Preface

The 9th Eurosim Congress on Modelling and Simulation (Eurosim 2016) and the 57th SIMS conference on Simulation and Modelling (SIMS 2016) were held jointly in the City of Oulu, Finland. The Federation of European Simulation Societies (Eurosim) was set up in 1989. The purpose of EUROSIM is to provide a European forum for regional and national simulation societies to promote the advancement of modelling and simulation in industry, research and development. The program committee has organized an exciting and balanced program comprising presentations from distinguished experts in the field, and important and wide-ranging contributions on state-of-the-art research that provide new insights into the latest innovations in the field of modelling and simulation. EUROSIM 2016 was organized by Scandinavian simulation society (SIMS), Finnish Society of Automation (FSA), Finnish Simulation Forum (FinSim), University of Oulu and Finnish Automation Support Ltd. SIMS was founded in 1959. The event was technically co-sponsored by IEEE Finland Section, IEEE Computer Society and International Federation of Automatic Control Technical Committees on

- TC 3.2. Computational Intelligence in Control,
- TC 6.1. Chemical Process Control,
- TC 6.2. Mining, Mineral and Metal Processing,
- TC 6.3. Power and Energy Systems, and
- TC 6.4. Fault Detection, Supervision & Safety of Technical Processes-SAFEPROCESS.

Networking events were organized on three levels: Federation of European Simulation Societies (Eurosim) had Executive Board and Board meetings; Scandinavian simulation society (SIMS) had Board and Annual Meetings and Finnish Simulation Forum (FinSim), founded in 2001, had Board and Annual Meetings.

The overall management was done by the Eurosim Board, consisting of representatives of 17 European Simulation Societies lead by the Eurosim President Dr. Esko Juuso. The NOC was chaired by Prof. Kauko Leiviskä with Co-Chair Dr. Esko Juuso and Vice-Chair Industry Dr. Timo Ahola (FinSim). The IPC Chair Prof. Erik Dahlquist (SIMS), Co-Chair Prof. Bernt Lie (SIMS) and Vice-Chair Industry Dr. Lasse Eriksson were leading the IPC which consisted of 49 scientists. The Publication committee was chaired by Dr. Peter Ylén with C-Chairs Prof. Lars Eriksson and Prof. David Al-Dabass. Industry-based people participated in the congress committees. Eurosim and SIMS Boards were in the IPC. Eurosim members participated actively: 20 Eurosim countries from 14 member societies participated in the congress.

EUROSIM 2016 proved to be very popular and received submissions with authors from more than 40 countries. The conference program committee had a very challenging task of choosing high quality submissions. Each paper was peer reviewed by several independent referees of the program committee and, based on the recommendation of the reviewers, 184 regular papers were accepted for presentation. The papers offer stimulating insights into emerging modelling and simulation techniques and their applications in a wide variety of fields within science, technology, business, management and industry. Contributions are structured by

- Application domains, including Bio- and ecological systems, Building and construction, Economic and social systems, Energy, Industrial processes, Security and military, Transportation and vehicle systems, Water and wastewater, Weather and climate;
- Functionalities, including Control and optimization, Communication and security, Education and training, e-Learning, Fault detection & fault tolerant systems, Human-Machine interaction, Mechatronics and robotics, Planning and scheduling, Sensing, Virtual reality and visualization;
- Methodologies, including Computational intelligence, Conceptual modelling, Complex systems, Data analysis, Discrete event simulation, Distributed parameter systems, Parallel and distributed interactive systems, Simulation tools and platforms.
- Minisymposia integrate these areas in Control education, Wastewater, Applied energy, Solar thermal power plants, Complex dynamic systems, Chemical processes, Big data analysis and Soft computing, Innovative technology and Cooperative automation.

DOI: 10.3384/ecp17142

Panel discussions were organised for three topics: Modelling and Simulation in Processes and Cleantech, Future energy systems and Intelligent Systems and IoT in Future Automation. Three technical tours covered energy production, radio technology, printed electronics and mining. Tutorials were arranged on simulation tools and platforms.

The congress was very international: there were 181 participants from 33 countries. There were participants from all the continents, except Africa, but there were co-authors also from Africa. The program included 6 plenaries, 175 regular oral and 7 poster presentations. The focus was in Europe: 1/4 from Finland, 1/5 from other Nordic countries and 1/3 from other European countries. Far East was active: 26 participants, where 18 from Japan. In addition, there were 13 participants from other areas (Middle East, Americas and Australia). In total 22% of the participants were from outside Europe, almost as many as from Finland. The Proceedings includes includes 165 selected and revised papers.

Education for students was covered by the Control Education minisymposium organized The Education Committee of The Finnish Society of Automation and extended with papers from Education and Training, e-Learning track. IEEE Finland Section organized a workshop for early career development in the world of technology for young professionals. High school students visited some sessions.

We would like to express our sincere thanks to the plenary speakers, authors, session chairs, members of the program committee and additional reviewers who made this conference such an outstanding success. Finally, we hope that you will find the proceedings to be a valuable resource in your professional, research, and educational activities whether you are a student, academic, researcher, or a practicing professional.

Table of Contents

Congress location

The main venue and the exhibition site was the Oulu City Theatre in the City of Oulu, Capital of Northern Scandinavia.

Opening session, 13 September 2016

The Vice Rector for Cooperation affairs, Dr. Matti Sarén, University of Oulu, Finland
President of EUROSIM, Dr. Esko Juuso, University of Oulu, Finland
President of SIMS, Prof. Erik Dahlquist, Mälardalen University, Sweden
Congress Chair, Prof. Kauko Leiviskä, University of Oulu, Finland

Plenary presentations, 13 - 15 September 2016

Thermal Management Simulations within Power Engineering at ABB
Prof. Rebei Bel Fdhila, ABB Corporate Research, Sweden

Modelling and Simulation of the Electric Arc Furnace Processes
Assistant Professor Vito Logar, Laboratory of Modelling, Simulation and Control, Faculty of Electrical Engineering, University of Ljubjana, Slovenia

Part 1: Autonomous Driving and Levels of Automation,
Part 2: Situation Awareness and Early Recognition of Traffic Maneuvers
Dr Galia Weidl, Daimler AG, Germany

Simulating the Composition of the Atmosphere
Adjunct Professor Harri Kokkola, Atmospheric Research Centre of Eastern Finland, Finnish Meteorological Institute, Finland.

Using the Power of Simulation to bring Bottom Line Benefits to the Mining, Minerals and Metals Operations
Roy Calder, Director, Technical Sales, Global Solutions SimSci by Schneider Electric, Warrington, United Kingdom

Online Simulation Platform for Biophotonic Applications
Dr Alexey Popov, Optoelectronics and Measurement Techniques Laboratory, University of Oulu, Oulu, Finland

Congress topics, 13 - 15 September 2016

Application domains (pp. 19-340)

Functionalities (pp. 321-502)

Modelling and simulation methodologies (pp. 505-811)

Minisymposia, 13 - 15 September 2016 (pp. 812-1128)

Best practices and new trends in control education
Organizer: Finnish Society of Automation, Education Committee, Chair: Dr. Kai Zenger, Aalto University, Espoo, Finland

Modelling and control aspects in wastewater treatment processes
Organizer: Dr. Jesus Zambrano, Mälardalen University, Västerås, Sweden

Modelling and simulation in applied energy
Organizer: Prof. Erik Dahlquist, Malardalen University, Sweden

Modelling and simulation in solar thermal power plants
Organizer: Dr. Luis J. Yebra, CIEMAT, Plataforma Solar de Almería, Spain

Object-Oriented technologies of computer modelling and simulation of complex dynamical systems
Organizer: Russian Federation the National Simulation Society, Chair: Prof. Yuri Senichenkov St. Petersburg Polytechnic University, Russia

Chemical Process Systems Simulation
Organizer: Dr. Esko Juuso, University of Oulu, Finland

Industrial Optimization Based on Big Data Technology and Soft Computing
Organizers: Prof. Yukinori Suzuki, Muroran Institute of Technology, Japan, and Dr. Kai Zenger, Aalto University, Espoo, Finland

Simulation as Enabler for Innovative Technology
Organizer: Prof. Agostino G. Bruzzone, Genoa University, Italy

Cooperative Automation
Organizer: Dr. Esko Juuso, University of Oulu, Finland

Panel discussions, 13 - 15 September 2016

Modelling and Simulation in Cleantech
Chairs: Bernt Lie, University College of Southeast Norway, Norway
Jesús Zambrano, Mälardalen University, Sweden

Future Energy Systems
Chairs: Erik Dahlquist, Mälardalen University, Sweden,
Cristian Nichita. University of Le Havre, France

Intelligent Systems and IoT in Future Automation
Chairs: Esko K. Juuso, University of Oulu, Finland,
Lars Eriksson, Linköping University, Sweden

Workshops and tutorials

Career development in the world of technology and Young Professionals Meetup event
Chair: Rafal Sliz, University of Oulu, IEEE Finland Section

The basis of object-oriented modelling with Rand Model Designer
Prof. Yuri Senichenkov, St. Petersburg Polytechnic University, Russia

Introduction to modeling and simulation with Modelica using OpenModelica
Dr. Adrian Pop, Linköping University, Sweden

Closing session, 15 September 2016

Final Proceedings and Publication of revised papers
President of EUROSIM 2013-2016, Dr. Esko Juuso, University of Oulu, Finland

The Presidency period 2016 – 2019, EUROSIM 2019 Congress & Venue
President of EUROSIM 2016-2019, Prof. Emilio Jiménez Macías, CEA-SMSG, Spain

Technical tours, 16 September 2016

Tour I: Energia
Oulun Energia is the leading energy company in Northern Finland. Two power plants are visited:

- Laanila Eco Power Plant, 50 MW Waste to Energy Plant, uses municipal solid waste as a fuel.
- Toppila CHP Power Plants, 267 MW and 315 MW units, uses peat and wood as a fuel.

Tour II: Radio Technology and Printed Intelligence

- Factory tour at Nokia's Radio Technology Center Site.
- VTT, PrintoCent Pilot Factories, including the new 5G Test Environment and Maxi IoT pilot line

Tour III: Mining Engineering
Oulu Mining School (OMS) integrates scientific disciplines along the value chain from exploration to mining and mineral processing. OMS has a unique continuous and automated concentrator minipilot facility.

Social program

Welcoming reception, The Oulu City Theatre, 12 September 2016.

The City-Reception, Oulu City Hall, 13 September 2016.

Banquet, Hotel Radisson Blu Oulu, 14 September 2016

Organization

EUROSIM President
Dr. Esko Juuso, *University of Oulu, Finland*

Congress Chair
Prof. Kauko Leiviskä, University of Oulu, Finland

Congress Vice-Chair, Industry
Dr. Timo Ahola, FinSim, Outokumpu Stainless Ltd, Finland

Programme Chair
Prof. Erik Dahlquist, SIMS, Mälardalen University, Sweden

Programme Co-Chair
Prof. Bernt Lie, SIMS, University College of Southeast Norway, Norway

Programme Vice- Chair, Industry
Dr. Lasse Eriksson, FSA, Cargotec Corporation, Finland

Exhibition Chair
Dr. Pekka Tervonen, University of Oulu, Finland

Publication Chair
Dr. Peter Ylén, FSA, VTT Ltd, Finland

Publication Co- Chair
Prof. Lars Eriksson, SIMS, Linköping University, Sweden

Publication Co-Chair, IEEE-CPS
Prof. David Al-Dabass, UKSim, Nottingham Trent University, United Kingdom

EUROSIM Board Members

Esko Juuso	President	Finland
Borut Zupančič	Secretary, SLOSIM repr.	Slovenia
Felix Breitenecker	Treassurer, ASIM repr.	Austria

Plenary presentations

Plenary 1

Thermal Management Simulations within Power Engineering at ABB

Prof. Rebei Bel Fdhila

ABB Corporate Research
Sweden
Email: rebei.bel_fdhila@se.abb.com

The area of thermal management is driven by miniaturization in industry e.g. power electronics, motors or transformers. It is a natural response to size restrictions as in automotive and robotics, to space excessive costs e.g. offshore applications or simply to industrial or comfort requirements. Besides that, unceasing market and technology demand for higher currents, higher voltages or higher power is inevitably leading to a substantial power density increase justifying large losses and generating important amounts of heat. Confined electrical systems, enclosures containing electrical components and other apparatus and devices can generate a lot of heat able to significantly reduce the life time of an installation if no appropriate thermal solutions were adopted. Cooling is also needed to provide the appropriate process or product quality with minimizing energy consumption and environmental impact. An ever-increasing power density drives the need for more effective thermal management solutions where several phenomena e.g. electromagnetic, thermal and/or mechanical can be simultaneously taken into account. ABB is a leading company within power and automation technologies and to maintain its product quality and market penetration has always invested in acquiring state-of-the-art hardware and software tools to cope with its technology needs and ambitions. We are also building our own integrated multiphysics simulation methods able to develop accurate thermal solutions that account for the major interacting physical phenomena. This presentation can introduce you to our know-how in terms of numerical predictions of coupled systems and will also provide you with several examples of solutions where advanced simulations have been used.

