house 3, where the temperature slightly decreases during cold days. However, for the occupants the indoor temperature is never too cold, only sometimes slightly too warm. For the sleeping rooms, only the occupants of house 2 complain about the cold temperature in the north oriented sleeping room, but they never choose to put on the radiators in this room. For the other sleeping rooms of all houses, there were no complaints, although the measurements showed lower mean temperatures. This is probably due to the fact that these rooms are only used for sleeping and not for studying.

For the summer, the calculations showed a risk for overheating in house 1 and 2, but hardly any risk for house 3 and 4. However, in house 1, despite temperatures > 26°C during 10-15% of the time in all rooms, the occupants only had small complaints of overheating in the living

room and the south oriented sleeping room. In house 2, the monitoring did not show any overheating, although the occupants complained of overheating in the living room and the south oriented sleeping room and the overheating indicator indicates a 37% change that active cooling will be installed. The occupants of house 3 and 4 strongly complained of overheating in the south oriented sleeping room, which was confirmed by the measurements, but not predicted by the overheating indicator, that only assesses the overall thermal comfort.

4.3. Indoor air quality

Concerning IAQ, the monitoring showed a satisfactory IAQ in the living room of house 2 and 3 during more than 90% of the time. However, the occupants of house 3 were not totally satisfied with the IAQ and also had complaints about draft. The occupants of house 2 had no complaints on the IAQ. The IAQ was worst in house 1 and this was also confirmed by the occupants. In despite of the presence of a balanced ventilation system, they ventilate the sleeping rooms by opening windows and the living room by opening the door between sun porch and living room. They also confessed to adapt their behavior depending on the CO_2 value on the monitoring equipment. In house 4, the moderate IAQ can be explained by the fact that the balanced ventilation system was not yet installed. The occupants only ventilated by opening windows in the north oriented sleeping room in the morning.

5. Conclusions

This research shows that although the four houses are performing better than the current legal standard, there still is quite some potential for improvement. Especially the choice and use of the heating system can be improved. The soapstone wood stove has been chosen for its environmental friendliness, but practice shows that control of the system is very difficult. A robust and simple system like the condensing boiler shows to be a more energy saving solution. Furthermore, it can be concluded that there is no adequate comfort theory to assess the thermal comfort in dwellings, as the existing theories are developed for office buildings. Finally, design of low energy houses should not only focus on low energy consumption during winter, but also on good summer comfort to avoid installation of cooling afterwards by less environmentally conscious occupants. To assess the summer performance of a dwelling, summer comfort should be evaluated in detail during design and on room or zone level, based on an appropriate comfort theory.

Abstract: In a research collaboration between the National Institute of Advanced Industrial Science and Technology (AIST) in Japan and Uppsala University switchable mirrors have been evaluated from an energy perspective using energy simulations for smart windows based on gasochromic switchable mirrors. Optical properties and U values for the transparent and reflectivestates are used as input for the energy simulations. A test room has been built and is located in Nagoya, Japan. Simulations on energy use for smart windows based on switchable mirrors have been compared between three energy simulation tools. The simulations show good agreement and the simulation results also address the importance of a good control strategy for the smart windows.

Keywords: *Switchable Mirrors, Smart Windows, Energy Simulations, Gasochromic windows*

1. Introduction

A step towards a society not based on fossil fuels might be to use more renewable energy. Another step is energy conservation. Smart or switchable mirrors can be one way to conserve energy within buildings. They can reduce cooling needs in warm and/or varying climates since the transmittance of light and hence the solar heat gain factor can be reduced. This reduction can be achieved when people are present to give a comfortable level of daylight and when people are not present adapted to a level which leads to the lowest energy need for the building. The control strategy of such windows is important for their energy performance [1, 2].

In this study the focus has been on smart windows based on gasochromic switchable mirrors based on metal hydrides [3]. The state of the window is changed using a gas mixture with argon and hydrogen to turn the window to a transparent state and using a gas mixture with oxygen to revert the window back to a reflective state. This means that it is necessary to combine a switchable glass in a window of at least two panes and control the window by letting in either gas mixture in between the panes.

2. Methodology

2.1. Energy simulations

Proper energy simulations on smart windows require that the simulation tool can handle building components with varied properties over time. In this project three simulation tools were used. WinSel is a static window simulation tool developed at Uppsala University, VIP Energy [4] is a commercial dynamic building simulation tool and eQuest [5], which is also a dynamic building simulation tool developed by Lawrence Berkeley National Laboratory. Meteorological input data have been obtained from the software tool Meteonorm [6].

2.1.1. WinSel

WinSel is a software tool for evaluating and comparing windows. The software calculates the energy for heating and cooling caused by the windows as a building component. The purpose

is to be a simple tool for selecting windows. Using the window properties solar gain and U value, different windows can be compared for a building located in a specific climate using just balance temperature and a climate data file as input. The WinSel simulation parameters can be found in table 1. Due to the simplicity of the program, it is suitable as a tool for selecting the right type of window for a certain building. The result achieved from the program is the energy balance for the heating season and the cooling season. The energy balance is calculated per square meter glazing area from the equation:
Energy balance = Solar heat gain - Thermal losses

Table 1. WinSel simulation parameters.

Parameter	Value
Climate (from Meteonorm 5.0):	Nagoya
Ground reflection	20%
Building balance temperature	12°C
Allowed temperatures	20-26°C
U value, transparent state	2,40 W/m^{2}K
g-value, transparent state	50%
T_vis, transparent state	35%
U value, reflective state	1,67 W/m^{2}K
g-value, reflective state	6%
T_vis, reflective state	5%

WinSel can simulate smart windows with variable solar gain, g-value, and variable thermal performance, U value. In the software the g-value and the U value can be time dependent and are regulated using different control strategies. Six different control strategies have been developed to exemplify different approaches for controlling smart windows:

EO – "Energy optimization" means that the windows are always kept in the state which is best from an energy perspective. In the simulations the windows are kept in mirror state whenever there is a cooling need and in a transparent state whenever there is a heating need.

DO – "Daylight optimization" means that the windows are in a state which is optimized from a daylight perspective. The perpendicular component of the transmitted direct solar radiation was thus regulated by the switchable mirror in the window to a maximum of 200W/m2. This mode of the control mechanism reduces annoying glare when the sun is low in the sky and when the solar irradiation is close to perpendicular to the window. Solar radiation at glancing incidence angles does not turn the window into a reflective state.

O1 – "Office 1" mode corresponds to having the window in "daylight optimization" mode between 7:00 a.m. and 6:00 p.m. and otherwise in "energy optimization" mode.

O2 – "Office 2" mode corresponds to having the window in "daylight optimization" mode during half of the time between 7:00 a.m. and 6:00 p.m. and otherwise in "energy optimization" mode. This is a simplified way of simulating that the office is occupied only during half of the time.

R1 – "Residential 1" mode corresponds to having the window in "daylight optimization" mode between 6:00 a.m. and 8:00 a.m. and also between 4:00 p.m. and 10:00 p.m. and otherwise in "energy optimization" mode.

R2 – "Residential 2" mode corresponds to having the window in "daylight optimization" mode during half of the time between 6:00 a.m. and 8:00 a.m. and also between 4:00 p.m. and 10:00 p.m. and otherwise in "energy optimization" mode. This is a simplified way of simulating that rooms in the building are only occupied during half of the time.

The different control strategies can easily be modified. Over a year the time resolution of an hour is assumed to be averaged and the simplifications of the strategies is a way to make the results more comprehendible. Switchable windows can then be evaluated and compared to static windows at different locations and in different buildings.

2.1.2. VIP Energy and eQuest

VIP Energy is a commercial software simulation tool for whole building simulations and eQuest has been developed by the Lawrence Berkeley National Laboratory and is based on DOE2.2. These software tools are based on dynamic simulation models and thus take the heat storage in the building structure into account. They also take the air flows in the ventilation system and leakage in other building components into account.

Since user precence is assumed to be time dependent and this controls the window state, it is desirable if the software tool can handle time dependent building components. Unfortunately this is not the case for VIP Energy. Instead separate simulations were made for transparent and reflecting states and the energy needs were summarized hour by hour manually. To be able to do this we had to set the indoor temperature to a constant 22°C for the whole year. For eQuest the indoor temperature were allowed to vary between 20-26°C. Other simulation parameters were kept as similar as possible and a list of the most important can be found in table 2.

Table 2. Common building parameters used in VIP Energy and in eQuest.

Parameter	Value
Climate (from Meteonorm 5.0):	Nagoya
Ground reflection	20%
Ventilation volume	14 m^2
Floor area	5.75 m^2
U value, roof	0.49 W/m^2K
U value, south/west wall	0.33 W/m^2K
U value, window	2.40/1.67 W/m^2K

3. Results and Discussion

3.1. WinSel

The results from the WinSel simulations show the importance of the control strategy. For a south facing window for example the energy balance of the window switches from negative to positive with more advanced control strategies for the Nagoya climate as can be seen in figure 1. The energy balance results are presented per square meter window area.

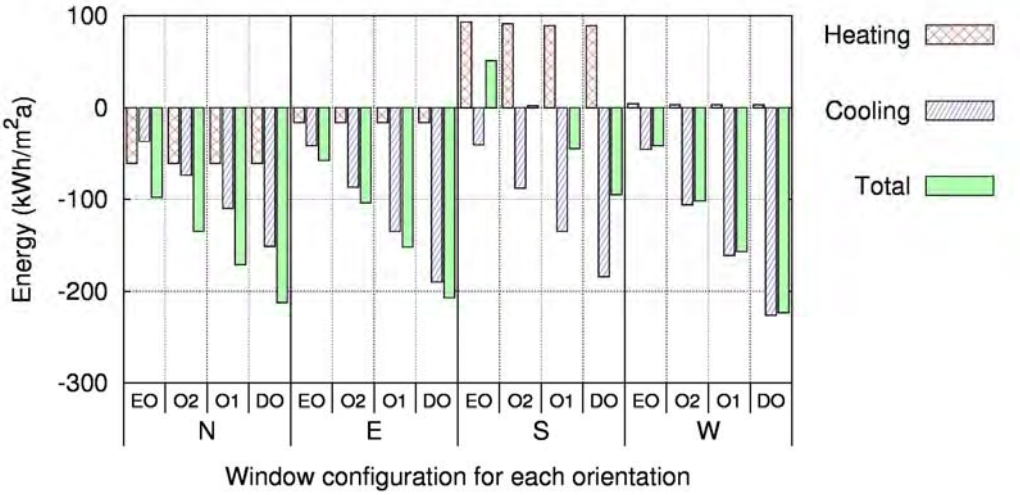

Fig. 1. Simulated energy balance for the test building located in Nagoya using WinSel.

3.2. VIP Energy

The whole building simulations made in VIP energy show similar results, found in figure 2, but are presented as energy use per square meter floor area. Comparisons are also made with static windows having g values equal to 30 and 70 % respectively showing that the switchable windows outperform the static windows if using control strategies "O2" (office with presence detectors) or "EO" (switchable window always controlled for a low heating and cooling need.)

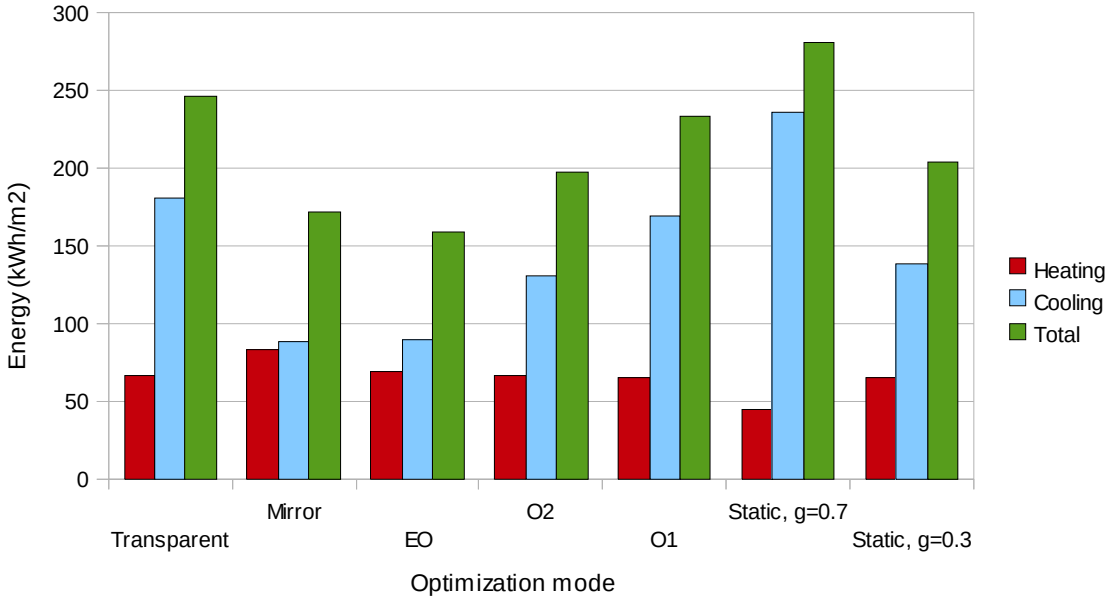

Fig. 2. Simulated energy balance for the test building located in Nagoya using VIP Energy.