Biography

Rebei Bel Fdhila (male), Adjunct Professor in Process Modelling and Computational Fluid Dynamics at Mälardalen University since 2006. Got a PhD in 1991 from the National Polytechnic Institute of Toulouse, France “INP Toulouse/ENSEEIHT” within multiphase flows and worked as a post-doc with EDF and CNRS in France followed by Twenty University in Holland. Since 1995 he joined ABB Corporate Research in Sweden first as a researcher and today acting in his global role as a Corporate Research Fellow in Thermal Management. He has a large experience within the advanced modeling and simulation world. 30+ publications and 9 active patent families.

Plenary 2

Modelling and Simulation of the Electric Arc Furnace Processes

Assistant Professor Vito Logar

Laboratory of Modelling, Simulation and Control,
Faculty of Electrical Engineering, University of Ljubjana, Slovenia

Email: vito.logar@fe.uni-lj.si

Current market demands on steel quality, price and production times dictate the introduction of several technological innovations regarding the electric arc furnace (EAF) steelmaking. One of the fields, which is rapidly developing and has significant potential is related to the advanced software support of the EAF operation, which combines data acquisition, advanced monitoring and proper control of the EAF. This paper briefly presents the idea and development of all key EAF-process models, which are together with measured EAF data used to estimate the unmeasured process values. The models are based on fundamental physical laws and are implemented mainly using nonlinear, time-variant ordinary differential equations. The validation results that were performed using operational EAF measurements indicate high levels of estimation accuracy and the final outcome of the study results in a fully operational EAF model, describing all crucial steel-recycling processes. The accuracy of the presented models is in the range of +/- 15 K for steel temperature and +/-10 % for steel composition. Therefore, the versatility and accuracy of the models allows the usage of the models in broader software environments in a form of soft sensors for process monitoring, process optimization and operator decision support.

Biography

Vito Logar is an Assistant Professor at the Faculty of Electrical Engineering, Univ. of Ljubljana. He is working on the described area for many years in several projects. So his research interests include modelling and optimization techniques regarding the electric arc furnace steel recycling processes. In 2013 he received the award for outstanding scientific achievement for the year 2011 from the Slovenian Research Agency (ARRS). In 2014 he received the award for outstanding scientific and pedagogic achievements from the University of Ljubljana. He is currently also the president of the Slovenian society for modelling and simulation SLOSIM.

Plenary 3

Situation Awareness and Early Recognition of Traffic Maneuvers

Dr Galia Weidl

Daimler AG, Germany

Email: galia_weidl@hotmail.com; galia.weidl@daimler.com

We outline the challenges of situation awareness with the early and accurate recognition of traffic maneuvers and how to assess them. This includes also an overview of the available data and derived situation features, handling of data uncertainties, modelling and the approach for maneuver recognition. An efficient and effective solution, meeting the automotive requirements, is successfully deployed and tested on a prototype car. Test driving results show that earlier recognition of intended maneuver is feasible on average 1 second (and up to 6.72 s) before the actual lane marking crossing. The even earlier maneuver recognition is dependent on the earlier recognition of surrounding vehicles.

Keywords – bayesian networks, massive data streams

Biography

Galia Weidl obtained the MSc.degree in physics and mathematics from St.Petersburg State University, Russia, in 1993, and Fil.Lic. degree in theoretical physics from the University of Stockholm, Sweden, in 1996, and a Tekn.Dr. doctoral degree in process engineering from Mälardalen University, Sweden in 2002. Until 2006 she held a postdoctoral appointment at Stuttgart University, Germany. She has held appointments with the research teams at ABB Sweden (1997-2002), Bosch (2006-2008) and Daimler (since 2008). Her current research topic focuses on Bayesian networks in the area of autonomous driving. Galia Weidl was appointed in June 2015 by the European Commission as invited independent expert for Horizon2020.

Plenary 4

Simulating the Composition of the Atmosphere

Adjunct Professor Harri Kokkola

Atmospheric Research Centre of Eastern, Finland
Finnish Meteorological Institute, Finland.

Email: harri.kokkola@fmi.fi

Climate models are an essential tool when estimating how climate will change in the future. The atmospheric core of these models simulates the circulation of the atmosphere by solving fundamental physical equations of conservation of motion, mass, and energy as well as the equation of state. However, climate is affected also by several other processes than the atmospheric circulation and to get an accurate projection of future climate, it is necessary to incorporate all these processes in the model. Such processes include cloud formation (warm clouds, ice clouds), cryosphere (ice/snow), land surface (soil, reflectance), biosphere (ecosystems, agriculture), ocean (heat transport). These processes are calculated with individual submodels which are coupled to the core atmospheric model and they are also coupled to each other so that they interact. However, machine learning methods and emulator techniques are emerging in the climate science. We have investigated the potential of these methods to decrease the error coming from simplifications of aerosol processes in global aerosol models. Our results show that machine learning methods can significantly increase the accuracy of coarse aerosol models without significantly increasing their computational burden.

Biography

Harri Kokkola is the group leader of Atmospheric Modeling group at the Research Centre of Eastern Finland, Finnish Meteorological Institute. He is working on atmospheric modeling and aerosol-cloud interactions. The main focus in his research is global scale aerosol-climate modeling and has been one of the main developers of the aerosol-chemistry-climate model ECHAMHAMMOZ. His research group has developed an aerosol microphysics module SALSA which has been implemented in a cloud scale model, an air quality model as well as regional and global climate models. They are also actively involved in AeroCom project which is an open international initiative of scientists interested in the advancement of the understanding of the global aerosol and its impact on climate.

Plenary 5

Using the Power of Simulation to bring Bottom Line Benefits to the Mining, Minerals and Metals Operations

Roy Calder

Director, Technical Sales, Global Solutions
SimSci by Schneider Electric, Warrington, United Kingdom

Email: roy.calder@schneider-electric.com

While today's economic climate for the Mining, Metals and Minerals (MMM) industries may not be at its best; the industry is still faced with the need to deliver products cost effectively, at the correct specification, while maintaining a high level of safety for the plant and the personnel. For many years the MMM industry has lagged behind the Hydrocarbon Processing Industry (HPI) with regard the use of Simulation, however as the level of investment has grown over the years the need to ensure cost effective design, allied to improvements in delivery time the use of Simulation has become an integral part of the design, construction and commissioning of new plants across the globe. One area Simulation applications are proving themselves is in the area of Operational Safety. The HPI has long used Simulation based Operator Training Simulators to ensure safe operations and this is being carried over with increasing uptake happening in the MMM industry. In the future as the MMM industry becomes increasingly sophisticated at the same time facing the difficulties of shrinking bottom lines it is clear that Simulation will become fundamental in delivering the tools and solutions that will enable the industry to ensure growth in its bottom line in years to come. Schneider-Electric has had a long history in the MMM industry and this paper will highlight how the acquisition of Invensys has brought a completely new perspective to the industry and, most importantly, allows MMM companies to grow their Bottom Line.

Biography

BSc in Chemical Engineering, 1984, University of Strathclyde, Glasgow, then wide ranging industrial experience as: 1) in South Africa as a Metallurgist on Westonaria Gold mine, 2) SASOL in Rosebank as a Process Engineer, 3) L'Air Liquide, 4) INHER SA as Divisional Head, Process Engineering in 1991, where he managed the SULZER Chemtech Agency delivering process plant in multiple industries, 5) Process Sales Director, BHR, UK, 6) SimSci Division of INVENSYS, now Schneider-Electric. Currently Director of Technical Sales, SimSci regional team, 80 strong, on Simulation in engineering and operations community of industries as varied as Oil Production, gold and coal mining and the power industry. The team directly serve the EURA (Europe, Russia and Africa) activities of SimSci. Written numerous papers and presented at World Petroleum Congress, ERTC, SAICHE, AICHE, IChemE & DECHEMA events as well as numerous industrial symposiums. He is joint holder of a patent on the application of Structured Packing in Wax Separation.
He is devoted to Rugby, though no longer playing, and heads the Mini and Junior Section of his local club of some 300 budding young players.

Currently optical methods are gaining ground for biomedical applications such as cancer and cardiovascular diagnostics, dermatology, ophthalmology, pharmaceutical research, cosmetics and healthcare industry. Benefits of optical techniques are their non-invasiveness, ability for remote monitoring and access to biological objects from cell to body level, to name a few.

The light irradiation dose, measurement volume, sensitivity of optical modalities are of crucial importance in biomedical diagnostics before implementing the developed techniques in in vivo research and clinical trials. An essential part of the preliminary studies is the use of phantoms and simulations for the optimal configuration of the setup and refining the measurement procedure. Up to now, such simulations were performed in every lab using own codes and local resources.

We report about the next step in the computational diagnostics, an online computational platform for the needs of biomedical optics and biophotonics. The platform serves as a tool for calculation of a sampling volume, fluence rate, skin spectrum, skin colour, and a number of optical techniques including optical coherence tomography, polarization, coherent backscattering, pulse oxymetry, confocal microscopy, fluorescence, and diffuse wave spectroscopy.

We used the inheritance feature of Object-oriented programming (OOP) to create a ‘smart’ hierarchical structure of the Monte Carlo (MC) code to avoid having multiple classes for similar tasks. The hierarchy allows ‘allied’ objects to share variables and members, significantly reducing the amount of source code and paving the way to extend and generalize the MC. Depending on the application, objects can be tuned to an appropriate state of light-tissue interaction and to a particular optical diagnostic technique.

To achieve optical simulation performance, we employed a developed parallel computing framework known as Compute Unified Device Architecture (CUDA), introduced by the NVIDIA Corporation. Specially designed for professional 3D graphics applications, this technology allows each graphic chip to be logically divided into hundreds of cores, turning the graphics processing unit into a massive co-processor for parallel computations. This capability enables the simulation of thousands of objects, i.e. the simultaneous propagation of photons in the medium - that speeds the process of simulation up to 103 times.

The computational solution utilizes recent developments in HyperText Markup Language (HTML) 5, accelerated by the graphics processing units (GPUs), and therefore is convenient for the practical use at the most of modern computer-based devices and operating systems. Figure 1 shows the interactive user interface for selecting a particular MC application. The results of imitation of human skin reflectance spectra and the corresponding skin colors are presented in Figure 2.

The platform can ease research in a number of areas and can be used for professional and educational purposes.

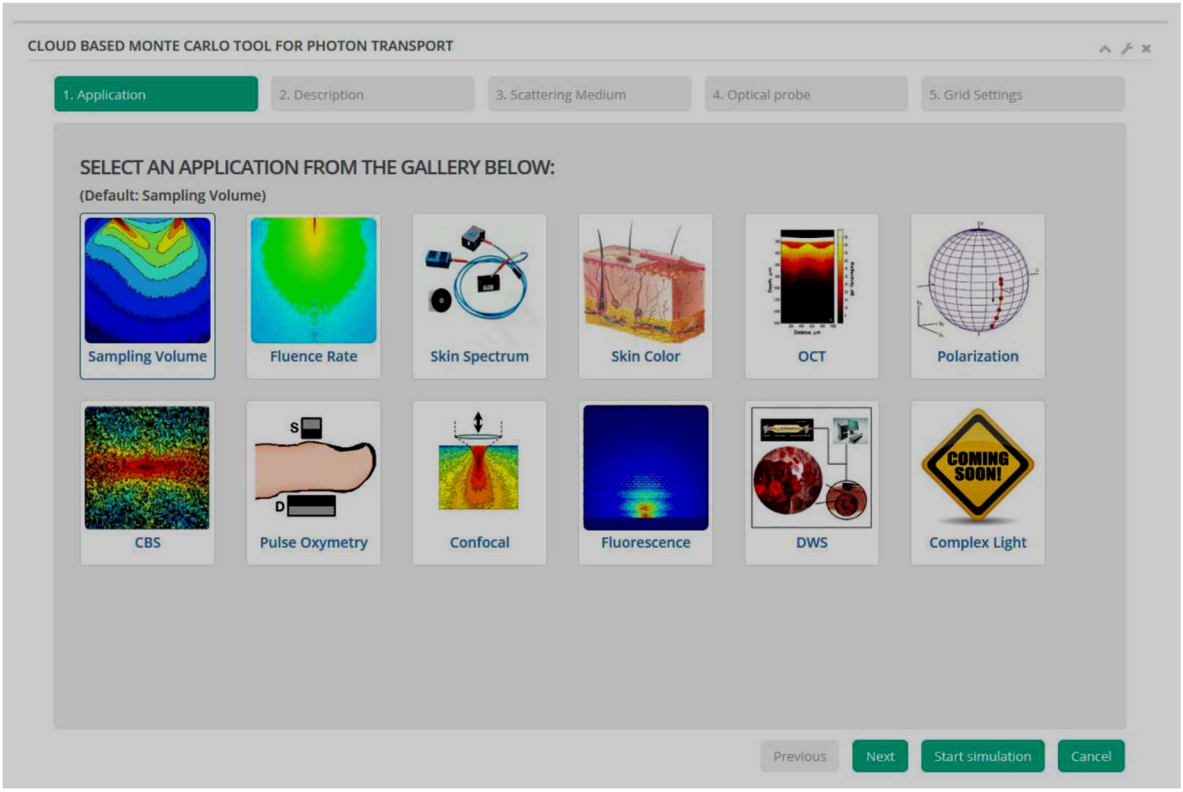

Figure 1. A variety of options offered by the online platform (www.biophotonics.fi).

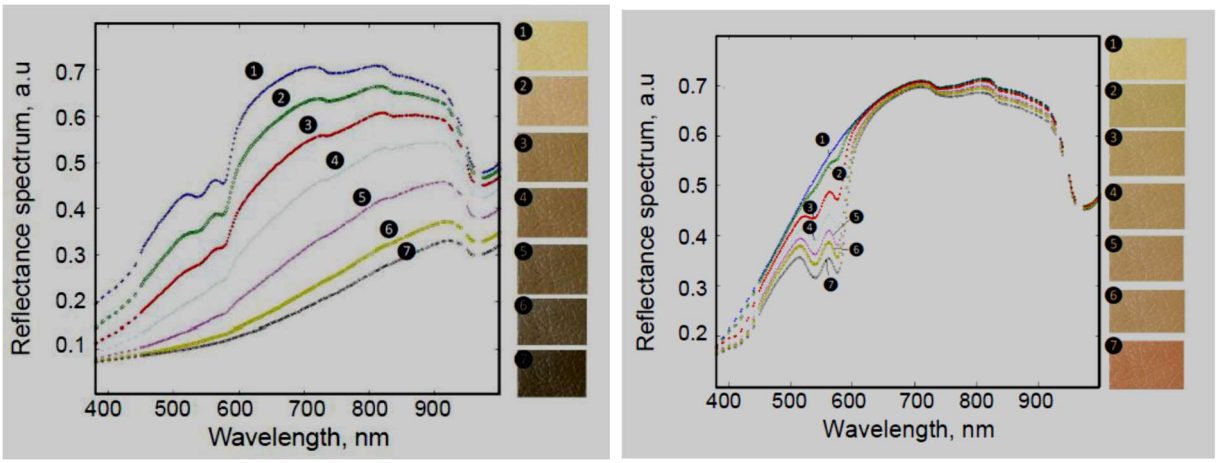

Figure 2. Results of MC simulations of human skin spectra and corresponsing colors while varying the melanin content in living epidermis (left): (1) – 0%, (2) – 2%, (3) – 5%, (4) – 10%, (5) – 20%, (6) – 35%, (7) – 45%; and while varying the blood concentration (right) in the layers from papillary dermis to subcutaneousl tissue: (1) – 0%, (2) – 2%, (3) – 5%, (4) – 10%, (5) – 20%, (6) – 35%, (7) – 45%, respectively.

Biographies of the authors

Alexey Popov, D.Sc. (Tech.) is a Senior Researcher and Docent in Optoelectronics and Measurement Techniques Laboratory at the University of Oulu, Finland. He graduated from the Physics Department of M.V. Lomonosov State University (Russia) with M.Sc. degree in 2003 and was awarded with PhD degree in 2006. He received his D.Sc. (Tech.) degree from the Faculty of Technology of the University of Oulu (Finland) in 2008. He is an author of 90 papers in international peer reviewed journals and SPIE proceedings and ca. 100 presentations at major international conferences, symposia and workshops including 15 invited lectures. Currently, he is a Senior Researcher and Docent in the Optoelectronics and Measurement Techniques Laboratory at the University of Oulu; a member of SPIE and a Faculty Advisor of the SPIE Student Chapter of the University of Oulu, Northernmost and 1st in Finland.

Alexander Bykov, Ph.D. (Phys.) and D.Sc. (Tech.), born in 1981, is curently a Postdoctoral Researcher at the Optoelectronics and Measurement Techniques Laboratory, University of Oulu. He has over ten-year experience in research in the fields of photonics and biomedical optics. He received M.Sc. diploma in Physics at the M.V. Lomonosov Moscow State University in 2005 and Ph.D. in 2008 from the same university. In 2010, he received D.Sc.(Tech.) degree from the Faculty of Technology at the University of Oulu and continued as a postdoctoral researcher at the Optoelectronics and Measurement techniques laboratory. He is an author and co-author of over 60 scientific papers published in refereed international journals and book chapters, cosupervisor of undergraduate and postgraduate students.

Alexander Doronin is a Postdoctoral Associate in Computer Science working in Computer Graphics Group, Yale University, USA. His research interests are interdisciplinary and lie at the interface between Computer Science, Physics, Optics and Biophotonics focusing on Physically-Based Rendering, Development of realistic material models, Monte Carlo modeling of light transport in turbid media, Color Perception, Translucency, Appearance and Biomedical Visualization.

Hannu Sorvoja, D.Sc. (Tech.), born in 1966, is currently a Laboratory Manager at the Optoelectronics and Measurement Techniques Unit, University of Oulu. He has over twenty-year experience in research in the fields of biomedical engineering. He received M.Sc.(Tech.) in Electrical Engineering 1993, Lic.Sc.(Tech.) in 1998, and D.Sc.(Tech.) 2006, all from the Faculty of Technology at the University of Oulu, and continued as a professor and a postdoctoral researcher. He is an author and co-author over 40 scientific papers published in refereed international journals or conferences and three patents. In addition, he has supervised over 30 M.Sc.(Tech.) and Lic.Sc.(Tech.) theses.

Professor Igor Meglinski, Ph.D. is Head of Optoelectronics and Measurement Techniques Laboratory, Faculty of Information Technology and Electrical Engineering, University of Oulu. He has over 20 years experience in biomedical optics, biomedical engineering, medical physics, and sensor technologies. He is an author and coauthor of over 200 research papers in the peer reviewed scientific journals, proceedings of international conferences and book chapters, and over 400 presentations at the major international conferences and symposia, including over 200 invited lectures and plenary talks. His research interests lie at the interface between physics, medicine, and biological sciences, focusing on the development of new non-invasive imaging/diagnostic techniques and their application in medicine and biology, material sciences, pharmacy, food, environmental monitoring, and health care industries. For the last ten years, he has been a Principal Investigator and/or Coordinator for over 60 research projects, supported by various funding bodies, including UK NHS trust, NATO, Royal Society, U.S. CRDF, New Zealand Ministry of Business, Innovation & Employment, Maurice Wilkins Centre (MWC), New Zealand Ministry of Foreign Affairs and Trade, A*STAR (Singapore), Federal Agency for Science and Innovations (Russia), Weizmann Institute of Science (Israel) and industrial partners including Procter & Gamble, Philips, General Electrics, Unilever and other (with a total cumulative budget of over $16M). Prof. Meglinski is a Fellow of the Institute of Physics (London, UK) and Fellow of SPIE.

What is cleantech? Cleantech consists of products and services which are focused on the use of renewable natural resources and recycled materials in an energy-efficient way. Cleantech utilizes biological natural resources and turns them into food, energy, and other products and services. Cleantech uses clean technologies, which saves the environment by efficient recycling of materials. How? We have a broad range of technologies related to recycling, renewable energy, information technology, green transportation, electric motors, green chemistry, lighting, grey water, and more. Does this mean that cleantech is gradually introduced in all areas?

The environment is restored with pollution removal and avoidance. What can we do in practise? Air has been a focus area in industry, energy and traffic. Water treatment has been developed to remove undesirable chemicals, biological contaminants, suspended solids and gases from contaminated water. Where do we have the main risks? Availability of usable water may set constraints on operation. In industrial processes, closed water circulation is a goal which is beneficial for the environment. Wastewater treatment is needed for purifying contaminated water before returning it to the nature. Why are there difficulties in combining industrial and domestic wastewater treatment? Mining introduces many challenges for the environment. Renewable energy, including wind power, solar power, biomass, hydropower, biofuels etc., is an essential part in integrating cleantech with the energy production. Waste can be used as raw material or fuel in many ways. Power plants can use waste in energy production. What are the main challenges?

A circular economy aims to close the loop to make economy more sustainable and competitive. This should be more than just recycling. What does this mean? Water and wastewater treatment are good examples. There are challenging tasks for Information technology, modelling, control and optimisation. How can we proceed? What kind of Modelling and Simulation is important in cleantech? How can we compare alternative solutions and build situation awareness? The problem solving in cleantech includes the smart integration of all the historical elements, earth, fire, water and air, with data.

Rebei Bel Fdhila, ABB Corporate Research, Sweden
Luis J. Yebra, CIEMAT-Plataforma Solar de Almería, Spain Panelists:

A thermal power station or a coal fired thermal power plant is by far, the most conventional method of generating electric power with reasonably high efficiency. Technology has reached very high levels and environment is in focus in many ways. Bioenergy takes an increasing portion of the production: a wide variety of materials are used as fuels. Oil and gas hold a very strong position in overall energy usage. Biofuels provide new competing alternatives. CO_2 capture has taken a high role in research. Is it important also in practise? Are we going to bioeconomy? Is the thermal power a necessity in our energy balance?

Sustainable or renewable energy is considered as a future source of energy, but it is already strong in many forms: water power is well integrated in the energy system; solar and wind are getting more popular; geothermal, wave and tide energy can be locally very important. Electricity is increasingly popular both in solar and wind power. To what level it is sufficient? Efficiency is not very high in solar panels. Wind power cannot reach sufficient operating hours. We need storages but can we find practical solutions? Solar thermal power plants, especially concentrating technology, provide higher efficiency. There are many feasible solutions to thermal storage. What to use? How to design a system? What is needed in control? There are unavoidable disturbances.

Where do we use energy? Industry needs high reliable levels. Is the nuclear power a solution? Adaptation is easier in domestic use, but how to do it? Heating and cooling take the highest part. Solar energy can help but needs storage. Geothermal can be used as storage. What is the potential of buildings as storages? Do we need small scale Combined Heat and Power (CHP)? District heating systems are good solutions to bring the thermal energy to buildings. Smart grids have studied mainly for electricity. What do we need for smart thermal grids? In northern areas, we have consumption peaks. Can we cut them with smart adaptation? Traffic is under change: electricity is gaining popularity; interesting biofuels have been introduced; fuel cells are considered as a future option in the way to the hydrogen economy. How to integrate these with sustainable energy? How to choose an operable portfolio from the increasing alternatives of energy production?