3.3. Comparisons between three simulation softwares

Comparisons between simulations made in VIP Energy, eQuest and WinSel show differences of about 20% for the total energy need. Unfortunately the building models in the simulation softwares cannot be set up in exactly the same way. In VIP Energy there is no built in support for time dependent components. Therefore the indoor temperature had to be set to a constant value at 22°C and two separate simulations for transparent and reflective state were made and the results from these simulations were summed up manually. It is reasonable that this leads to a higher than expected energy need, as also can be seen in figure 3.

The results for WinSel and eQuest are lower but an explanation to the somewhat higher energy need given by the WinSel simulation software might be that the balance temperature is assumed constant over the entire year. One should also remember that this is a static simulation tool and has a very simplified way of handling heat storage within the building.

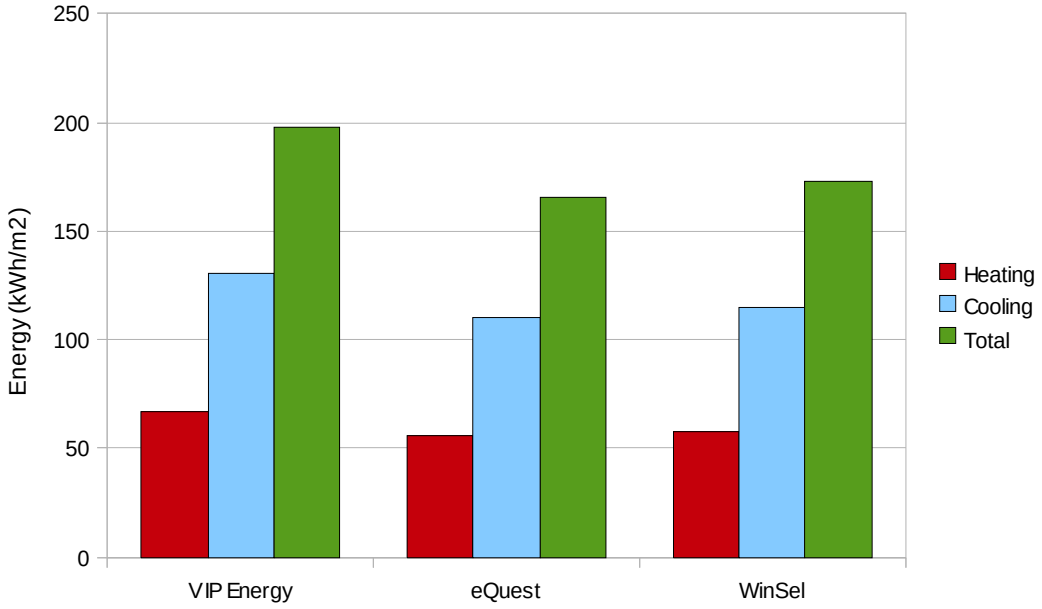

Fig. 3. Simulated energy balances for "O2" optimization mode (office with presence detectors) for three different simulation software tools for the test room located in Nagoya.

Abstract: The population and urbanization growth will lead to more dependency on mechanical cooling which is not a long term sustainable strategy. Therefore, it is important to ensure all elements involved in urban sustainable developments are well performing. Of these elements, building materials have an essential role to adjusting outdoor heat environment transfer to the indoors. As part of the research society work in Cairo towards minimizing the "black cloud" generated due to burning rice roots and straw after cultivation, this paper studies the thermal performance of a novel manufactured brick using rice straw fibbers on a cement-aggregate mixture basis. It has been designed to provide a recycled constructional biomaterial, to help healthy urban environment and reduce cooling energy demands. ENVI-met BETA5 numerical simulations were held for an existing microclimatic area to assess the impact of this brick on outdoor comfort in terms of Predicted Mean Vote, PMV, as well as for indoor conditions in terms of ambient air temperature. Among the many mixtures to produce the least bricks number suitable for transportation (1000 bricks), only two were optimum for cost, mechanical and thermal properties. In comparison with normal cement brick, PMV records showed fixed values using the selected rice-straw based cement brick mixture. In evening, it recorded less mean outdoor air temperature as different wall heat interaction occurred due to the new brick k-value. This suggests that the new brick balances between indoor and outdoor needs and contributes to further investigations in terms of energy conscious urban planning.

Keywords: *Rice-straw cement brick, thermal impact assessment.*

1. Introduction

Cooling energy consumption increase due to climate change [1-5] and due to unsustainable urban developments [6-8] has motivated research society in Egypt towards urban planning applied solutions by urban form design [9-12]. And despite the initiative building construction energy code [13] to legislate energy saving conscious materials for single building, there still no consideration for the recycled materials and biomaterials specially with regard to the large urban development movements around major cities of Egypt. From this standing point, rice crop is considered one of the major agriculture products in the world and in Egypt as a food supplementary as well as many by-products using its remnants and residuals after cultivation. Agriculture by-products are acknowledged as biomass energy source [14], as low cost building materials [15] and as reinforcing materials [16], whereas all these approaches stand as recycling strategies to reduce environmental impacts such as increase of CO_2 emissions [15, 17].

Rice-straw based brick is one of the agriculture by-products internationally acknowledged such as through the development of either clay sand or cement mixtures with rice-straw [18]. In India, [19] presented the rice-straw based cement panel but didn't consider the commercial sizes of brick, or its thermal properties on a neighborhood scale which is considered a local scale from a climatology point of view.

In Egypt what is so called a black cloud is basically attributed to two reasons; burning the remnants of rice straw and the brick industrial pollution. Rice straw residuals per year is around 3.5 million tons, of which about 1.5 million tons is used in production of organic

fertilizers, to be used with storage of some crops (onions - potatoes), plantation of non-traditional crops (mushrooms) and to feed farm animals instead of hay [20].

A wasted amount 2: 2.5 tons per year of rice straw are disposed of burning which has a big share in the formation of the black cloud specially in southern delta governorates and almost whole Greater Cairo specially in winter when humidity settles the suspended smog [19] which causes a serious health problem. The ministry of state for environmental affairs, MSEA, in cooperation with many sectors started establishing factories in delta for composting and converting rice-straw to other forms such as untraditional fertilizers, thermal gas and bio fuels but a recycling towards involvement in construction industry such as low-cost housing materials hasn't been approached yet [17].

2. Methodology

The main objective of the research is to preserve the environment benefit from rice straw recycling so that a low cost building material is produced and sustainable implications on a neighborhood scale can be achieved in terms of energy saving and thermal comfort. The Egyptian standards for the concrete work was the base of the brick sample and then some differentiations in the components were done [21, 22].

2.1. Field work

The starting blend idea was the addition ratio of rice straw to mix the concrete bricks to replace the aggregates (Haswa) part as filler and for non-loaded bearing brick to achieve less dense as possible to save the cost of the structure of the building, less cost as possible to achieve an economic retrofit, and enough coherent brick for the trading and handling with minimum damage. Research was conducted with more than 250 different mixtures divided into three main groups based on the ratios of sand to aggregates of 2:1, 4:3 and 1:1 with varying amounts of rice straw and cement in kilograms with each ratio as fiber filler, fig. 1. A mixture without using aggregates to reduce the weight and increase the amount of straw was also prepared. The parameters of the density-price were initially compared with its corresponding normal cement bricks (1880:1720 Kg/m^3) manufactured by the National Company of Cement and then on a local scale thermal performance basis to assess their impacts on the pedestrian comfort as well as on the ambient air temperature which is associated with specific indoor climate conditions, comfort, cooling energy demand and green house gases emissions.

Fig. 1: Instrumentations used to prepare the different mixtures' samples.

2.2. Measuring brick properties

In order to assure the strength of each brick sample from each mixture, solid and hollow bricks were produced for the common size 25 × 12 × 13cm, fig. 2. The first set of samples were manufactured on the basis of 4 cm3 aggregate + 4 cm3 Sand + straw + Cement. By gradually increasing the amount of straw to a range of mixtures ranging from 2 kg to 7 kg straw for the same mixture with the change in the percentage of cement added to the mixture from 10: 30 kilograms cement as the volume of the mixture increases with the amount of straw added. Samples with the first increase in the proportion of straw had been inconsistent, even with the increase in the proportion of cement; therefore, according to the mechanical pressure test, other groups of samples have been fixed of sand to aggregate to be 4: 3, 2: 1 and new 15 samples designed to produce only solid brick with a size of 25 × 12 × 6 cm. The most successful mixtures with respect to cost were of the brick blend no.1 and no.4 as fig. 2 and table 1 indicate. Measures were done for samples in the Housing and Building Research Centre in Cairo and in the main laboratories of Major Projects Corp of the Egyptian Armed forces. Results of measure show that all samples of both solid and hollow bricks don't have any color change due to chemical salts' residuals from hydration process. Water absorption factor varied from 4-21% of the brick weight for 25 × 12 × 13cm, 25 × 12 × 6cm and 25 × 12 × 13cm solid, solid, hollow bricks respectively. Adding coloring powders didn't affect any of the mechanical or physical properties of any sample. The most important factor was the brick breaking stress which was best for the mixtures no. 1 and 4 as highlighted in table 1. Samples of each brick mixture have been produces for measurements and analysis purposes with ratios of sand : aggregates and by increasing the amounts of cement and rice-straw in 15 steps, table 1. To produce (1000) bricks of both these two bricks, unlike the samples components amounts produced just for measurements, amount of materials of the brick mixture were for mix. no. 1; 8.5cm^3 sand, 8.5cm^3 aggregate, 42kg straw, 180kg cement and its properties for the less cost of 46.8EGP were 1545kg/m3 density, and 18.7kg/m^2 stress. Mix. no. 4 was 8.0cm^3 sand, no aggregate, 100kg straw, 350kg cement and its properties for the less cost of 48.4EGP were 884kg/m^3 density, and 4.4kg/m^2 stress. The later mixture had to have a compression of about 15% of its height due to the more straw. Cost (on 2005) was calculated according to about 270EGP/tone cement, 10EGP/m^3 of Sand, 25EGP/m^3 of aggregate 50 EGP/tone of rice straw and 80 EGP/tone of stone powder. Despite brick stress varied between 4-20 kg/m^2 which is not compared with the stress of the brick used as bearing walls, but this brick is designed for non-loaded walls usage.

2.3. Numerical simulation:

As the main idea of this paper is to study how biomaterial such as rice-straw based cement brick can modify outdoor-indoor climate in terms of pedestrian comfort and outdoor air temperature T_a, ENVI-met BETA5 urban climate numerical package has been used. Numerical simulations were held to easily simulate neighborhood complexities to help providing design and planning decision support [23]. ENVI-met [24] is a three-dimensional numerical model that can simulate the surface-plant-air interactions of urban environments with a typical resolution of 0.5 to 10m in space from a single building up to neighborhood. It is CFD based but with much improvements than only a package for fluid dynamics' simulations [25]. Simulations using the k-value of the rice-straw based cement brick in comparison with normal cement brick were applied on the 1st of July which is the extreme summer hot day analyzed by ECOTECT2010 [26].

Table 2 show the data input for simulations for brick mixture no. 4 which has the less density and hence the less k-value. Nevertheless, first parameter assessed is the PMV at 1.2m above ground level to represent outdoor conditions modifications in terms of pedestrian comfort. Second is the ambient temperature T_a also at 1.2m above ground level to represent the site air temperature modified after the new brick which gives impression about reductions of indoor cooling demand in comparison of that of using normal cement brick. For these purposes, a case study in Cairo, latitude of 30° 7'N and longitude of 31° 23'E, is a semi-arid mid-latitude climate zone [27], is examined. The case study is part of the Fifth community which is built in late 20th century, as one of New Cairo communities. It lies to the east of the 1st Greater Cairo's ring road, fig. 3.