Panel 3: Intelligent Systems and IoT in Future Automation

Chairs:
Esko K. Juuso, University of Oulu, Finland
Lars Eriksson, Linköping University, Sweden

Panelists:
Roy Calder, Schneider Electric, United Kingdom
Yukinori Suzuki, Muroran Institute of Technology, Japan
Galia Weidl, Daimler AG, Germany

In industry, intelligent systems have been developed for integrating data and expertise to develop smart adaptive applications. Recently, big data, cloud computing and data analysis has been presented as a solution for all kinds of problems. This provides feasible new things in global business and digitalisation in new applications. Can we take this as a general solution for automation? Are sensors only for collecting data to clouds? However, e.g. condition monitoring introduces huge volumes of data. Wireless solutions are improving fast: 3G, 4G, 5G. But can we transfer signals to clouds and store the data? Is this too much? Where is the expertise? Obviously, local calculations are needed. Are they based on intelligent systems? Also the security of the automation becomes increasingly important in distributed systems.

Transport systems are analysed as discrete event systems to find bottlenecks and avoid risks. Urban traffic is becoming an important area. Autonomous driving is a hot topic. What is needed to embed this in the urban traffic? Are there analogies with industrial systems? Mechatronics is an essential part in machines and many process devices. IoT with sensor development and access to traffic information opens up many opportunities for planning and control of transport through optimization.

What are the main differences between industrial systems and transport systems? Can we use similar control solutions? What can we learn from other areas? Can we find analogies? What is common? Where do we have differences? What kind of models do we need? What should the control

Modelling and Simulation of the Electric Arc Furnace Processes

Vito Logar

Faculty of electrical engineering, University of Ljubljana, Slovenia, vito.logar@fe.uni-lj.si

Abstract

Market demands on steel quality, price and production times dictate an introduction of technological innovations regarding the electric arc furnace (EAF) steelmaking. A developing field with significant potential is related to the advanced software support of the EAF operation, combining monitoring and proper control of the EAF. Such systems include process models, capable of continuous estimation of the unmeasured process values, such as chemical compositions and temperatures of the steel, slag and gas. The paper briefly presents the features of all developed EAF models, which are used together with the measured EAF data to estimate the unmeasured process values. The models are mainly implemented using non-linear, time-variant ordinary differential equations. The parameterization of the models was performed using the available EAF data, such as temperatures, steel and slag compositions, melting programs etc. The validation results that were performed using measured EAF data indicate high levels of estimation accuracy of all crucial steel-recycling values and processes. The accuracy of the presented models is in the range of +/- 15 K for steel temperature and +/-10 % for steel composition. Thus, accuracy of the models allows them to be used in broader software environments, such as soft sensors for process monitoring, optimization and operator decision support.

Keywords: electric arc furnace, EAF, modelling, simulation, validation

1 Introduction

Current market demands on steel quality, price and production times dictate an introduction of several technological innovations regarding the electric arc furnace (EAF) steelmaking. An emerging field with huge potential, but yet rather unexplored, is also advanced software support of the EAF operation. Running in parallel to the EAF process such systems allow online monitoring, fault detection and even model-based control of the process. Using such systems in parallel to the actual EAF process can have several advantages in comparison to the manual EAF operation, arising from the nature of the steel-melting process. As known, several crucial process values are hard to measure continuously, such as temperatures and chemical compositions of the steel, slag and gas etc. Using EAF process models, which integrate all significant EAF phenomena and use available EAF data to calculate the missing process values, results in a system, which is able to estimate the process values with sufficient accuracy. In this manner, better insight to the melting process can be established and consequently a more optimal operation of the EAF can be performed.

The paper presents an overview of the proposed EAF model, including electrical, hydraulic, mass-transfer, heat-transfer and chemical submodules in terms of modelling approach, modelling detail and schematic representations of the model structure. Since the mathematical models of the EAF have already been developed, validated and extensively described (Logar *et al* 2011, 2012) the paper presents only the key characteristics of each separate submodule and its importance for the overall accuracy of the calculations. Furthermore, the paper discusses possible and necessary upgrades of the models to implement them in process-optimization and decision-support frameworks. The aim of those is to present an EAF operation-support tool, which will be running in parallel to the EAF process and will be used for enhancement of the operation, such as: a) EAF operation monitoring based on soft-sensing technology, allowing a better insight to the melting process and consequently more optimal control of the EAF; b) process-optimization based on process models, optimizing the melting programs, according to the current state in the EAF; c) operator decision support, combining the advantages of model-based soft sensors and process optimization in one solution, representing the highest level of EAF software support.

2 Modelling of the EAF processes in general

Section The literature review in the field of modelling, optimization and control of the electric arc furnaces shows that many different models and engineering approaches studying the EAF processes have been developed. Most of these are focused on particular processes of the EAF and were developed for the purpose of the field research or simulation of the EAF operation. A few models were designed especially for their implementation into industrial applications as an operator-support tool for monitoring of the recycling process and thus easier decision making and control of

the processes. First models associated with the EAF processes were introduced back in 1980s and were functionally extremely limited. Modern models have progressed in their complexity, usability and accuracy and are also used in industrial applications for monitoring of the EAF during the steel-melting process. Below, some of the most relevant research and practical applications in the field of modelling, optimization and control of the EAF processes are described.

Woodside (1970) introduces a concept for optimal EAF control, based on Pontryagin approach and uses it for optimization of the energy input during coke injection. The simplified model was introduced in 1970 and was able to estimate bath temperature and carbon concentration. Montanari *et al* (1994), Tseng *et al* (1997), Collantes-Bellido and Gomez (1997) introduce mathematical models describing the electrical part of the EAF and the impact of the EAF operation on electrical grids in terms of disturbances (flickers) and their elimination.

In 1999, Bekker *et al* (1999) develops a mathematical model implementing thermodynamic relations for the purposes of EAF-process simulation. The model is simplified and assumes that all available heat is transferred directly to the steel bath and further from the bath to the solid steel. Although it addresses some important chemical reactions and the released energy, the presented simulation results are not validated and thus applicable only with limitations. Nonetheless, the Bekker model represents one of the first attempts to model all crucial processes of the EAF. Additionally, Bekker *et al* (2000) introduces a concept of model-predictive EAF control (MPC).

Oosthuizen *et al* (2001, 2004) designs a mathematical model of the EAF processes derived from the Bekker model. Using a more complex modelling approach, the proposed model gains on estimated offgas temperature accuracy and allows a calculation of the slag foaming. Furthermore, optimal controller is introduced, which should control the furnace in a manner to reduce its operational costs. Similarly to Bekker, a simulation study involving a model-based control (MPC) is performed on the model for the purposes of cost reduction.

One of the most sophisticated EAF models up to 2005 was introduced by MacRosty and Swartz (2005, 2007) and used for optimization of the EAF process. The model considers the complete EAF and includes chemical, mass- and heat-transfer processes. Due to modelling simplifications, the EAF layout is divided into four zones with similar physical characteristics. Chemical reactions in each zone are based on molar-mass equilibria, while the overall model is based on energy and mass equilibrium. The model was validated using the measured operational data and can be used to estimate bath temperature, bath composition and slag composition. Further on, the model is implemented in a simulation study to optimize the operational costs of the EAF. The authors report of several issues regarding the optimization procedure and its unreliability.

Logar *et al* (2011, 2012) introduce complex EAF models, including electrical, hydraulic, chemical, heat- and mass- transfer processes. The models are based on fundamental physical laws and are validated on measured operational data of the EAF. The results show high levels of similarity between the measured and the simulated data. The combination of all developed models in one functional model represents the most complex approach to EAF modelling found in literature. Many studies have been performed in the field of numerical modelling of the EAF. The field has been established as a new, fast emerging science and engineering discipline that encompasses computational solid mechanics (Fung *et al*, 2001) and fluid mechanics (Schiestel, 2008), connected with solidification phenomena (Dantzig et al, 2009, Glicksman, 2010), allotropic transformations phenomena (Hazotte, 2003), and put into the context of computational microstructure evolution (Janssens *et al*, 2007) in processes like casting (Fredriksson and Åkerlind, 2006), heat treatment (Gür and Pan, 2009) etc. The use of numerical modelling proved to be an efficient approach for modelling the relations between bath stirring, fluid flow and electromagnetic (EM) forces. Due to the complex coupling between flow and EM forces, numerical modelling is the most economical way of analyzing, optimizing and developing new applications. Many modern industrial processes, such as electrical arc furnaces, rely on findings of EM, heat-, mass-transfer and metallurgical science. Their interconnections are currently not sufficiently understood and computationally modelled.

Furthermore, modelling approaches to gas-phase phenomena (Meier *et al*, 2015, Kolagar *et al*, 2015) and EAF off-gas heat recovery have been proposed (Gandt *et al*, 2016).

The implementation of the mathematical models in industrial applications can be found at renowned EAF manufacturers and users, such as Tenova, Siemens VAI, SMS Siemag, Centre de Recherche Métallurgiques (CRM), ArcelorMittal and BFI (Clerici *et al*, 2008, Dorndorf *et al*, 2007, Khan *et al*, 2013, Natschläger *et al*, 2008 and Nyssen *et al*, 2007). The developed models vary in modelling approach, modelling detail, usability, accuracy and types of input data used for estimating the process values. Reviewing the available literature, most of these models are based on static calculations using statistical or regression methods, i.e. SMS Siemag, BFI and Tenova. The model, based on dynamic modelling approach was introduced by CRM. It relies on fundamental laws of thermodynamics and is used to estimate the end-point bath temperature. It is claimed that the accuracy of the model is +/- 50 K, which

indicates that further improvements of the model are possible.

The literature review reveals that all models used in industrial applications are designed solely for estimation of the process values, while no support to the operators in the sense of optimal control is given. Thus, the main challenge in EAF operation, i.e. determination of optimal melting programs, times and amounts of charged materials, is therefore still left to the operator and his experience.

Regarding the literature review, a design of the overall EAF process model was initiated, incorporating all crucial EAF processes and focusing on accuracy and usability of the obtained solution for further development and its inclusion to several other software environments.

3 Modelling approach

3.1 General

The models as presented in this paper have been developed according to the fundamental physical laws by means of non-linear, time-variant, first order differential equations; although, several other approaches could be implemented as well. The selected approach has its advantages and drawbacks when compared to other possibilities; however, the possibility to use the developed models with as many EAF designs as possible was the main aim of the study and for this reason the models are based on fundamental mathematical/physical approaches. The model can be presented schematically as in Fig. 1.

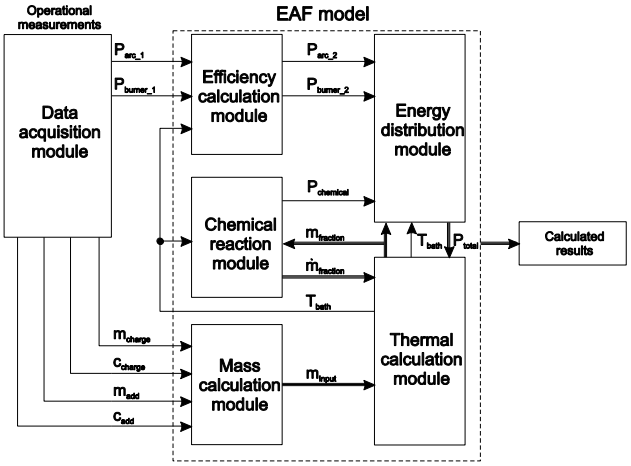

Figure 1: Schematic presentation of the developed EAF models

The presented model as shown in Fig. 1 comprises mathematical descriptions of all main physical processes appearing during the steel-recycling process, i.e. electrical, hydraulic, thermal (including radiation), chemical and mass transfer. As shown in Fig. 1, the model for estimation of the EAF process values is composed of several modules, which contain mathematical relations describing the physical properties of the EAF steel melting process and the corresponding model parameters. The calculations are grouped in submodules in order to simplify the model structure and assure low computational loads.