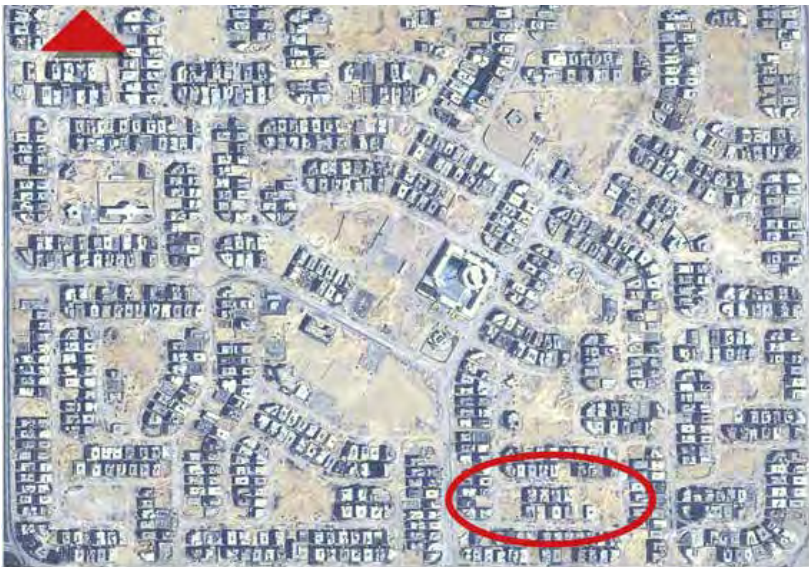

Fig. 3: Location of the case study area on the layout of the neighbourhood located in New Cairo.

Table.2: Inputs used in simulations for both rice-straw and normal cement brick [13, 24, 28].

No.	Parameter	Value
1	*Ta*	301.95˚ K
2	*RH*	59%
3	*V*	3.5 m/s at 10m height
4	k-value Walls	0.41 and 1.25 watt/m.K for rice-straw and normal cement brick respectively
6	Albedo Walls	0.25
8	Human walking speed	1.1 m/s
9	Pedestrian Clo.	0.50

3. Results implications

Basically, as ENVI-met model considers the fabric as heat sink for the outdoor environment, a heat exchange should have generated the shift in air temperature as shown if fig. 4. A ir temperature using the normal cement brick T_n is less than its corresponding of the Rice-Straw based brick by about 0.1 ˚C early simulation time and the opposite at evening time.

Outdoor temperature was less than indoors attributed to the less k-value of the Rice-straw brick of 0.41 which intercept more outdoor heat compared with 1.25 k-value for the normal cement brick. This clarifies why pedestrian comfort in terms of PMV hasn't any change in its values which can be attributed to the holistic nature of PMV as it considers all environmental and personal aspects which haven't been changed except the air temperature, therefore there was no need to add PMV figure. Just to mention not to list these factors affecting PMV; the outdoor radiation environment and the walls reflectivity factor stayed fixed in both simulations and in turn PMV stayed as it is using both the thermal conductivity k-values for of both brick types.

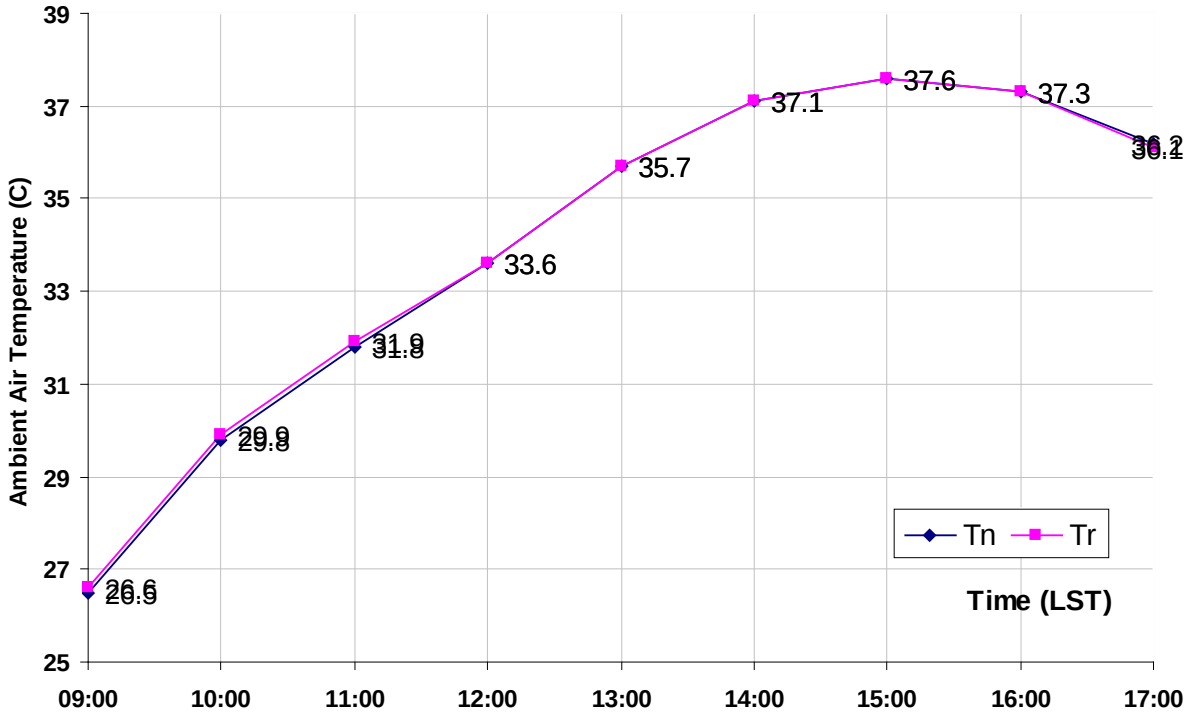

Fig. 4.

4. Discussion and conclusion

Studied in this paper, a new brick type based on the recycled rice-straw was innovated. The rice-straw has replaced part of the aggregates used in the normal cement brick by the try and error to generate a stable blend after which mechanical and thermal experiments have been conducted. Among the many mixtures examined, both mixtures highlighted in table 1 were only the stable but the mixture of 1 sand: 0 aggregate with 2kg cement and 10 straw and a pressure of 0.15 from the brick height, was the most efficient in terms of cost. Eventually, to examine its environmental thermal impact, ENVI-met BETA5 numerical simulations were held to generate pedestrian comfort levels and ambient air temperature.

The fist parameter hasn't been changed due to the fixation of the many environmental and personal factors affecting PMV. The later parameter showed promising changes and in turn a

promising energy savings in the cooling demand especially with respect to the time simulations were held in at which electricity used in mechanical cooling in Egypt suffers many cut off. Moreover, this recycled bio-brick not only helps in decreasing air pollution, but also reduces construction cost and indicate a maximized cost reductions if added to energy reductions. However, further simulations can be on larger scales and different cases' climate conditions to ensure quantitevily such numerical simulation findings in this work.

Abstract: In this study using two low-energy systems to enhance passive cooling and natural ventilation in a solar room have been compared. First system consists of a Solar Chimney (SC) and an Evaporative Cooling Cavity (ECC) and the second one includes a Solar Chimney (SC) and an Earth-to-Air Heat exchanger (EAHE). To determine the heat and mass transfer characteristics of the systems, a mathematical model based on conservation equations of mass and energy has been developed and solved by an iterative method. The findings show that when the cooling demand of the room is 116W and the relative humidity is lower than 50%, the SC-ECC system can make acceptable indoor air conditioning even at ambient 40°C, with weak solar intensity of 200 W/m^2. It is also found that, the proposed system can provide thermal comfort conditions even during the night with zero solar radiation. The results about SC-EAHE system show that when the ambient temperature and cooling demand are high (1500W), proper configurations could provide good indoor condition even at poor solar intensity of 100 W/m^2 and high ambient air temperature of 50°C. Comparative survey shows the SC-EAHE system is the best choice for buildings with poor insulation at day time, but SC-ECC system is better for night ventilation and cooling purposes especially in arid climates.

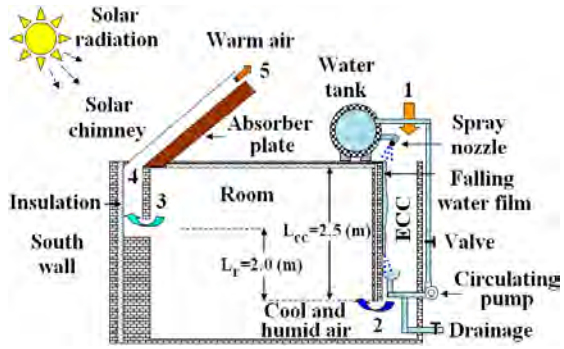

Fig. 1. Schematic diagram of SC-ECC system.

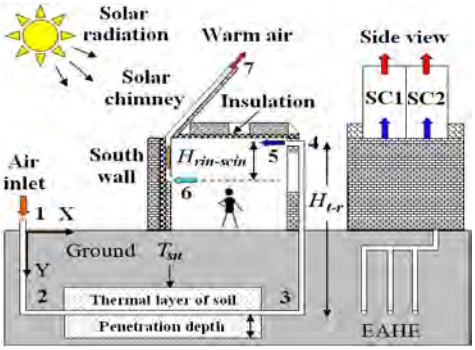

Fig. 2. Schematic diagram of SC-EAHE system.

1. Introduction

In order to reduce global warming and to reduce electricity peak demands during summer time low or zero energy cooling systems are required. passive cooling applications shall offer great advantage and it is growing at an increasing rate worldwide. These systems had attracted much attention of investigators and researchers. Giabaklou and Ballinger [1] presented a method of passive cooling in low-rise multi-storey buildings through a simple water cascade associated with openings and balconies of individual. This system applies the evaporative cooling technique to reduce ambient air temperature by passing air over the water falling film. Manzan and Saro [2] studied a system consisting of a ventilated roof with a wet lower surface of the cavity which flows the external air. They investigated thermal performance of the system by numerical modeling of evaporative cooling process through the chimney. Dai et al. [3] presented a new passive cooling system for humid climate using the solar chimney and adsorption cooling system. They showed that the system increases the rate of ventilation and provides the cooling without increasing humidity of the room. Chungloo and Limmeechokchai [4] experimentally investigated the performance of a system consisting of a solar chimney and water spraying system that was placed on the roof under hot and humid climate. They reported that the system performed well in high ambient temperature. Maerefat and Haghighi [5] presented another technique, using a system consisting of a SC and an ECC. The capability of the system to meet the required thermal needs of individuals, the effects of main geometric parameters on the system performance and the dependence of the system performance on outdoor air temperature was also studied. Maerefat and Haghighi [6] introduced and investigated integrated EAHE-SC system. They showed that the SC can be perfectly used to power the underground cooling system during the daytime, without any need for electricity.

Here, using SC-ECC and SC-EAHE systems to enhance passive cooling and natural ventilation in a solar room have been compared together. Figs.1 and 2 illustrates a schematic plan of the two systems. The SC consists of a glass-made surface faced to the south and an absorber wall. EAHE consists of horizontal long pipe placed underground. The air gets warmed in SC, and by natural convection mechanism, the outside air is sucked-in through the pipe or ECC. It will be shown that these systems can provide good indoor condition in accordance with the Adapted Comfort Standard (ACS) (Fig. 3). ACS does not recommend the ventilation rate. Therefore, the minimum ventilation rate is set around 3 ACH [7].

2. Problem formulation

The modeling includes models of SC (Fig. 4), ECC (Fig. 5) and EAHE (Fig. 6). The following assumptions are made in this analysis.
1. The air temperature at the room is uniform.

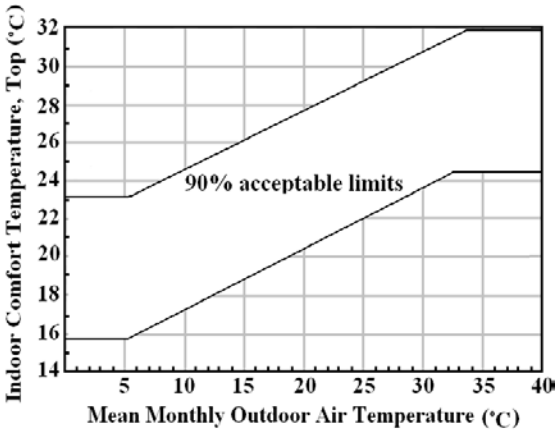

Fig. 3. Adaptive Comfort standard.

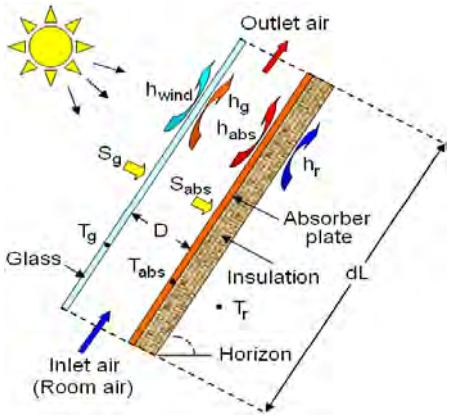

Fig. 4. Diagram of the heat transfer in the SC.

2. Only buoyancy force is considered and wind induced natural ventilation is not included.
3. The flows in the channels are laminar and hydro dynamically and thermally fully developed.
4. The glass cover is opaque for infrared radiation.
5. Thermal capacities of glass and wall are negligible.
6. The air flow in the channel is radiative non-participating medium.
7. The soil is homogeneous and the soil type does not change along the channel.
8. Thermal resistance of water film is negligible.
9. The spray enthalpy is negligible.
10. The air enthalpy is expressed as linear function of wet bulb temperature.
11. The Lewis number correlating heat and mass transfer is 1.0.
12. All thermo physical properties are all evaluated at average temperature.
13. The system is at steady-state condition.