Due to complexity of the modelled processes and in order to simplify the obtained models, the EAF layout has been divided into several zones, assuming that each zone is homogenous and possesses equal physical characteristics, such as temperatures, densities, heat transfer coefficients etc. The zones used in the model are solid steel, liquid steel, solid slag, liquid slag, gas, roof and walls, as shown in Fig. 2.

According to the above, calculations of a separate submodule are limited only to certain zones, i.e. electrical and hydraulic models appear in no zone directly, heat-transfer model appears in all zones, mass transfer model appears in solid steel, liquid steel, solid slag, liquid slag and gas zones, and the chemical model appears in liquid steel, liquid slag and gas zones.

3.2 Model characteristics

Each of the above models utilizes different physical laws and mathematical equations in order to obtain the values needed by other models or as an end result/estimation. The electrical and hydraulic models can be characterized by the following:

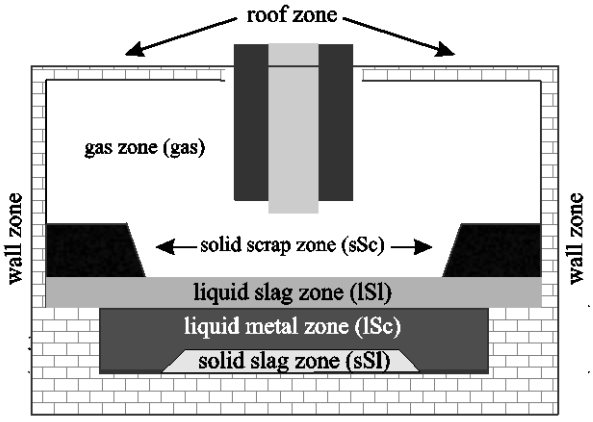

Figure 2: Division of the EAF layout to different zones

- all electrical values are calculated using harmonic analysis, i.e. in complex space,
- Cassie-Mayr arc model (1st order ODEs) is used with additional variable Lorentz noise,
- the models utilize transformer and reactor taps, resistances/reactances of lines, transformer, arcs and steel, all electrical values (voltages, currents, powers, energies, power factors, impedances etc.),
- electrode control is carried out using a hydraulic model and three independent PI controllers,
- the model parameters are variable for different stages of the melting process, i.e. electrode bore-down, melting, flat bath.

The heat-transfer model can be characterized by the following:

• the melting process is divided to different phases of the melt-down (electrode bore-down, exposing panels, flat bath etc.)

• 1st order ODEs are used to calculate the temperatures based on energy input/output balances

• heat-transfers are utilized to each zone from: arcs, burners, chemical reactions, volatile oxidation, electrode oxidation and other zones,

• heat losses are utilized due to cooling of the furnace, offgas extraction, steel and slag enthalpy,

• implementation of geometry supported (view-factor based) radiative heat exchange,

• taking into the account temperature-dependent burner efficiency and continuous transitions between the zones (geometry supported).

The mass-transfer model can be characterized by the following:

• the melting process is divided to different phases of melt-down (electrode bore-down, exposing panels, flat bath etc.)

• 1st order ODEs are used to calculate mass transfers based on temperature levels (melting) and energy input/output balances,

• elements and compounds which are taken into the account in calculations are:

- steel zone: Fe, C, Si, Cr, Mn, P

- slag zone: FeO, SiO_2, MnO, Cr_2O_3, CaO, MgO, Al_2O_3, P_2O_5

- gas zone: N_2, O_2, CO, CO_2, CH_4 (gas burners),

• implementation of reversible dynamics (cooling and solidification of the steel),

•calculation of mass transfers due to: melting, charging and slag addition, oxygen-fuel burners, oxygen lancing, carbon injection and chemical reactions.

The chemical model can be characterized by the following:

• implementation of all main chemical reactions appearing in the steel-melting process (oxidation/reduction of Fe, FeO, Si, SiO_2, C, CO, Mn, MnO, Cr, Cr_2O_3, P and P_2O_5),

• 1st order ODEs are used to calculate rates of change of elements/compounds based on molar equilibria with reaction equilibria constants dependent on molar composition of the zone,

• utilization of chemical energy exchange due to exothermic and endothermic reactions,

• calculation of foaming slag height based on slag density/viscosity/surface tension and superficial gas velocity (CO) including slag decay,

• calculation of online and endpoint steel/slag/gas compositions and relative pressure.

The parameters of the model (approximately 100) were obtained using known data or conclusions of different studies (transformer taps, resistances/reactances, furnace dimensions, heat capacity coefficients, densities, emissivities, enthalpies of formation, reaction rates, molar masses etc.) or were determined experimentally using the available initial, online or endpoint operational EAF measurements (cathode voltage drops, arc temperatures, arc conductances, arc cooling constants, slag-reactance coefficients, heat-transfer coefficients, specific area coefficients, arc-energy distributions etc.). The validation of the models was carried out using operational EAF measurements, which were obtained during different melting scenarios. In this manner, an accurate model of the actual EAF recycling process was obtained.

4 Results

The displayed results show the most important estimations of the process values while operating the EAF, i.e. bath temperatures, steel compositions and slag compositions. Fig. 3 shows the comparison between measured and model simulated values for initial steel mass, endpoint steel mass, power on time and bath temperatures. The results were obtained from several heats and are represented in a form of a mean value with standard deviation.

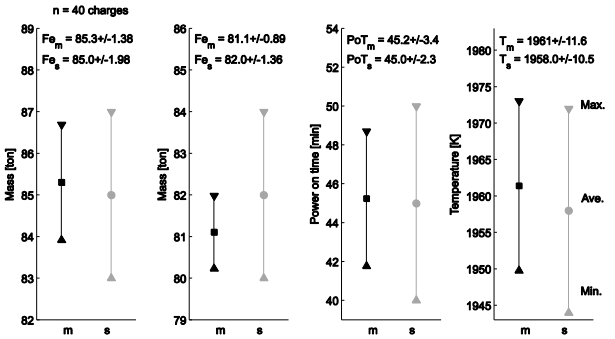

Figure 3: comparison between measured and simulated values for initial (1st) and enpoint (2nd) steel mass, power on time (3rd) and bath temperatures (4th). Black squares and grey circles represent measured and simulated mean values, while black and grey triangles represent measured and simulated standard deviations, respectively.

As can be seen in Fig. 3, all measured and simulated values are similar, both in mean values and in standard deviations. The most important validation values from Fig. 3 are steel yield (difference between the initial and endpoint steel masses) and steel bath temperature. Bath temperature is usually measured one to three times before tapping, while steel yield is determined at

tapping. Neither of these values is measured continuously during the EAF operation.

Fig. 4 shows the comparison between measured and model simulated endpoint steel composition in a form of a mean value with standard deviation.

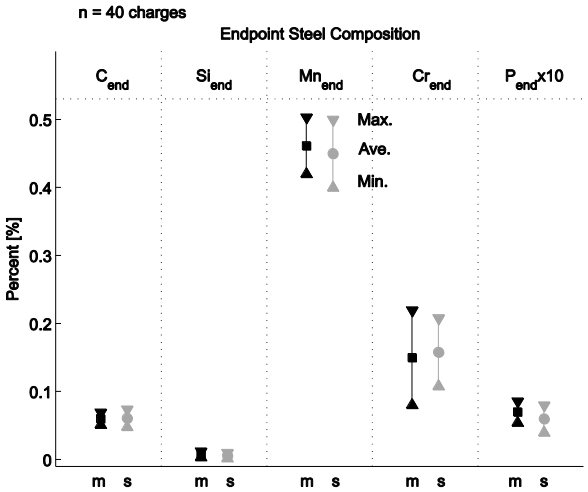

Figure 4: comparison between measured and simulated endpoint chemical compositions of the steel

As can be seen in Fig. 4, all measured and simulated values are similar, both in mean values and in standard deviations. The most important validation value from Fig. 4 is the carbon content in the steel, since carbon percentage is (among others) directly linked to different steel grades produced and has to be determined and contained in proper amount. Complete steel composition is determined at tapping and is otherwise not measured continuously.

Fig. 5 shows the comparison between measured and model simulated endpoint slag composition in a form of a mean value with standard deviation.

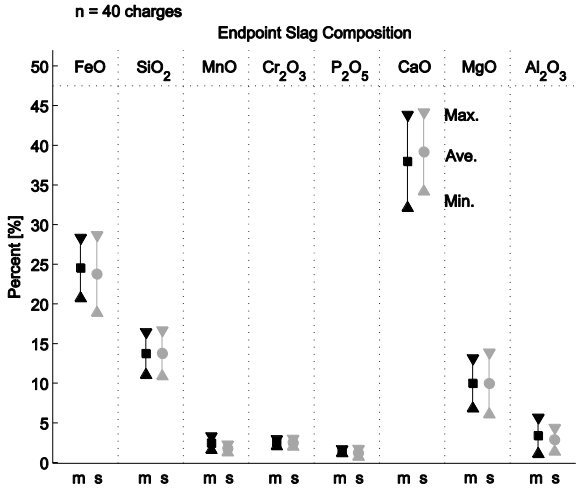

Figure 5: comparison between measured and simulated endpoint chemical compositions of the slag

As can be seen in Fig. 5, all measured and simulated values are similar, both in mean values and in standard deviations. The most important validation value from Fig. 5 are FeO, SiO2, MnO, CaO and MgO contents in the slag, since these compounds define the properties of the slag, which are linked to its foaminess and protective characteristics.

Fig. 6 shows the energy balance as calculated by the proposed model.

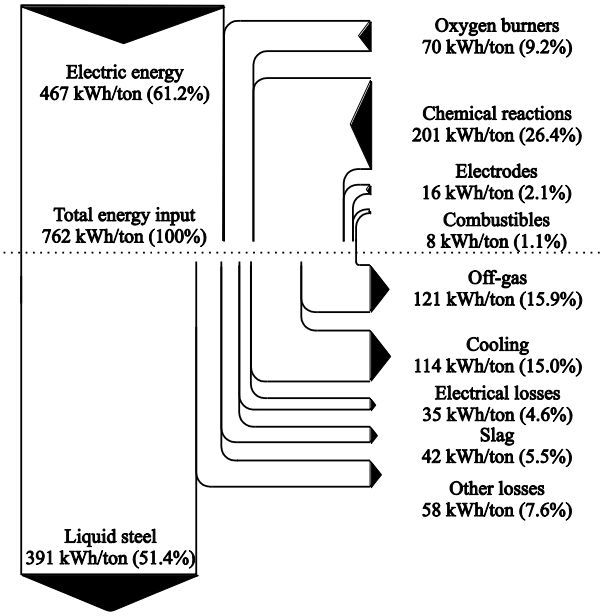

Figure 6: energy balance of the EAF as obtained by the proposed model

As can be seen in Fig. 6, total energy input required to produce 1 ton of steel is approximately 760 kWh. More than a half of this energy is represented by electrical energy, while other important sources of energy are oxygen burners and chemical reactions. Regarding the losses of energy, approximately 390 kWh of energy is held by steel enthalpy due to its high temperature. This energy is later lost to the environment as the steel cools down. Furthermore, off-gas extraction and cooling of the furnace vessel also represent an important sinks of energy.

5 Practical applications of the model

Due to the nature of the EAF steel-recycling process (high temperatures and electric currents), performance of the crucial process measurements is difficult. Consequently, monitoring and control of the melting process is performed using the operator's experience and is based on indirect measurements (e.g. power-on time, consumed energy, arc stability etc.) and not on the actual conditions in the EAF (e.g. stage of melting, bath composition, bath temperature), which leads to suboptimal operation, i.e. lower energy and raw material efficiency, increased off gas and CO2 emissions, decreased quality of the steel; and consequently higher operational costs.

Furthermore, operational efficiency is influenced also by variable composition of the input materials (steel scrap, non-metallic additives). The fluctuations in EAF operation can be resolved using a combination of EAF

process models, optimization techniques and decision support methods. The combination of these methods together with available process measurements forms a supporting system for operation of the EAF. Such a system uses process measurements as inputs, in order to provide a better insight into the current EAF conditions and to suggest the most appropriate action, leading to more efficient operation of the EAF. Using mathematical models, which are designed in compliance with the physical laws and using available measurements as inputs, crucial process values, which are not measured, can be estimated in parallel to the EAF process with high accuracy.

In this manner, an optimal operation of the EAF can be established, leading to higher steel yield, lower energy, raw material and additive consumption, shorter production times, higher steel quality etc. The introduction of such operation indirectly leads to improved economic, ecological and technological aspects of the mills, with such system installed.

6 Conclusions

In this paper a brief explanation of the modelling approach to crucial EAF processes as well as its potential use in higher-level applications is presented. Furthermore, some key comparisons between the measured and the simulated values are presented, showing the overall accuracy of the calculations.

The objective of developing a complete EAF model is to use it in application frameworks for different purposes, such as online monitoring, process optimization or operator decision support. Since the description and modelling details are far too great and extend the frame of this paper, all interested readers can refer to the reference list (Logar et al.) for further information.

Abstract

We outline the challenges of situation awareness with early and accurate recognition of traffic maneuvers and how to assess them. This includes also an overview of the available data and derived situation features, handling of data uncertainties, modelling and the approach for maneuver recognition. An efficient and effective solution, meeting the automotive requirements, is successfully deployed and tested on a prototype car. Test driving results show that earlier recognition of intended maneuver is feasible on average 1 second (and up to 6.72 s) before the actual lane marking crossing. The even earlier maneuver recognition is dependent on the earlier recognition of surrounding vehicles.

Keywords: Bayesian networks, massive data streams

1 Introduction

A highway, typically providing several traffic lanes, is characterized by complex scenes with many vehicles. Reliable situation assessment requires multi-sensor fusion and management of uncertainty in order to interpret accurately the traffic environment. To reduce the risk of accidents and congestions, an autonomous system must analyze and be aware of possible hazards of a driving situation. This includes: correctly recognizing intended maneuvers of all surrounding vehicles at an early stage and using this information to enable corrective actions like braking or steering, thus helping to avoid or mitigate potential collisions. Situational awareness and recognition of traffic maneuvers are key elements of modern driver assistance and autonomous driving systems (Kasper *et al*, 2011, 2012, 2013; Morris *et al*, 2011; Kumar *et al*, 2013; Tereshchenko, 2014; Schlechtriemen *et al*, 2014; Weidl *et al*, 2014, 2015, 2017; Mori *et al*, 2015; Satzoda *et al*, 2015; Zeisler *et al*, 2015).

A probabilistic approach, using Object-Oriented Bayesian networks (OOBNs) for maneuver recognition has been proposed in (Kaper *et al*, 2011, 2012, 2013) and (Zeisler *et al*, 2015). It is based on the own (ego) vehicle dynamics, its driving path in relations to the lane markings and/or surrounding vehicles, to evaluate the vehicles' relevance as possible target objects and to recognize earlier maneuvers in real traffic. In addition to the data from in-vehicle sensors, including both the vehicle kinematics and vehicle surround dynamics, (Satzoda *et al*, 2015) also uses visual data from multiple perspectives to characterize lane changes. In (Kaper *et al*, 2011, 2012, 2013), we use pairwise vehicle-vehicle relations; as far as the sensors can percept the surrounding objects.

In (Mori *et al*, 2015) an approach, based on Hidden Markov Models computes the driver's intent on lane change and/or potential risk of accidents. This work studied the driver decisions whether is safer to change lane in front of a faster car closing the gap or to brake for keeping a safe distance to a slower car in front, by evaluating the time-to-collision (TTC). We have used similar features in the safety model (in section 3) to infer the intention on lane change for the situations shown in Figure 1, utilizing the relative longitudinal dynamic between a vehicle (own, neighbor) and the vehicles in front and back, driving on the target lane (Tereshchenko, 2014). This effectively builds a gap for finishing a lane change maneuver and has an impact on the decision for lane changing, see (Tereshchenko, 2014; Mori *et al*, 2015; Weidl *et al*, 2015; Yan *et al*, 2015). The mentioned features, characterizing the vehicle state, were extended in (Li *et al*, 2015) with the driver's operation signals to enhance by hidden Markov models the classification of lane change maneuvers.

In our recent work (Weidl *et al*, 2015) and for the results reported here, we have focused on the development of a solution for maneuver recognition and its deployment on a Linux based system emulating the automotive target platform, using commercially viable sensors, image processing and multi-sensor fusion. We use the commercial software HUGIN, allowing efficient BN modelling and automated c-code generation. All

current and future developments are compared to our initially developed "Original (ORIG)" OOBN, which has shown promising results as described in (Kasper *et al*, 2011, 2012, 2013; Weidl *et al*, 2014). Our latest work (Weidl *et al*, 2015) describes three statistical classifiers as deployed on the prototype vehicle as well as the planned dynamic extension into a Dynamic Bayesian Network (DBN). The DBN are now deployed on the vehicle and evaluated in highway drive and in statistical comparison to other static classifiers. The main contribution of this work is the extension of all four classifiers with special evidence for better accuracy. The DBN deployment on the automotive target platform has been successfully tested in real highway driving.

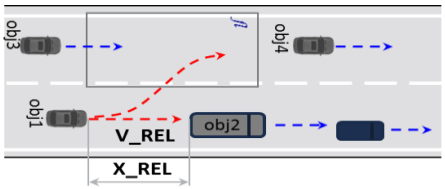

Figure 1. *Longitudinal* relative dynamics between following and front vehicles, both moving on the same lane. *Lateral* relative dynamics towards the lane marking, when initiating a lane change maneuver.

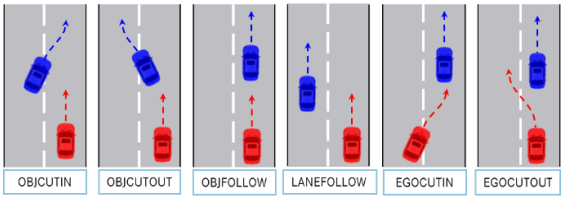

Figure 2. Maneuver recognition as a vehicle-vehicle relation between the own EGO-vehicle (red) and a neighbor OBJ-vehicle (blue).

The automotive target platform represents both a storage and an inference challenge. The requirement on automotive safety demands accuracy close to 100% for a prediction horizon of 1 second. Moreover, the solution should scale to the specification of the hardware restrictions of the target platform. It should meet the automotive requirements on computation time and memory space, which are strongly constrained by the electronic control unit. The quick development of situations over time requires an automatic system, capturing and analyzing massive data streams, under uncertainties, every 20 milliseconds for several safety applications, resulting in 0.15 milliseconds for maneuver recognition.

This paper is organized as follows. Section 2 gives an overview of the used method, section 3 – on efficient modeling, section 4 - on proper treatment of data uncertainties and their use for building of hypotheses on driving behavior for event (maneuver) recognition. The approach is outlined in section 5, while section 6 describes the evaluation of classifiers. Section 7 summarizes the results with outlook.

2 Method for Probabilistic Reasoning

2.1 Bayesian network (BN)

A Bayesian network $\boldsymbol{BN:= (G, P)}$ is defined as a directed acyclic graph $\boldsymbol{G}$ and $\boldsymbol{P}$ - a set of CPDs (conditional probability distributions) $\boldsymbol{P(X \mid pa(X))}$ of a variable X conditioned on its influence variables $\boldsymbol{pa(X)}$, (Friedman and Koller 2009, Kjærulff and Madsen 2013). The joint probability of a BN is computed by the *Chain rule for BNs*:

$$\boldsymbol{P(X_1, \ldots, X_n) = \Pi_{i=1..n}\, P(X_i \mid pa(X_i))} \qquad (1)$$

The graph $G=(V,L)$ contains nodes V (to represent random variables) and edges L to represent the conditional dependency relations between the nodes. A BN can be used as a knowledge representation to compute the probability $\boldsymbol{P(X=x|e)}$ given a set of observations e. The Bayesian theorem allows inverting the probability computations, i.e.

$$P(X|Y) = P(Y|X)P(X) / P(Y) \qquad (2)$$

An *object-oriented Bayesian network (OOBN)* contains instance nodes in addition to the usual BN nodes. An instance node is an abstraction of a net fragment into a single unit (network class) (Friedman and Koller 2009, Kjærulff and Madsen 2013). Therefore, instance nodes can be used to represent different network classes as well as repetitive structures within other nets (encapsulation). Thus an OOBN can be viewed as a hierarchical (data/information fusion) model of a problem domain. Every layer in this hierarchy expresses another level of abstraction in the OOBN model. The modeling extensions in this work explore also *dynamic Bayesian networks (DBN)*, which use a time series of observations for information fusion and inference (Friedman and Koller 2009; Zhang and Ji 2009; Kjærulff and Madsen 2013; Weidl *et al*, 2015-2017). In this work, we use OOBN and DBN to represent the extension for both the lateral and longitudinal relative dynamics. DBN combine repetitive BN structures as discrete time slices. They follow the 1st order Markov assumption, i.e., the future $\boldsymbol{X^{t+1}}$ is independent on the past $\boldsymbol{X^{t-1}}$ given the present $\boldsymbol{X^t}$: $\boldsymbol{(X^{t+1} \perp X^{t-1} \mid X^t)}$ together with the stationary assumption, that the transitional probability distributions do not change between the time slices:

$$\boldsymbol{P(X^{t+1} \mid X^t) = P(X^t \mid X^{t-1})}.$$

3 OOBN for Maneuver Recognition

To recognize the maneuvers considering the relative vehicle-vehicle motion (Figure 2), we have modeled them as states of variable MNVR(≡Maneuver of Pairs)

at the top layer (Figure 3, Figure 4) of the OOBN. The pairwise combination of vehicles' maneuvers ensures scalability of the approach. It reduces the memory requirements and uses computation resources only for the actually present surrounding vehicles. The OOBN fuses in the hypotheses at the lowest level of abstraction (see Figure 3) features under uncertainties (Figure 5, Figure 6), i.e. measured multi-sensor data and computed situation features.

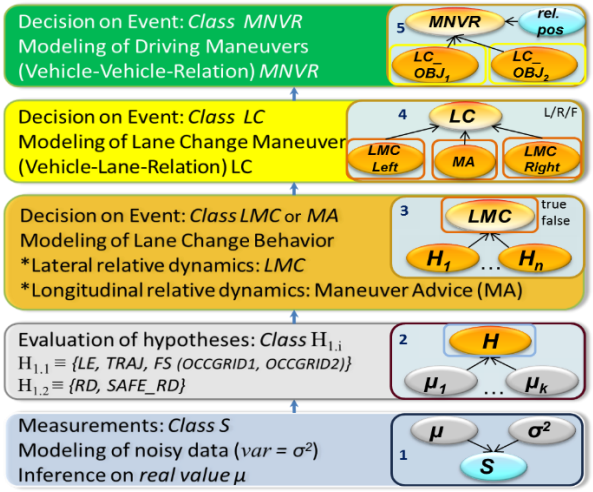

Figure 3. OOBN structure and layers for maneuver recognition.

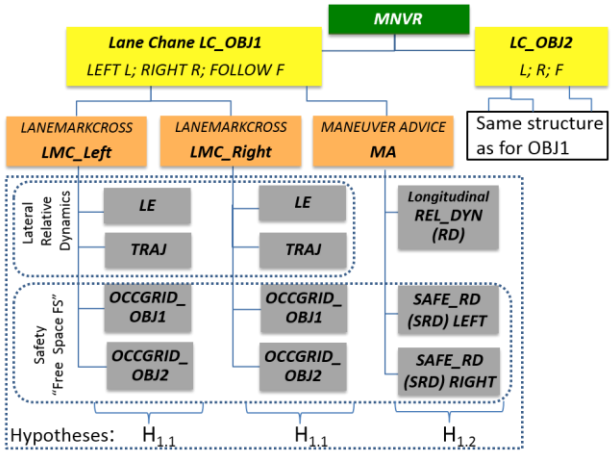

Figure 4. Class hierarchy of the OOBN for maneuver recognition between two vehicles (OBJ1 and OBJ2), expressed as lateral and longitudinal relative dynamics, including their safety (see Figure 1**).**

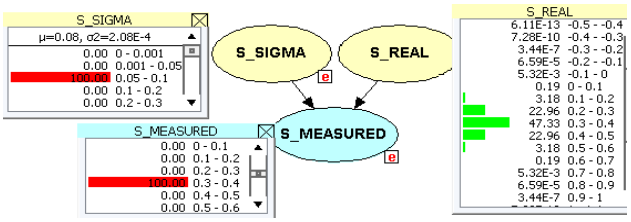

Figure 5. BN fragment for modeling of sensor's uncertainties with a discrete MEASURED variable.