2.1. Mathematical modeling of SC-ECC

An element of the model for SC is shown in Fig. 4. In principle and based on the energy conservation law, a set of differential equations are obtained along the length of SC [5].

$$S_g A_g + hr_{abs-g} A_{abs}\left(T_{abs} - T_g\right) = h_g A_g\left(T_g - T_{fsc}\right) + U_{g-a} A_g\left(T_g - T_{fsc}\right) \quad (1)$$

$$h_{abs} A_{abs}\left(T_{abs} - T_{fsc}\right) + h_g A_g\left(T_g - T_{fsc}\right) = -mC_{fsc}\left(T_{fsc} - T_r\right)/\gamma \quad (2)$$

$$S_{abs} A_{abs} = h_{abs} A_{abs}\left(T_{abs} - T_{fsc}\right) + hr_{abs-g} A_{abs}\left(T_{abs} - T_g\right) + U_{abs-a} A_{abs}\left(T_{abs} - T_a\right) \quad (3)$$

All of coefficients and the overall heat transfer coefficients are obtained from Ref. [5].

An element of the model for ECC is shown in Fig. 5. For the energy and mass conservation law a set of differential equations are to be considered along the length of the cooling cavity.

$$\frac{d\omega_{fcc}}{dx} = -h_m fb\left(\omega_{fcc(T_w)} - \omega_{fcc}\right)/m \quad (4)$$

$$\frac{dT_{fcc}}{dx} = \frac{bh_{fcc} f\left(T_w - T_{fcc}\right)}{mC_{fcc}} + \frac{H_{fcc(T_w)} - H_{fcc}}{C_{fcc}} \frac{d\omega_{fcc}}{dx} + \frac{bU_{a-fcc}\left(T_a - T_{fcc}\right)}{mC_{fcc}} \quad (5)$$

$$\frac{dT_w}{dx} = \left[m\frac{dH_{fcc}}{dx} + b\left(U_{r-w} f\left(T_r - T_w\right) - mC_{pw} T_w \frac{d\omega_{fcc}}{dx} \right) \right] / m_w C_{pw} \quad (6)$$

The required boundary conditions for solving Eq. 4-6 in a cocurrent type air flow configuration are:

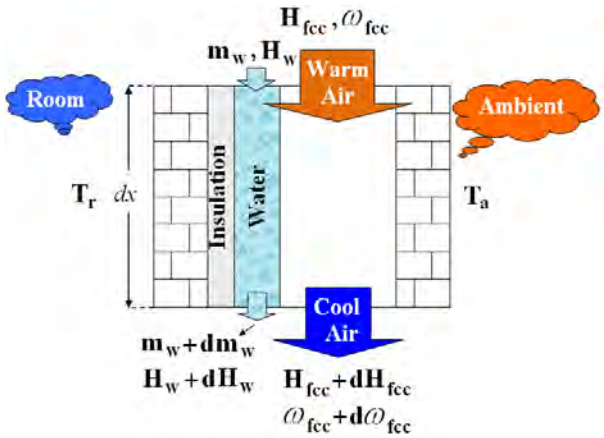

Fig. 5. Diagram of heat and mass transfer in the ECC.

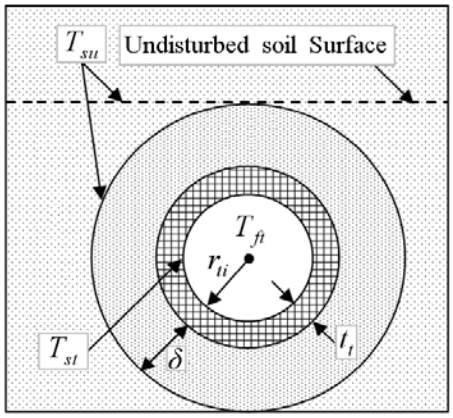

Fig. 6. Cross section of an EAHE.

$$T_{fcc}(0.0) = T_a,\ T_w(L) = T_w(0.0) \tag{7}$$

$$RH_{fcc}(0.0) = RH_a \tag{8}$$

A mathematical model based on *Bernoulli's* equation is used to estimate the system flow rate. The air velocity in the SC can be obtained as [5]:

$$u_{fsc} = \sqrt{\frac{Bouyancy\ \ Terms}{Friction\ \ Terms}} \tag{9}$$

$$Bouyancy\ \ Terms = 2\left\{\left(\rho_{fa} - \rho_{fsco}\right)gL_{sc}\mathrm{Sin}(\theta) - \left(\rho_{fcco} - \rho_{fr}\right)gL_r + \left(\rho_{fcco} - \rho_{fa}\right)gL_{cc}\right\} \tag{10}$$

$$\begin{aligned} Friction\ \ Terms = {} & \left\{c_5 + \xi_{sc}\frac{L_{sc}}{\left(d_{hyd}\right)_{sc}}\right\}\rho_{fsco} + c_4\left(\frac{\rho_{fsco}A_{sco}}{\rho_r A_{sco}}\right)^2\rho_{fr} + c_3\left(\frac{\rho_{fsco}A_{sco}}{\rho_r A_{scin}}\right)^2\rho_{fr} \\ & + c_2\left(\frac{\rho_{fsco}A_{sco}}{\rho_{fcco}A_{cc}}\right)^2\rho_{fcco} + c_1\left(\frac{\rho_{fsco}A_{sco}}{\rho_{fa}A_{cc}}\right)^2\rho_{fa} + \xi_{cc}\frac{L_{cc}}{\left(d_{hyd}\right)_{cc}}\left(\frac{\rho_{fsco}A_{sco}}{\rho_{fcco}A_{cc}}\right)^2\rho_{fcc} \end{aligned} \tag{11}$$

The coupled governing equations (1)-(3), (4)-(6) and (9) are the full description of the system. The governing equations have to be solved iteratively until convergence of the results.
The ACH is calculated under steady-state conditions by the following equation:

$$ACH = 3600m/\left(\rho_{fsc}V\right) \tag{12}$$

The room air temperature which depends on room heat gain (Q_r) is given by:

$$T_r = T_{fscout} - Q_r/\left(mC_{fr}\right) \tag{13}$$

2.2. Mathematical modeling of SC-EAHE

The cross section of EAHE used in the model is shown in Fig. 6. In order to impose the ground thermal loads as boundary conditions at the EAHE wall, the undisturbed soil temperature (T_{su}) has been applied in the equations as well. The soil temperature is nearly constant at the penetration depth. It is defined when the surface of the soil is subject to periodic temperature [6].

$$\delta = \sqrt{2\lambda_s / fre} \tag{14}$$

The air temperature through the EAHE is calculated by the following equation [6].

$$T_{ft}(x) = T_{su} + \left(T_a - T_{su}\right)\exp\left(-x/\left(m_{ft}C_{ft}R_{total}\right)\right) \tag{15}$$

Where R_{total} represents the overall thermal resistance and is given by [6]:

Table 1. Thermophysical properties.

Parameter	Value
Absorptivity of the glass	0.06
Emissivity of the glass	0.90
Transmissivity of the glass	0.84
Absorptivity of the absorber wall	0.95

Thickness of SC and ECC insulation	0.002 (m)
Thermal conductivity of the pipe (PVC)	0.23 (Wm^{-1} K^{-1})
Soil density	2050 (kg m^{-3})
Thermal conductivity of the Soil	0.52 (Wm^{-1} K^{-1})
Specific heat of soil	1840 (J kg^{-1} K^{-1})

$$R_{total} = \frac{1}{2\pi L_t}\left(1/h_{ft} + \ln(\frac{r_{ti}+t_t}{r_{ti}})/k_t + \ln\left(1+\frac{\delta}{r_{ti}+t_t}+\sqrt{\left(1+\frac{\delta}{r_{ti}+t_t}\right)^2-1}\right)/k_s\right) \quad (16)$$

The air velocity in the SC based on *Bernoulli's* equation can be obtained by the Eq.9 [6].

$$Bouyancy\ \ Terms = 2\begin{Bmatrix}\left(\rho_{fa}-\rho_{fsco}\right)gL_{sc}\mathrm{Sin}(\theta)-\left(\rho_{fscin}-\rho_{fr}\right)gH_{rin-scin}\\-\left(\rho_{ft}-\rho_{fr}\right)gH_{t-r}\end{Bmatrix} \quad (17)$$

$$Friction\ \ Terms = c_6\left(\frac{\rho_{fsco}A_{sco}}{\rho_{fr}A_{scin}}\right)^2\rho_{fr}+\left\{c_7+\xi_{sc}\frac{L_{sc}}{\left(d_{hyd}\right)_{sc}}\right\}\rho_{fsco} + \left\{\left(\sum_{j=1}^{5}c_j+\xi_t\frac{L_t+H_{t-r}+Burried\ \ depth\ \ of\ \ EAHE}{d_t}\right)\left(\frac{\rho_{fsco}A_{sco}}{\rho_{ft}A_t}\right)^2\right\}\rho_{ft} \quad (18)$$

All of coefficients and the overall heat transfer coefficients are obtained from Ref. [6]. The coupled governing equations have to be solved iteratively until convergence of the results.

3. Methodology

Two systems are located in Tehran, having 35.44°N latitude position. A south-facing solar chimney with the length of 4.0 m, air gap depth of 0.2 m and inlet dimensions of 0.4 ×0.4 m is assumed for analysis. The outlet dimensions of SC and room are 0.2 m×1.0 m and 0.1 m×4.0 m respectively. A detailed study on solar chimney found the optimum angle of 50° to capture more radiation [5].

The ECC is a Cubic channel with the height of 2.0 m and 2.0 m×0.05 m inside cross section. The wettability percent of wetted wall is 0.7. The calculations are carried out for a room, having a size of 4.0 m×4.0 m× 3.125 m without air infiltration. The ECC outlet is lowered 2.0 m below the SC inlet (Fig.1).

The cooling pipe of EAHE is a PVC pipe with 25.0 m length, 0.002 m thickness, and inside diameter of 0.5 m and is buried 3.0 m below the soil surface. The initial soil temperature at surrounding is approximated to be 19°C and it is considered to be the heat source temperature. It should be noted that the SC inlet is lowered 0.5 m below the EAHE outlet (Fig.2). The cooling demand is assumed to change within the range of 0.0-1000W in the calculations.

Table 2. Performance of the SC-ECC system at different indoor and outdoor conditions.

Cooling demand (W)	Ambient air RH. (%)	Ambient air temp. (^oC)	Solar radiation (W/m^2)	ACH (h^{-1})	Room air temp. (^oC)
		40	100	2.12	31.18
	30	42	500	3.76	31.34
		43	900	4.76	31.92
		40	200	2.23	31.45

	70	29	500	4.34	31.67
		31	900	5.23	32.00
1000	Thermal comfort cannot be provided.				

The indoor room air temperature is kept in the thermal comfort range (Fig. 3) to secure the desired condition inside the room space. The ambient air temperature, relative humidity and wind velocity are 34oC, 30% and 1.0 m/s, respectively. The thermo physical properties of the materials included in the modeling are given in Table 1. The values of the properties specified in the table are kept constant in the computation unless specifically noted otherwise.

4. Result and discussion

4.1. Effects of environmental conditions on the performance of SC-ECC system

The influence of solar radiation and humidity on ACH and room air temperature is investigated herein. The ACH depends on the density difference between ambient air and SC outlet air. This difference is more highlighted when the solar radiation rises therefore leading to higher ACH as shown in Table 2. Comparison of the results which are obtained for one SC and ECC shows that the variation of ACH due to the variation of ambient RH is not significant. However, the applicability of system to provide thermal comfort conditions is reduced at higher ambient air RH. At low ambient air temperatures, good indoor condition can be achieved in a wide range of the ambient air humidity. The results also shows that when ambient R.H. and temperature are less or equal to 50% and 40^{o}C, respectively, room air temperature and ACH would remain in the desired range of thermal comfort. It means that when air temperature rises, thermal comfort can be achieved in lower humidity. It is found that the proposed system can provide thermal comfort conditions even during the night with zero solar radiation (Table 3). It is due to the buoyancy effect in the cooling cavity which can

draw the cooled air into the room. At night, the chimney effect is non-existant. Therefore, the buoyancy effect of the ECC will be the dominant. Anyhow, to reduce the pressure losses of the air flow during the night, the discharged air may leave the room through an opened window.