4 Modeling of Data and Driving Behavior

4.1 Modeling of sensor data and its uncertainty

The maneuver recognition represents a task of the type reasoning under uncertainties with heterogeneous data. These data are acquired from multi-sensors measurements as well as from thereof fused and computed (by physical models) situation features. All data have naturally inherited uncertainties. The data characterize a traffic situation and define the set of situation features for maneuver recognition. The data input is represented as variables in the OOBN to support the inference process by allowing the measured (or computed) values of the variables to be inserted as evidence. For discrete variables, to be able to distinguish between the states of deduced features and to deal with the uncertainties in the sensor signals (Kaper *et al*, 2011, 2012, 2013), the measured signals are discretized in predefined partitions (Figure 5). In general, the measured signal $S_{measured} \equiv S_m$ is composed of its real (expected) value S_REAL $\equiv S_{expected}$ under measurement and its disturbance (sensor noise) S_{err} around the real value, i.e. $S_m = S_{expected} + S_{err}$. In many practical applications (and in our work), the sensor noise is assumed as a zero-mean Gaussian random process. Then, the disturbance is described by the signal variance $S_{err} \equiv S_\sigma^2$.

If the measurement instrument is not functioning properly (due to senor noise or fault), then the sensor-reading (S_MEASURED $\equiv S_m$) and the real variable (S_REAL) under measurement do not need to be the same. This fact imposes the causal model structure as shown in Figure 5, taking care of the uncertainties in the input data. The sensor-reading S_m of any measured variable is conditionally dependent on random changes in two variables: real value under measurement (S_REAL$\equiv S_\mu$) and sensor fault (S_SIGMA$\equiv S_\sigma^2$):

$$P(S_m \mid S_\mu, S_\sigma^2) = N(S_\mu, S_\sigma^2) \qquad (3)$$

where $N(S_\mu, S_\sigma^2)$ denotes the Gaussian distribution with mean value S_REAL $\equiv S_\mu$. Then, in principle, the probability distribution of the real value S_μ of the measured variable is inferred by equations (2) - (3), given the observation (evidence) from its sensor measurement S_m and its sensor disturbance S_σ^2. The last is obtained from the sensor diagnostics by use of a Kalman filter.

In the discrete case, the CPD of S_m, expressed as (3), is represented by a conditional probability table (CPT), while in the continuous case S_m is modeled by a continuous random variable with a linear continuous Gaussian (CG) conditional distribution function $N(S_\mu, S_\sigma^2)$. A BN with CG nodes is referred to as a Conditional

Linear Gaussian BN. It induces a multivariate normal mixture density of the form:

$$P(\Delta)\, f(\Gamma) = \Pi_{X \in \Delta}\, P(X \mid pa(X))\; \Pi_{X \in \Gamma}\, f(X \mid pa(X)),$$

where Δ are the discrete and Γ are the continuous variables.

The degree of uncertainty for a variable, which is *computed* from noisy sensor data measurements, is obtained as error estimation by variance calculus. For example, the uncertainty in velocity Δv and in distance measurement Δs directly affects the uncertainty of the computed time to reach a certain point at distance s with velocity v. The time is computed as a function of these two variables, i.e. $t = \frac{s}{v} = f(s, v)$. Its uncertainty value or its variance $t_\sigma^2 \equiv \delta t$ is computed for each vehicle object by taking the partial derivative of the time function $f(s, v)$:

$$\delta t = \sqrt{\left(\frac{\delta f}{\delta s}\right)^2 + \left(\frac{\delta f}{\delta v}\right)^2} = \sqrt{\left(\frac{\partial f}{\partial s}\delta s\right)^2 + \left(\frac{\partial f}{\partial v}\delta v\right)^2}$$
$$= \sqrt{\left(\frac{1}{v} \cdot \Delta s\right)^2 + \left(-\frac{s}{v^2} \cdot \Delta v\right)^2}$$

To model the uncertainty in a variable, which has been computed from noisy sensor measurements, we use Normal (continuous linear Gaussian LCG) distribution. By analogy to (3), similar distribution holds for its conditional probability, which is expressed by (4)

$$P(t_{computed} \mid t_\mu\, ,\, t_\sigma^2\,) = N(t_\mu\, ,\, t_\sigma^2) \qquad (4)$$

and its causal model structure is shown in Figure 6. Here, the computed variable $t_{computed}$ is denoted by an ellipse with a double line boarder. The root nodes - real value denoted as $t\_real \equiv t_\mu$ and the sensor noise denoted as $t\_sigma \equiv t_\sigma^2$ - are modeled as discrete variables with uniform distributions for the purpose of independent treatment of the influence variables on the computed variable.

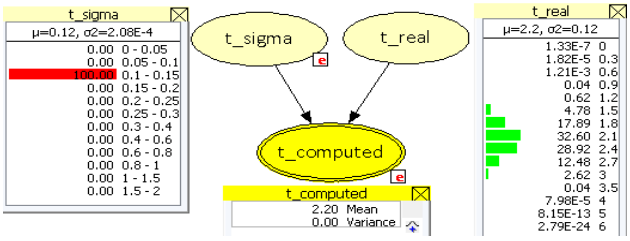

Figure 6. BN fragment, modeling uncertainties in a continuous variable $t_{computed}$, influenced by discrete variables t_μ and t_σ^2.

Similar principle of error estimation can be applied to any computed variable of interest for the BN modelling. The computed uncertainties complete the set of situation features, used for maneuver recognition.

In (Weidl *et al*, 2014), we proposed a number of modelling approaches to meet the automotive requirements on RAM and ROM memory size, and on computation time. These included besides the continuous nodes, also the use of function nodes as an alternative modeling of the sigmoid growth of probability for the hypotheses nodes; the use of expressions to specify the conditional probability distributions (CPDs) compactly and a divide-and-conquer approach to update of probability.

4.2 Modeling of driving behavior (hypotheses)

The ***lateral*** **relative dynamics (**Figure 4) is inferred from the actual lateral movement of a vehicle towards the lane marking. It is fused from the set of hypotheses $H_{1.1} \equiv$ {lateral evidence LE, actual movement trajectory TRAJ and free space FS, computed by the occupancy grid OCCGRID}. Here, the hypothesis LE fuses the vehicle's lateral offset to the lane marking (O_LAT) and its lateral speed (V_LAT) as shown in Figure 7. Its CPD is represented by a sigmoid function to expresses the growing probability for LE (and possible lane change) when the vehicle is coming closer to the lane marking (modeled by O_LAT_MEASURED) by growing lateral velocity (modeled by V_LAT_ MEASURED (see (Kaper *et al*, 2011, 2012, 2013) and for modeling optimization with continuous variables – see (Weidl *et al*, 2014). By analogy, the hypotheses TRAJ fuses: lateral acceleration (A_LAT), gear angle (vehicle's orientation in the lane) and the time-to-lane-crossing. For safety of lane change, $H_{1.1}$ checks available free space by assessing the risk of simultaneous occupancy of surrounding target cells (OCCGRID). This free space is inferred based on the times to enter and to leave the occupancy cells (Kaper *et al*, 2011, 2012, 2013).

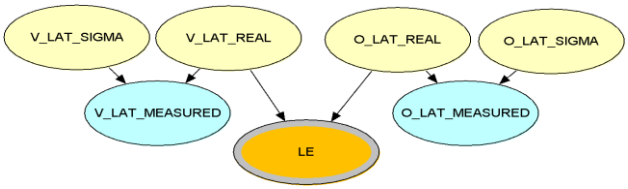

Figure 7. BN fragment modeling the hypothesis LE with discrete variables V_LAT_MEASURED and O_LAT_MEASURED.

The ***longitudinal*** **relative dynamics** (Figure 1, Figure 4) is fused from the set of hypotheses $H_{1.2} \equiv$ {longitudinal relative dynamics (RD) and its safety SAFE_RD}, see section 3. In the Original OOBN the BN-hypothesis *LE*, used for the evaluation of *LMC* (Figure 3, Figure 4), can recognize a maneuver only when the car approaches the lane marking. Hence, the intention of a driver to make a lane change cannot be detected with it. Therefore, we explore the longitudinal

relative dynamics (Figure 1) which is characterized by hypothesis "Relative Dynamics" (*REL_DYN* ≡ RD). Here we use the radar-measured features, characterizing the relation between a follower-vehicle and its front-vehicle on the same lane. The radar provides additional advantage of a longer view-horizon (up to 200 m) than the camera (up to 60 m). Since the hypotheses *REL_DYN* is contributing to the recognition of maneuver intention, it can be considered as "Maneuver Advice" and should be integrated in the higher abstraction OOBN layers, i.e. into the third layer in parallel with LMC and its output on "Maneuver Advice" further into the forth layer LC of the OOBN (Figure 3, Figure 4), since we use information on how fast the vehicles in front on the same lane are driving.

First, we apply the model for handling of uncertainties in measurements (described in section 4.1) - see layer 1, Figure 3. For simplicity, we will take two measured features (relative distance *X_REL_MEAS* and relative velocity *V_REL_MEAS* to the vehicle in front) and their variances σ^2 to improve the maneuver recognition time performance, i.e. earlier as with hypotheses $H_{1.1}$. The structure of the static BN-Model on relative dynamics is shown in Figure 8.

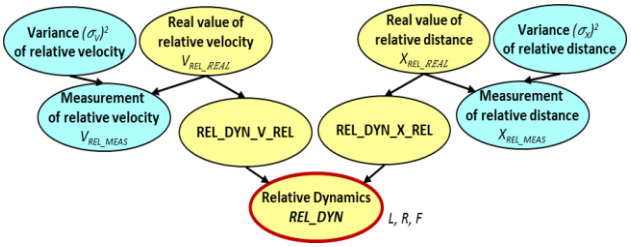

Figure 8. Static BN-Model for hypothesis "Relative Dynamics". Evidence nodes are coded with blue color; chance nodes – with yellow; decision hypothesis for maneuver L/R/F – with red border.

At the next abstraction level: $H_{1.1}$ contribute to the recognition of an event lane marking crossing by class LMC≡LANEMARKCROSS (where the classification node LMC is Boolean), which is reused at the next abstraction level for the recognition of LEFT and RIGHT lane marking crossing to infer on event LC≡lane change for each vehicle (OBJ1 and OBJ2). The OOBN model structure and parameters are based on domain knowledge and physical models, as described in details in (Kaper *et al*, 2011, 2012, 2013; Weidl *et al*, 2014, 2015). The initial OOBN parameterization has been specified qualitatively and quantitatively by use of expressions, like sigmoid functions or kinematics relations. The parameters have been initially hand tuned by domain experts to reflect expected lane change behavior for the conditional probability distributions of the hypotheses variables, which represent qualitatively a typical vehicle behavior at lateral and longitudinal relative dynamics with safety aspects.