Table 3. Performance of the system at zero solar radiation (cocurrent type)

Cooling demand (W)	Ambient air temp. (^oC)	Ambient air RH. (%)	ACH (h^{-1})	Room air temp. (^oC)	Number of SC & ECC

4.2. Effects of environmental conditions on the performance of SC-EAHE system

In the present study, the environmental conditions are referred to as solar radiation and outdoor ambient temperature. Table 4 shows the summary of results pertinent to theoretical calculations for different environmental conditions related to SC-EAHE system. The

buoyancy driving force increases directly with increment of solar intensity and it causes higher ACH. Thus, less number of SCs are required to drive the cool and heavy air through the EAHEs and to compensate the pressure drops. The results of calculations also show that the required number of EAHEs should be increased to retain the thermal comfort condition when the number of ACH and indoor air temperature are increased at high solar radiation. The effect of ambient air temperature on stack effect of SC is vice versa. The stack effect decreases when the ambient outdoor temperature rises. Under these conditions, more number of SCs will be required to suitably ventilate the room. The results show that the system can provide the required indoor temperature and ACH number even at harsh environmental conditions i.e. high temperature of 45^{o}C and low solar radiation of 100 W/m^{2}. If the temperature is higher than 45^{o}C, the SC won't be able to provide the stack effect and the use of a small fan can help the cool air to flow from EAHE into the room in order to provide thermal comfort conditions.

5. Conclusions

In this paper using two solar systems (SC-EAHE and SC-ECC) to meet the cooling load of buildings and thermal needs of inhabitants were compared. The numerical experiments showed that, although the performance strongly depends on the indoor air heat gain and ambient air conditions; the SC-ECC system can prepare good indoor thermal conditions when both cooling demand of the room and the relative humidity of ambient air are low. It was also revealed that, this system can provide thermal comfort conditions even during the night with zero solar radiation. The results about SC-EAHE system show that when both the ambient temperature and cooling demand are high, proper configurations could provide good indoor condition even at poor solar intensity and high ambient air temperature. It should be noted that proper insulation is useful for reducing the number of required SCs and buried pipes and consequently the total initial cost. Comparative survey shows that the SC-EAHE system is the best choice for buildings with poor insulation, but SC-ECC system is better for well insulated building, especially in dry and arid climates and also for low cost night ventilation.

Abstract: An experimental study to determine the net flux of long wave radiation from the earth's surface to the atmosphere in Owerri, south east Nigeria for passive cooling applications is presented. The values of the effective sky temperatures are also determined. The experimental rig which is a thermal radiator consists of a flat mild steel plate of dimensions 152.2cm x 38.1cm x 0.3cm coated with high emissivity black paint. A copper tube was used to form five turns and then soldered to the steel plate. Water from a well insulated tank placed at about 0.8 m above the surface of the thermal radiator flowed through the radiator. Thermocouples were strategically inserted on the radiator assembly to measure the plate temperature and water temperature as it flowed along the copper tube. The tests were conducted under the meteorological conditions of Federal University of Technology, Owerri for the period covering March to May; a period often free from the harmattan dust haze. The results revealed that a net long-wave nocturnal cooling power of 66.1 W/m^2 is possible. These results are in the same order of magnitude with those obtained elsewhere with similar climatic condition as Owerri, Nigeria.

1. Introduction

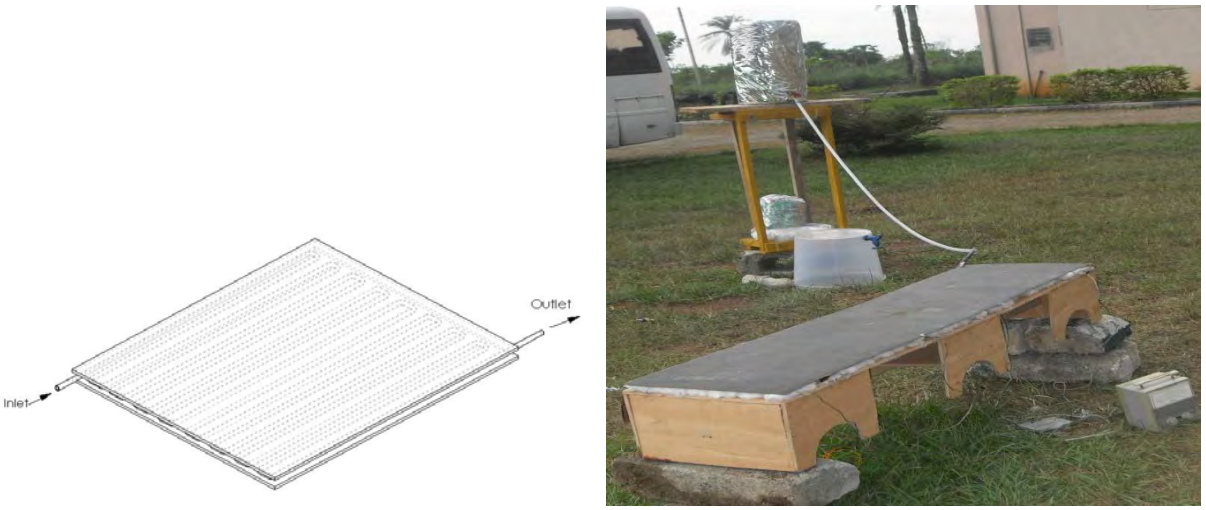
There is a growing demand for space cooling in hot climates resulting from increasingly harsher climatic conditions as a result of global warming and climate change. This has resulted to an increase in demand for grid connected electrical energy, hence reducing the available energy for other services. Countries with such climates like Nigeria therefore face serious peak energy demand problems. Interestingly, the sky is known to be very cold and as such it can be used as a heat sink for radiating bodies on the earth's surface. This is because the atmospheric temperature decreases with elevation and the atmosphere is partly transparent to some radiation within the infrared region of the spectrum. This concept, which requires a good knowledge of atmospheric radiation flux at the earth's surface, if effectively harnessed could be used significantly to reduce the demand placed on grid connected electricity from air conditioning as well as reduce the energy bills resulting from it. Apart from air condition for comfort, it can also be used for agricultural studies and solar collector analysis [1].

Ordinarily if the emitted radiation from a surface exceeds its absorbed radiation, cooling will result. Thus it is possible to cool hotter surfaces and objects on the ground by radiation to the night sky; a concept called nocturnal (night sky) radiation. The cooling resulting from it is called radiative cooling. Rate and degree of radiative cooling achieved depend on the intensity of the nocturnal radiation. Many factor affect nocturnal radiation intensity; they include weather condition as well as the nature of the radiating surface. Some works have been reported on efforts to measure nocturnal radiation intensity in different locations. Angstrom [2] and Maurer [3] investigated the nocturnal cooling of bodies exposed to the sky, Ezekwe [1] carried out nocturnal radiation measurements in Nsukka, Nigeria while Armenta-Déu et al [4] carried out a thermal analysis of a prototype to determine radiative cooling thermal balance. More recently, knowledge of availability of nocturnal radiation in some regions have been used to design and construct nocturnal radiators for space cooling. These include the works of Cheikh and Bouchair [5], Khedari et al [6], Bagiorgas and Mihalakakou [7] and Dimoudi and Androutsopoulos [8]. Results obtained from these indicate the possibility of significant space cooling by effectively harnessing the nocturnal radiation available in a particular locality.

This work therefore deals with an experimental investigation of the nocturnal radiation intensity in Owerri, a tropical south eastern town in Nigeria. It has three major seasons in a year (rainy, dry and harmattan seasons) with an average day time temperature for all the seasons being in the range of 31 – 35^{o}C. At night these temperatures scarcely come down, especially during the dry seasons, thus there is the need to artificially drop them to fairly comfortable values, particularly within a building envelope.

2. Description of the Thermal Radiator.

The experimental rig is a thermal radiator consisting of an unglazed mild steel plate of dimensions 152.20 cm x 38.10 cm x 3.30 cm. Copper tube of outer diameter 12.20 cm was curled into five equal turns covering the plate area and then soldered to the mild steel plate such that a perfect thermal contact was achieved between the plate and the tube. The radiator assembly was mounted on a ply wood base 1 cm thick with an insulation material (cotton wool) 1 cm thick placed between the thermal radiator and the ply wood base to further reduce heat transfer by conduction. The mild steel plate of the radiator assembly was painted black to increase its emissivity. Water is made to flow through the radiator by gravity by connecting it to a water tank (using an insulated flexible hose) placed on a wooden stand higher than the height of the thermal radiator. Water was continuously circulated through the array of copper tubing. The tank is made of galvanized steel drum and perfectly insulated using fibre glass insulation. The insulation was subsequently wrapped in an aluminium foil; all to reduce heat transfer to the ambient air. Two manual valves were installed on the tank; a wedge valve (inner valve) which was used to start up or stop the process and a parallel gate valve (outer valve) used to control the mass flow rate of water through the thermal radiator assembly. The tank was kept about three metres away from the thermal radiator assembly to avoid obstruction of long-wave radiation. Five K-type thermocouples were inserted at equal distances each on the thermal radiator to measure the temperature of water along the various points on the mild steel plate and hence, determine the average temperature of the radiator. Other parameters monitored are the water tank temperature, ambient temperature and exit water temperature from the thermal radiator. Figs 1a and 1b show the schematic diagram of the thermal radiator and a picture of the experimental rig used for the experiment while Fig. 2 shows the sectional view of the radiator assembly.



(a) (b)

Fig 1 (a): Schematic diagram of the thermal radiator and (b): the pictorial diagram of the experimental rig.

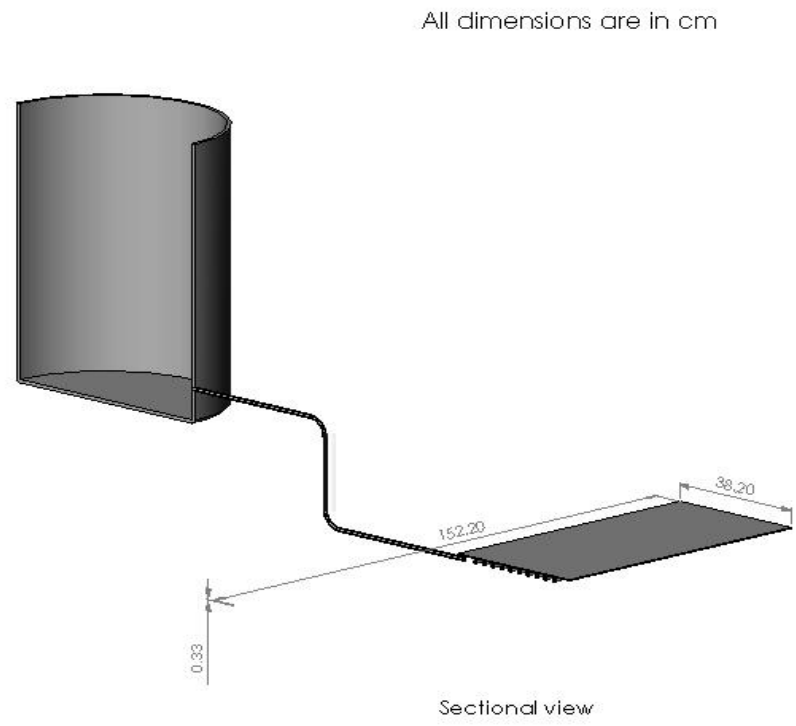


Fig. 2 Sectional view of the radiator assembly

3. Experimental Tests and Analysis

Experiments using the thermal radiator were conducted in Owerri, a city in south eastern Nigeria with three major climatic conditions namely; wet, dry and harmattan seasons. During the experimentation, the following parameters were measured: temperature of water at five different points on the mild steel plate, plate temperature, water tank temperature, ambient temperature and exit water temperature from the thermal radiator. The readings were taken at intervals of 30 mins, beginning from 19:00 hrs to 06:00 hrs the following day. These

temperatures were determined with a K-type thermocouple connected to a 10 – channel Comark electronic thermometer with an accuracy of ±0.1^{o}C. Data collected were analysed as given below.

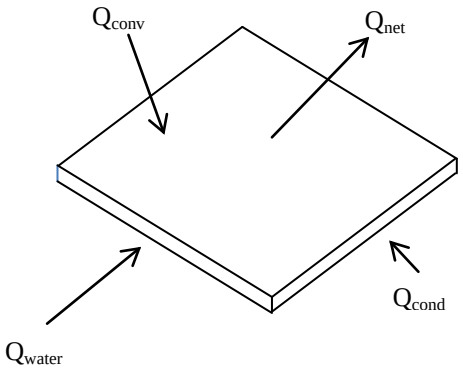

Fig. 3 An energy balance on the nocturnal radiator.

Considering an energy balance on the nocturnal radiator as shown above, the following eqn. (1) results, which enables the determination of the effective sky temperature as well as the downward atmospheric radiation and hence the net outgoing radiation from the plate to the night sky.

$$Q_{water} + Q_{conv} + Q_{cond} = Q_{net} \tag{1}$$

Q_{net} is the net thermal radiation from the plate to the sky and it is obtained from

$$Q_{net} = \sigma \varepsilon_p A_p F_p \left(T_p^4 - T_{sky}^4\right) \tag{2}$$

The heat transferred from the water flowing through the tubes to the plate, Q_{water} is obtained from eqn. (3) below

$$Q_{water} = \dot{m}_{water} c_{water} \left(T_{in} - T_{out}\right) \tag{3}$$

while the natural convection heat transfer to the plate is obtained from

$$Q_{conv} = hA_p \left(T_{amb} - T_p\right) \tag{4}$$

The heat transfer by conduction through the plywood and insulation to the plate, Q_{cond} is obtained from the relation;

$$Q_{cond} = A_p U_{ins} \left(T_{pwb} - T_p\right) \tag{5}$$

Eqn. (1) was solved using the data collected from various experimental measurements to obtain the only unknown parameter, the effective sky temperature. Assuming the sky to be a black body at an effective temperature T_{sky}, the downward long-wave sky radiation was computed with the Stefan-Boltzmann law using the sky temperature. This is given as eqn. (6).

$$\varphi_d = \sigma T_{sky}^4 \tag{6}$$

Similarly, the upward long-wave sky radiation flux was obtained from eqn. (7) by using the ambient air temperature.

$$\varphi_u = \sigma T_{amb}^4 \tag{7}$$

Consequently the net outgoing radiation flux from the earth's surface was obtained using eqn. (8) below.

$$q_{net} = \varphi_u - \varphi_d \tag{8}$$

4. Results and Discussion

Readings were taken between March and May, a period often free from the harmattan dust haze and enough to give considerable insight into the night sky radiation pattern during the dry season. The month of May however, marks the outset of rainy season. Based on data collected, values of the night sky temperature, downward long wave sky radiation, upward long wave sky radiation and the net long wave sky radiation were determined using eqns. 1, 6 – 8. Figs. 4 and 5 show the hourly variation of the night sky temperature and its depression below that of the ambient for the dry and rainy seasons while Figs. 6 and 7 show the hourly variation of the upward and downward long wave radiation as well as their net long wave radiation.

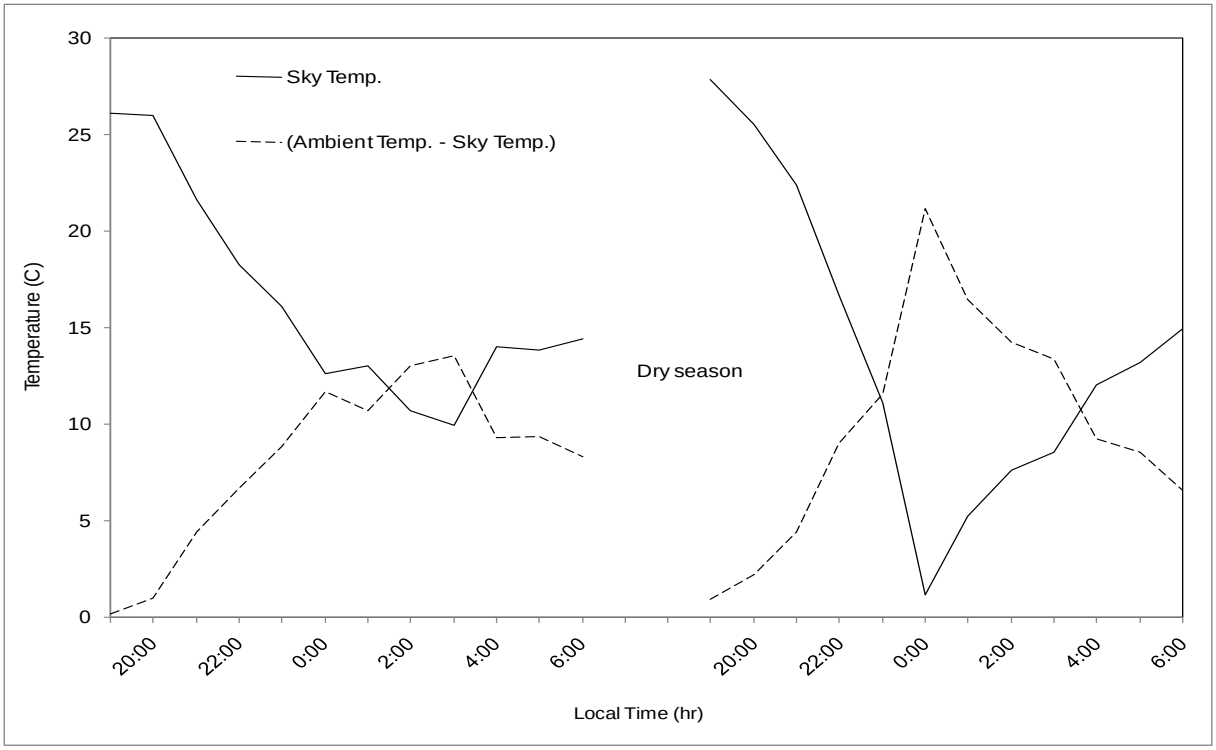

Fig. 4 The night sky temperature and its depression below ambient temperature during the dry season.

It can be seen from these figures that the dry season (characterized by high dry bulb temperature and sometimes a low relative humidity) has lower sky temperatures and higher net long wave radiation than the rainy (wet) season though the variation pattern showed more strong dependence on time of day. The rainy season, with much lower dry bulb temperature and high relative humidity, on the other hand, has more steady sky temperature with a minimum value of about 12^{o}C. Its net long wave radiation was mostly below 70 W/m^2. These results show that net log wave radiation is higher during the dry than in the rainy season. This may be as a result of a combination of the following factors; clear night sky and lower relative humidity than the rainy season. The rainy season is characterized by overcast sky and high

relative humidity, hence the lower values recorded. However ambient temperatures are generally lower within this period, thus less cooling is required in order to achieve comfort. In general the net long wave radiation is highest between 22:00 hours – 5:00 hours of the following day with the values ranging between 50 – 130 W/m^2. These values are well in the same order of magnitude with those obtained for similar climatic conditions and if properly harnessed could provide cooling; enough to provide reasonable comfort during the night times, especially during the dry season when high ambient temperatures make sleeping difficult.

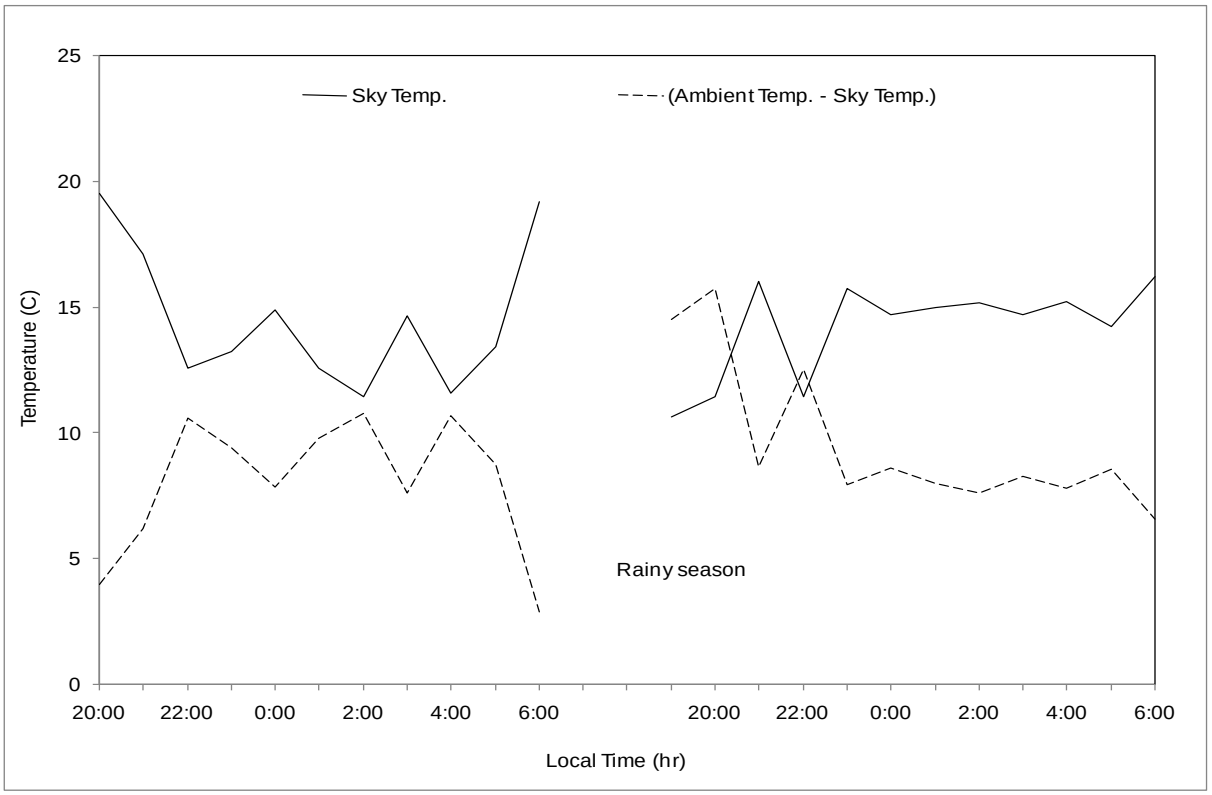

Fig. 5 The night sky temperature and its depression below ambient temperature during the rainy season.

5. Conclusion

Measurements to experimentally determine the long wave night sky radiation in Owerri, a tropical south eastern city in Nigeria, have been conducted. Measurements were taken at periods of the year representative of the three major climatic conditions of this city. Based on the results obtained after analysis of data collected, the following conclusions may be drawn.

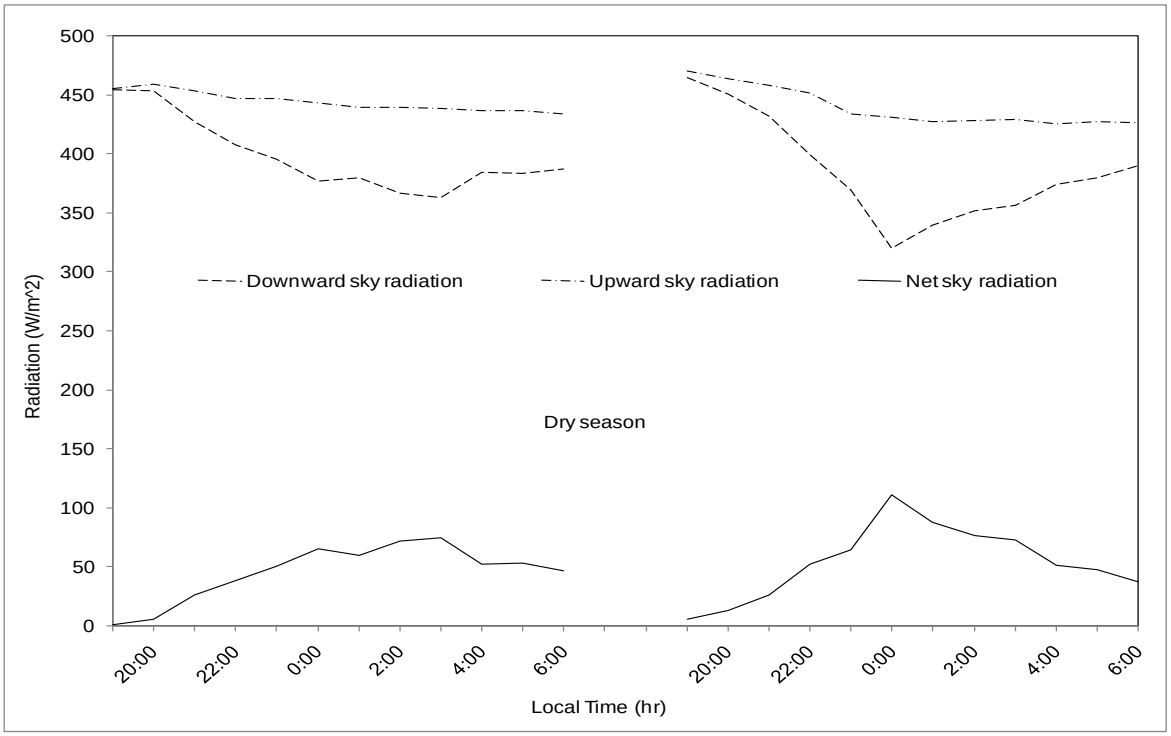

Fig. 6 The night sky radiation at the location during the dry season.

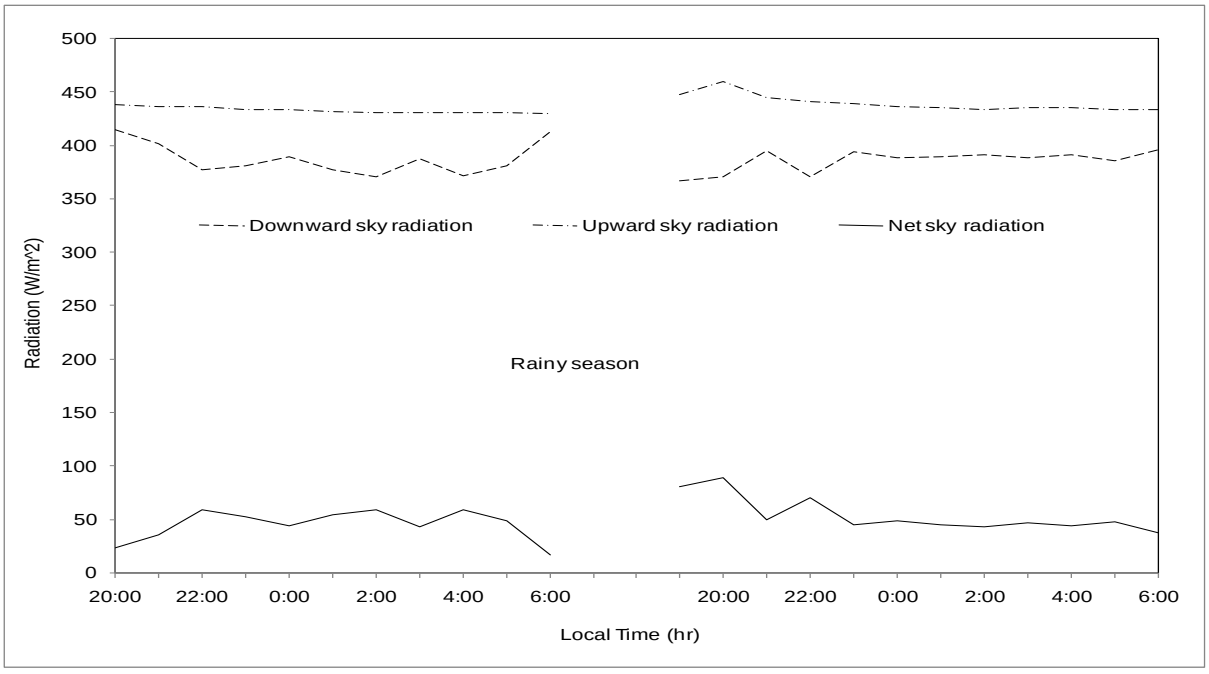

Fig. 7 The night sky radiation at the location during the rainy season.

i.) The net radiation to sky of up to 130 W/m^2 is possible depending on time of day and period of the year. Overall, an average value of about 66 W/m^2 is possible.

ii.) The dry season presented better potential for space cooling using the night sky radiation. Fortunately, this is the period of year when comfort is desired most.

Abstract: Green Building is a philosophy aiming to maintain a high quality of the built environment while optimizing the use of resources, both materials and energy. Related to green building, sustainable construction consists in the creation and operation of a healthy built environment giving rise to high-performance green buildings.
These building concepts have already been taken into account by the European Union (EU) that has promoted the use of alternative energies, thermal insulation and responsible consumption programs, among others. The Directive 2002/91/EC came into force to regulate energy efficiency in new buildings. Member States transposed this text to their legal systems, considering the particularities of to their territories, geography, economy and society. In Spain, the Spanish Technical Building Code (*CTE- Código Técnico de Edificación*) promotes sustainable building. Other regulations regarding energy buildings certification, energy efficiency or renewable energy promotion have already been adopted.
This work presents a house designed taking into account some aspects of the sustainable house design, and compares it with a reference house. These aspects include the thermal requirements of the house following a simplified option established in the basic documents HE1 (Limitation of the energetic demand) and HE4 (Minimal solar contribution for heating domestic water) of the Spanish Building Technical Code

Keywords: *Sustainable construction, Thermal insulation, CTE, Energetic demand*

1. Introduction

Almost 30% of world's energy is used in housing (40% in Europe [1]) and the 50% of this energy is used in building for the weather conditioning systems [2] (heating or cooling), and lighting. Energy consumption for housing and services was 371.4 Mtoe (millions tons of oil equivalent) in 2000 [3], which is higher than for other sectors such as transport and industry.

Due to the figures of the increased CO_2 emission levels associated with this energy production, the EU has decided to harden the standards for building and their heating and hot water systems in order to reduce the amount of energy consumed [4]. Simultaneously to these new standards a new philosophy, Green Building, has emerged, with the aim of maintaining high quality of the built environment while optimizing the use of resources, both materials and energy. On the topic of green building, sustainable construction is about the creation and operation of a healthy built environment based on ecological principles and resource efficiency [5], giving rise to "high-performance green buildings". The main characteristics of these constructions are [6]: significantly less energy, materials and water consumption; healthy living and working atmosphere; and great improvements on the quality of the built environment. The control of natural lighting and ventilation as well as better insulation also help, not only reducing energy consumption but also increasing safety and security, promoting welfare and helping assisted living [7].

Housing energy use has been a concern for the European institutions, which have promoted the application of alternative energies, thermal insulation and responsible energy usage campaigns by developing a specific legal framework. Accordingly, the European building

sector has provided itself with the Directive 2002/91/EC [1], which aims to control the energy efficiency in buildings, and the Directive 2006/32/EC [8], whose purpose is to enhance the cost-effective improvement of energy end-use efficiency. Several Member States have transposed these European directives to their own legal systems, trying to adapt them to their geographic, economic and social characteristics. That is the case of Spain, where the European directives have been adapted to the national legal framework by Royal Decree 1027/2007 [9], on Thermal Installations in Buildings (*RITE –Reglamento de Instalaciones Térmicas en los Edificios*), that controls heating systems and hot sanitary water in buildings in order to reach a good comfort level and an optimal energy use, and Royal Decree 1675/2008 [10], the Spanish Technical Building Code (*CTE – Código Técnico de Edificación*), that came into force to promote sustainable building.

This work presents the energy-related considerations taken into account during the design of a sustainable house intended to be energy efficient, including the requisites of the Spanish Building Technical Code (*CTE*). The energy parameters of this house will be compared with a reference house designed under conventional criteria.

2. Methodology

This work compares energetic parameters of two houses intended to be in the same location and with the same space distribution, but that have been designed under different building criteria. The first one is the "reference house" (RH), designed using conventional building criteria. The second house, the "sustainable" one, is the so called "insulated house" (IH), which applies the *CTE*, specifically the simplified option established in the basic document HE1 about *Limitation of the energetic demand*, as well as the guidelines set by the basic document HE4 about *Minimal solar contribution for heating domestic water*. This calculation option is based on the indirect control of the building energetic demand, limited by the characteristic parameters of the internal and external walls (thermal envelope). Accordingly, the methodology includes the following steps:

- Definition of the climatic area.
- Classification of the spaces of the building.
- Thermal isolation.
- Analysis of the thermal requirements of the house.
- Air infiltrations.
- Underfloor heating system.
- Boiler selection.
- Solar collectors for hot water production.
- Materials selection.

Finally the energetic parameters proposed in the *CTE* are compared for both houses, showing the benefits of the "sustainable" design.

3. Characterization of the houses

3.1. Definition of the climatic area

The proposed houses will be located in Lugo (Galicia), in the northwest of Spain. Lugo is classified by the *CTE* climate severity criteria as a D1 region, which means that the Winter Climate Severity (WSC) is high (D in a scale from A to E), and the Summer Climate Severity (SCS) is low (1 in a scale from 1 to 4).

3.2. Classification of the spaces of the building

Both the RH and the IH are intended to be located in a North-South oriented rectangular parcel with a 20% slope, which is not affected by any shadowing element in its environment. The houses will have four levels: the underground level, where the garage is located; the ground floor, with the kitchen, living-room, one bedroom and the access to the house; the first level, which is the dormitories area; and finally the top floor, which is really a terrace where the collectors and control devices will be located.

3.3. Thermal isolation

In the RH the external walls will be conformed by external plasterwork (25 mm), a double brick layer and an internal layer of plasterwork (25mm). The 290 mm width structure will be protected by both internal and external painting.

In the IH external walls are conformed by external plasterwork of 25 mm, a layer of light thermo-clay of 190 mm followed by another concrete layer. Insulation is provided by two layers: 20 mm of expanded polystyrene and an air chamber of 20 mm. Finally it is an internal brick layer covered by plasterwork. The 370 mm width structured is protected both internally and externally by painting. The formation of thermal bridges has also been considered, owing to the energy losses they involve.

3.4. Thermal requirements

The study of the thermal requirements will be based in the indirect control of heat demand as required in the *CTE*. This estimation method uses the characteristic parameters of the thermal envelop or U-values. Thermal transmittance U ($W/m^2 \cdot K$) is defined by Eq. (1), where R_T is the total thermal resistance for the constructive component.

In the case of associations of materials in homogeneous thermal layers, total resistance could be calculated by Eq. (2), where R_1, R_2 are the thermal resistances of the n layer conforming the wall, and R_{si}, R_{se} are the superficial thermal resistances corresponding to the internal and external air, considering the wall situation in the building and the direction of the heat flow.

The last consideration is the calculation of the thermal resistance in a thermal homogeneous layer provided by Eq. (3), where e is the thickness of the layer (m) and k the thermal conductivity of the material ($W/m \cdot K$).

Global transmission coefficient for the building also has been calculated, Eq. (4), in order to collect the previous parameters in a more representative figure, where sub-index w, s, r and h refer to walls, soil, roofing and holes respectively, and A is the area of each layer.

$$U = \frac{1}{R_T} \quad (1) \qquad R_T = R_{si} + R_1 + R_2 + ... + R_n + R_{se} \quad (2)$$

$$R = \frac{e}{k} \quad (3) \qquad U_G = \frac{(U_W \cdot A_W) + (U_S \cdot A_S) + (U_R \cdot A_R) + (U_H \cdot A_H)}{A_W + A_S + A_R + A_H} \quad (4)$$

3.5. Air infiltrations

Air renewal by infiltrations is an important parameter affecting both the hygienic conditions and the overall heating demand, as the incoming air must be conditioned. Air renewal takes place by infiltration through carpentries and by ventilation. Infiltration can be quantified by

permeability, defined by Eq. (5), where C_v is the window coefficient (specific for the woodwork, dimensionless), ΔP is the pressure difference between indoors and outdoors (mm H_2O) and S_h is the total surface of the hollow (m^2). Ventilation is mainly controlled by the inhabitants except for the kitchen and the bathrooms, both having independent mechanical ventilation systems.

$$\rho = C_v \cdot \Delta p \cdot S_h \qquad (5)$$

3.6. Heating System Design

Aiming to determine the heating requirements of the building, specific studies of every single space of the house have been carried out, considering heat losses by transmission and air renewal in each one of the spaces. Heating system, by underfloor heating, was designed considering that indoor temperature is set at 20 ºC and that the system must face up minimal temperatures of -5 °C during winter time.

Heating system design is based on the results obtained for the heat losses. Design parameters considered were water flow and water temperature, which can be calculated by Eq. (6) since Q is the known total heat losses, where T_{ma} is the average water temperature (ºC), T_{obj} is the objective temperature set in 20 ºC and U is the global thermal transmission coefficient, considering heat flow will occur by conduction and convection.

Water flow for heating system is calculated by Eq. (7), where C is the mass flow rate (kg/h), Cp is specific heat of the water (kJ/kg·K) and ΔT is the difference between inlet and outlet water in the system, considered to be 10 ºC.

$$Q = U \cdot \left(T_{ma} - T_{obj}\right) \qquad (6) \qquad\qquad Q = C \cdot C_p \cdot \Delta T \qquad (7)$$

3.7. Boiler Selection

The installation of efficient boilers is promoted by the *RITE* to reduce pollutant emissions and improve energy savings. In this case study a condensation boiler has been selected because it can be adapted to the thermal needs of an underfloor heating, providing hot water at 60 ºC. Moreover a 30% energy saving and a 70% NO_x y CO_2 emissions reduction is expected.

3.8. Sanitary Hot Water Installation

The sustainable design also includes a solar thermal installation able to provide a great percentage of the total hot water demand for the house, exceeding the 30 percent required by the *CTE* for this kind of houses.

Initial data needed for the design and calculation of this installation, will be the use conditions of the Sanitary Hot Water (SHW) and weather specifications of local region. Energetic demand is determined by the monthly hot water consumption rate and the temperature set for the SHW, while climatic specifications are obtained by the global radiation in the collecting field, average day temperature and network water temperature.

Calculation method was the f-chart method. This method allows the assessment of the solar device coverage as well as its average performance in an amount of time.

3.9. Fuel consumption

It is nearly impossible to estimate fuel consumption in heating systems, since it heavily depends in variable conditions such as weather, user needs or control systems. However, it is possible to perform yearly estimations by using a method that can be found in UNE 100002 [11] regulations. It can be done by using Eq. (8), where G stands for HDD (ºC), P for consumed power (kcal/h), U is the use coefficient (dimensionless), I is the intermittence coefficient (dimensionless), η is the boiler performance, LCP is the Lower Calorific Power of the natural gas (kcal/m^3N), (T_i-T_e) relates to the difference of temperatures between the inside and outside of the house. For this case, T_i is set as 20 ºC and T_e as 2 ºC.

$$C = \frac{G \cdot 24 \cdot P \cdot I \cdot U}{\eta \cdot LCP \cdot (T_i - T_e)} \qquad (8)$$

4. Results

This section presents the results obtained after applying the aforementioned equations to the proposed case studies. The limit values set by the *CTE* for the proper design of the IH are: 20 ºC indoors temperature, 55% indoors relative humidity, 273 $m^3/h \cdot m^2$ woodwork permeability for a D1 zone, and 30% of annual minimal solar contribution for fossil energy source at 60 ºC.

According to Eq. (1-3) and following the layer schema described in the previous section, calculations of the U-values have been done. The results obtained are presented in Tables 1 and 2, where sub-index W, S, R and H refer to walls, soil, roofing and holes respectively. Next sub-index are: IH: Insulated House, LV: Limit value set by the *CTE*, RH: Reference House.

Table 1. U-values comparison for the insulated house and the reference house with the limit values established by CTE.

Orientation	U_{WIH} (W/m^2 K)	U_{WLV} (W/m^2 K)	U_{WRH} (W/m^2 K)	U_{HIH} (W/m^2 K)	U_{HLV} (W/m^2 K)	U_{HRH} (W/m^2 K)
N	0.46	0.66	1.57	2.23	2.50	3.8
E	0.49	0.66	1.69	2.10	2.90	3.68
O	0.48	0.66	1.57	2.18	2.90	3.25
S	0.52	0.66	1.63	2.18	3.50	3.68

Table 2. U-values comparison between the insulated house and the reference one with the limit values established by CTE.

U_{SIH} (W/m^2 K)	U_{SLV} (W/m^2 K)	U_{SRH} (W/m^2 K)	U_{RIH} (W/m^2 K)	U_{RLV} (W/m^2 K)	U_{RRH} (W/m^2 K)
0.33	0.49	1.70	0.33	0.38	0.62

Fig. 1 represents the comparison of the U-values for the considered elements (walls, soil, roofing and holes) for the IH, LV and RH. The U-values selected for walls and holes correspond to the north orientation.

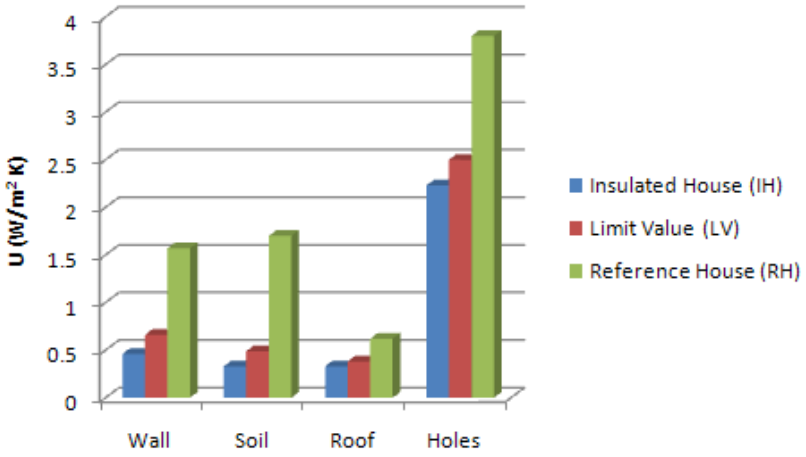

Fig. 1. Comparison of U-values for the walls, soil, roof and holes in the IH and the RH regarding the limit values set by the CTE.

The air renewal parameters have resulted in the data displayed in Table 3, whereas Table 4 shows the results obtained after calculating the thermal requirements for both houses. Heating system design results are included in Table 5.

Table 3. Calculations to establish the total ventilation of the buildings.

Air renewal	Reference house	Insulated house
Permeability (m^3/h)	1263,14	248,14
Mechanical Ventilation (m^3/h)	114,55	114,55
Natural ventilation (m^3/h)	97,52	97,52
TOTAL (m^3/h)	1475,21	460,21

Table 4. Thermal Requirements in the building.

	Reference House	Insulated House
Total Area (m^2)	204.91	204.91
Heat losses by transmission (W)	16,528.30	6,378.13
Heat losses by air renewal (W)	11,956.38	5,640.01
Total Heat losses (W)	28,484.68	12,018.14

Table 5. Resulting heating system parameters.

	Water temperature (ºC)	Flow rate (l/s)
Insulated House	30	0,267
Reference House	47	0,658

To calculate the SHW installation it is necessary to consider some additional factors. Hot water consumption is estimated to be 30 liters/inhabitant each day at 60 ºC. Concerning weather conditions, Lugo is located 465 meters high and in 43 º latitude. The house is placed in a flat ground with little vegetation, and atmosphere is considered clean since the house location is within a rural zone.

A Buderus Logasol SKN 3.0 is chosen as the collector. This device has an open surface of 2.25 m^2 and its efficiency slope parameters are η_0=0.775, k_1=3.599 W/m^2·K and k_2=0.008 W/m^2·K^2. Table 6 contains the results obtained for an installation comprising 3 collectors and an accumulator of 400 liters.

Table 6. Results for SHW installation calculations.

Parameter	Value
Total thermal load (MJ)	13,658.0
Net energy collected (MJ)	10,413.1
Yearly Solar Coverage (%)	76.2
Yearly Average Performance (%)	33.7

Finally, fuel consumption and CO_2 emissions were calculated to complete the analysis and comparison between both houses (Table 7).

Table 7. Fuel consumption estimation for each house and related economic costs and CO_2 emissions.

	Fuel consumption (m^3/year)	Economic costs (€/year)	CO_2 emissions (ton/year)
Insulated house	1,759	1372.20	4.00
Reference house	4,169	3252.17	9.60

5. Discussion

The comparison of both houses, RH and IH, leads to some obvious conclusions. First of all, when selecting building materials the priority has been their insulating capacity, but keeping also in mind their environmental impact and life-cycle. In fact, thermo-clay is a recyclable ceramic material with really good chemical, mechanical, thermal and acoustic properties. Expanded polystyrene is an excellent insulating material, also recyclable, and the woodwork employed is made of PVC with thermal break, with a Climalit glass of 9 mm thickness. Besides, aiming to reduce thermal gains through the windows in summer, eaves have been installed to reduce solar radiation penetration in the south faced windows and the balcony. This measure is expected to cause a 50% reduction in radiation depth for these rooms.

Concerning U-values for the thermal envelope (Tables 1 and 2), it is observed that the insulating measures used in the design of the IH make it possible to comply with the *CTE* requirements. More detailed analysis of these data reveals that U-values for the IH are about 24% lower than the limit values whereas the results for the RH are much higher in each part of the thermal envelope. For the global transmission coefficient, results are U_{GIH}=0.51 W/m^2·K and U_{GRH}=1.61 W/m^2·K. Coefficient value for the RH is about 3 times the insulated coefficient value.

The results obtained for air renewal show that, in the IH, the total air renovation is roughly the same as the volume of the house, as demanded in the *CTE* (Table 3). Concerning the RH, air renovation is 3 times the volume of the house, which is excessive and will lead to extra fuel consumption.

According to results shown in Table 4 for thermal requirements, it is possible to assess that total heat losses for the IH are only the third part of the RH. This fact leads to the reduction of the fuel oil consumption, and therefore the reduction of CO_2 emissions to the atmosphere.

Regarding the heating system design, results show that for the same heating system, water temperature and flow rate are lower in a well insulated house (Table 5). Consequently both the energy needed for water heating and electrical energy to drive the pump will be lower.
The fulfilling of the conditions of the *CTE* is proved, since the SHW installation provides a solar contribution of 76% of the total energetic needs in the house with a yearly average performance above 30%, as requested in the *CTE* (Table 6).

Finally, the application of constructive solutions in the IH project means saving around 5.5 ton CO_2/year emissions (Table 7).

Therefore it can be concluded that taking into account energy efficiency criteria during building design can result in important savings in energy consumptions, as heat losses are highly reduced (even three times shorter in the IH than in the RH) and hot water requirements are much lower than in a typical house. The application of the *CTE* not only limits the energy demand in buildings on the basis of U-values for thermal envelope, but it also avoids surface condensations inside the enclosure or the woodwork, limits energy loses by air infiltrations and minimizes solar contribution for sanitary hot water.

Abstract: Before 1930, most houses in the UK were built with solid brick walls, which have high heat losses and are difficult to insulate. These homes represent nearly one-quarter of the UK housing stock. This paper covers a case-study that shows some of the difficulties to meet the UK government's target to reduce carbon emissions by 80% by 2050. Such a target can only be met with refurbishment of all older properties and even then, energy-savings initiatives are probably not sufficient; integration of renewable energy sources is also necessary. Comparison with refurbishment initiatives in Germany demonstrates the massive investment that needs to take place, and some of the practical limitations. Strategies to limit increasing demand for energy use will be required in order to meet these ambitious targets. The case-study demonstrates the types of practical problems likely to be encountered, but also shows the importance of disseminating the experience gained by pioneers of refurbishing older homes in the UK.

Keywords: *Energy Efficiency, Refurbishment, Carbon Saving*

1 Introduction

In northern Europe, the energy use in residential buildings is largely associated with space heating and hot water provision as well as lights and appliances. Reducing energy consumption in residential buildings has the potential to help countries meet their targets to reduce carbon emissions. Approximately 30% of carbon emissions in the European Union are due to energy use in residential buildings, of which around 50% is used for space heating [1]. Significant reduction in these carbon emissions can be made by three methods – firstly, demolishing old homes and replacing them with new "low-carbon" dwellings; secondly, switching to energy sources that do not rely on fossil fuels; thirdly, making existing homes more energy efficient. In many parts of Europe, including the UK, the demand for new homes is high because the number of households is increasing. Apart from energy use, older houses have many attractive features, so demolition occurs at a very slow rate [2]. The second of these options requires investment in alternative energy infrastructure, which is occurring, but not fast enough to impact significantly yet on carbon emissions. The third of these options, i.e. refurbishment of existing buildings for improved energy efficiency, has other public benefits such as employment opportunities, increasing the aesthetic quality of existing housing stock and reducing the number of families suffering from fuel poverty. For the occupants, energy efficiency measures can lead to improved indoor comfort, lower running costs and a healthier indoor environment.

Government housing data shows approximately 23% of the UK housing stock is comprised of houses built between 1800 and 1930, of which over 70% are owner occupied. These houses are highly inefficient in their use of heating energy, contributing a disproportionate fraction of UK carbon emissions. It is logical that these should be a prime focus of energy efficiency improvements but there are significant barriers to implementing such changes. Before 1930, most UK houses were built without cavity walls and with other design features that make their energy performance difficult to improve. Much of the heat loss is through the walls of the house, which can only be reduced by applying internal or external insulation. External

insulation has the advantage of retaining the thermal mass of the building within the insulated envelope. It has been applied within a number of social housing projects in the UK, but so far has been rarely used in owner occupied houses, which is the focus of this paper.

The case-study energy use data has been analysed to find the contribution of the energy improvements to a reduced carbon footprint. Data from other examples has also been compared in order to identify the practical limitations to reducing the carbon footprint of older residential buildings. Carbon emissions for the UK have been calculated using data for 2007 published by the Carbon Trust: electricity: 0.544 kg CO_2/kWh; gas: 0.184 kg CO_2/kWh.

2 Refurbishment Case-study

The study analyses energy savings in a detached family house of 98 m^2 built in 1910 using 225 mm solid brick walls, some of which were rendered on the outside. This house is of typical construction for its era, with slated roof and originally with single-glazed windows. It is heated by a gas-fired central heating system and also had an open gas heater in the living room. The house has been refurbished since 2001 in two phases. In the first phase, improvements were made through installation of double glazing, replacement of an inefficient gas boiler by a Worcester Greenstar combi condensing boiler, which has a SEDBUK efficiency of 90.3% (previously water was heated by an electric immersion heater). The loft insulation was topped up to 200 mm using Warmcel recycled paper insulation. Energy efficient lighting, mainly compact fluorescent, was installed throughout the property. Draught-proofing was carried out and both external doors were replaced, as the original doors were ill-fitting. The energy savings from these improvements have been estimated using values from similar properties given by Lomas [3], which suggest that the energy use for space heating was reduced by 30% and energy use for lighting by 65%. Using the figures above, the resulting CO_2 emissions reduced from 7.8 to 4.4 tonne/year. One problem that was made worse by these initial improvements (apparently common in houses of similar construction, after fitting draught-proofing and double glazing [4]) was the incidence of mildew growth in poorly ventilated areas of external wall, due to condensation.

Figure 1. View of house from south side, before and after external insulation.