4.3 Free Space Model for Safety

The CUTOUT and CUTIN maneuvers (Figure 1, Figure 2) can be considered as a lateral relative dynamics motion, since they represent a vehicle, performing a lateral movement towards the lane marking and relative to neighbor vehicles. In addition to the lateral relative dynamics, the longitudinal relative dynamics becomes essential for earlier recognition of maneuver intentions on lane change. It assumes, the analyzed vehicle aims to keep certain comfortable speed during its highway drive. It considers the longitudinal relative speed and relative distance to a vehicle driving in front on the same lane, Figure 1. The modeling principle of safety for the longitudinal relative dynamics is similar to the safety for the lateral dynamics, relative to the lane marking crossing (LMC), i.e., the hypothesis lateral Free Space (FS) in (Kasper, 2013). For safety, the longitudinal relative dynamics requires the check of available free space on the target lane to finish a maneuver or the suitability of a gap between two neighbor vehicles. This is performed by evaluating the safety features for longitudinal relative dynamics: "SAFE_RD/LEFT or RIGHT" (Figure 4). The driving praxis shows, that if a vehicle in front is slower, usually it is overtaken on the left, if free space is available (Figure 1). On the other hand, when a vehicle intends to leave the faster moving lane, it is slowing to change to the most-right or to the highway exit lane. Therefore, to ensure safety, it is necessary to estimate two features: the relative velocity and time to collision with vehicles on the target lane. These features are calculated as a relation to the nearest vehicles on the target lane, both behind and in front of the analyzed vehicle with a possible intention of a lane change. This safety mechanism is reflected in the fusion of the mentioned features, which are calculated for the left and right neighbor lanes. Figure 9 shows the BN fragment structure of the hypothesis "Safe_RD" for longitudinal relative dynamics. By analogy to the evaluation of the longitudinal relative dynamics to the front vehicle on the same lane (Tereshchenko, 2014; Weidl *et al*, 2015), a similar structure is used to model the relation to both the front and behind moving vehicle on the target lane (same fragment is used to evaluate both its left and right side).

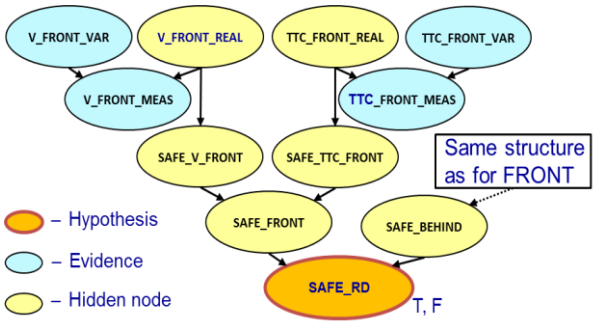

Figure 9. Safe hypothesis (SRD) for longitudinal Relative Dynamics.

The "Safe_RD" output nodes represent the interface nodes at the next layer of abstraction (Maneuver Advice ≡ MA, Figure 4).The evidence features are modeling the measurements (denoted as *_MEAS) with their uncertainty (variance denoted as *_VAR) which are assumed to have a Gaussian distribution. The distributions of nodes (V_FRONT_REAL, TTC_FRONT_REAL, etc.) are inferred based on the evidence. Nodes SAFE_V_FRONT and SAFE_TTC_FRONT are fused as an OR-relation in node SAFE_FRONT, i.e., a lane change to the target lane is safe only if at least one of the nodes has high probability. Thus, it models the relation between the "FRONT" input variables and the safety ahead on the neighbor target lane of the considered front vehicle. The CPD of SAFE_BEHIND is parameterized by analogy to SAFE_FRONT. Node SAFE_RD (evaluating the gap) combines the results from SAFE_FRONT and SAFE_BEHIND and is implemented as an "AND-relation", i.e. if both have a high probability for state "true", SAFE_RD will have also high probability for "true". However, if one of them is in state "false", SAFE_RD will have a high probability for "false".

4.4 Dynamic Models for Earlier Recognition

Here, we focus on the use of two-time slice dynamic Bayesian networks DBNs (2T-DBNs) to achieve earlier recognition of traffic maneuvers, see (Weidl *et al*, 2015). They are characterized by an initial model representing the initial joint distribution of the process and a transition probability distribution (TPD) representing a standard BN repeated over time. They satisfy both the first-order Markov assumption and the stationary assumption. Figure 10 shows the graphical structure of a 2T-DBN model for the hypothesis LE, while Figure 11 represents a DBN extension of hypothesis *REL_DYN*, with the hidden node $A_{REL\_REAL}(t)$, which was added for purposes as explained below. The TPDs between the time slices t and t+1 are assumed *conditional Gaussian* $N(\mu,\sigma^2)$. Here, since we do not have observations on the mean value μ, it is specified by physical models.

LE_DBN (Figure 10) is combining the real values of three lateral features: $O_{LAT\_REAL}(t)$, $V_{LAT\_REAL}(t)$ and $A_{LAT\_REAL}(t)$. When $O_{LAT\_REAL}(t)$ is steadily increasing and $V_{LAT\_REAL}(t)$ is high or increasing (requiring also $A_{LAT\_REAL}(t)$), their combination clearly indicates that the vehicle is leaving its lane. Note, that in (Kaper *et al*, 2011, 2012), A_{LAT_REAL} was included in hypothesis Trajectory (*TRAJ*) and not as part of *LE*. The TPDs for the *LE*-variables: $O_{LAT\_REAL}(t)$, $V_{LAT\_REAL}(t)$ and A_{LAT_REAL} are defined as shown in (5)-(7):

$$O_{LAT\_REAL}(t) \sim \mathcal{N}(O_{LAT\_REAL}(t\text{-}1) + V_{LAT\_REAL}(t\text{-}1) \cdot \Delta t,\ \sigma_{O\_LAT(t)}^2) \quad (5)$$

$$V_{LAT\_REAL}(t) \sim \mathcal{N}(V_{LAT\_REAL}(t\text{-}1) + A_{LAT\_REAL}(t\text{-}1) \cdot \Delta t,\ \sigma_{V\_LAT(t)}^2) \quad (6)$$

$$A_{LAT\_REAL}(t) \sim \mathcal{N}(A_{LAT\_REAL}(t\text{-}1),\ \sigma_{A\_LAT(t)}^2) \quad (7)$$

The time step Δt is the cycle time, i.e., 42 or 60 milliseconds depending on the camera used. The variances σ^2 are modeling the uncertainties of the variables. This dynamic extension incorporates the trend of real values, while their physics relations are represented as causal dependencies between time steps Δt. By analogy are defined the TPDs for the *REL_DYN* features: distance $X_{REL\_REAL}(t)$ and velocity $V_{REL\_REAL}(t)$ and the hidden variable relative acceleration $A_{REL\_REAL}(t)$.

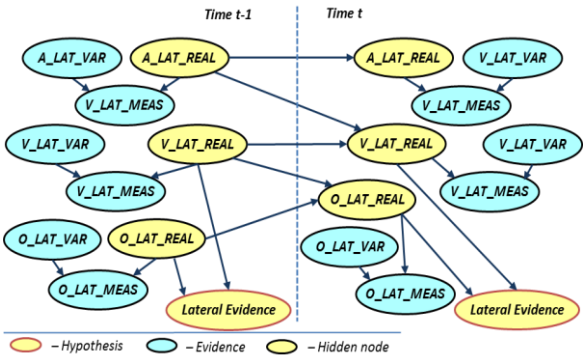

Figure 10. *LE_DBN*: 2T-DBN structure for the hypothesis *LE* (Lateral Evidence) for lateral Relative Dynamics towards the lane marking.

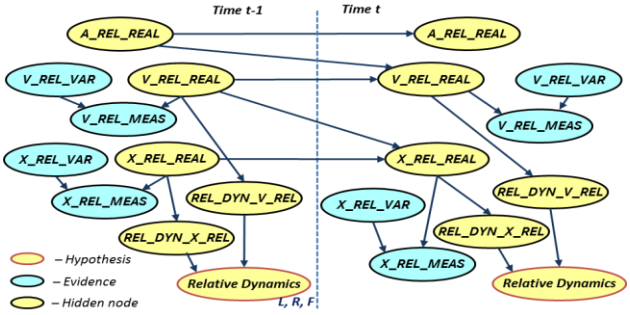

Figure 11. *REL_DYN_DBN*: The 2T-DBN structure for the hypothesis *REL_DYN* (Relative Dynamics) with *A_REL_REAL* as hidden node.

5 Approach

5.1 Combination of Methods

Our approach combines several methods to meet the deployment requirements on accuracy, less memory and faster inference. For resolving of programming paradigms, like efficient modelling and reuse of modeling fragments, we use OOBNs for information fusion from dynamic and/or static fragments. The accuracy requirement is reached by adding "special evidence" as described in section 5.3. Future study will also focus on parameters learning to further improve accuracy. In addition, to resolve the design paradigms for deployment on a prototype vehicle, i.e. to meet the requirements on computation time and memory, we have utilized parallelization of computations based on a divide-and-conquer strategy (D&C) (Weidl *et al*, 2014,

2015, 2017). This D&C parallelization splits the OOBN model into fragments and uses the posterior distribution of output nodes from the lower hierarchical fragments as likelihood over the corresponding input node at the next level of OOBN hierarchy, see (Weidl *et al*, 2017) for more details.

5.2 Modeling of the logical OOBN layers: LMC, MA, Lane Change Maneuvers and Driving Maneuvers (MNVR)

The network fragments, created to support the divide-and-conquer strategy to probability update in OOBN (Figure 3, Figure 4) are shown in Figure 12 and Figure 13. In Figure 12.A), LANEMARKCROSS (LMC) is the object class for *lateral* relative dynamics towards the lane marking. LMC represents the vehicle-to-lane-marking relation and is instantiated using the probabilities computed in the hypotheses TRAJ, LE, FS (OCCGRID for OBJ1 and OBJ2). In Figure 12.B), Maneuver Advice (MA) is the object class fusing the *longitudinal* relative dynamics REL_DYN (RD) between two vehicles driving on the same lane, and for safety evaluation on the left or right neighbor lanes, the available free space (Safe_RD) to a front and back vehicles, building the gap for completing a lane change (Figure 1). MA is instantiated using their probabilities.

The event class LANECHANGE (LC) is recognized by fusing LMC and MA (Figure 13). LC is instantiated by the probabilities, obtained from the hypothesis classes LMC towards left and right and from hypothesis class MA. The event class MNVR represents the vehicle-vehicle-vehicle LC-relation (denoted QMVT with 9 states, from all possible Left/Right/Follow LC-combinations of two objects) together with their relative lane-position to each other (denoted as POSDESCR with states: left, right, front). It infers the recognition of predicted maneuver, after instantiation by the probabilities, obtained from the two object classes LC.

5.3 Improving Accuracy by Special Evidence

Based on a performance analysis on sequences not included in the evaluation reported below, we have extended the OOBN models with measured/perceived variables representing *Special Evidence*. The evaluation has been performed with our statistical module and by additional visual examination. As typical for statistical classification, we use a confusion matrix to evaluate the classification results at each time step for all maneuver sequences. The corresponding maneuver state is classified (at each time step) as recognized (i.e. true positive TP, if corresponding to its reference data label) when its probability is bigger than 65%. This threshold value has been empirically derived in (Kasper, 2013). It has been derived from the confusion matrix and from a statistical evaluation of the probability of "false positives" for the Original OOBN on sequences not included in the evaluation reported below. Recall that all six maneuvers (Figure 2) are represented as a state of the MNVR variable, which has moreover one additional state for "DONTCARE" (i.e. pairs without any collision hazard).

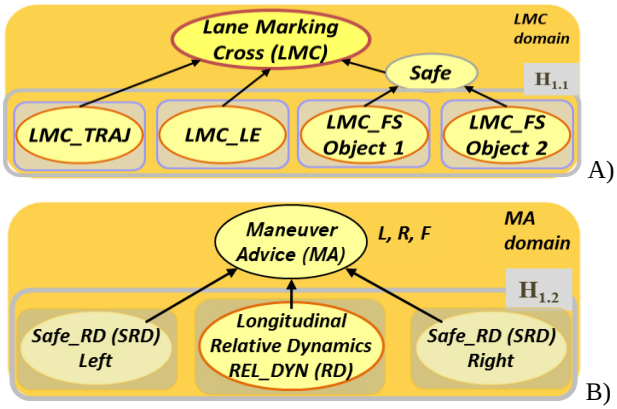

Figure 12. Classes: LANEMARKCROSS (LMC) and Maneuver Advice (MA).

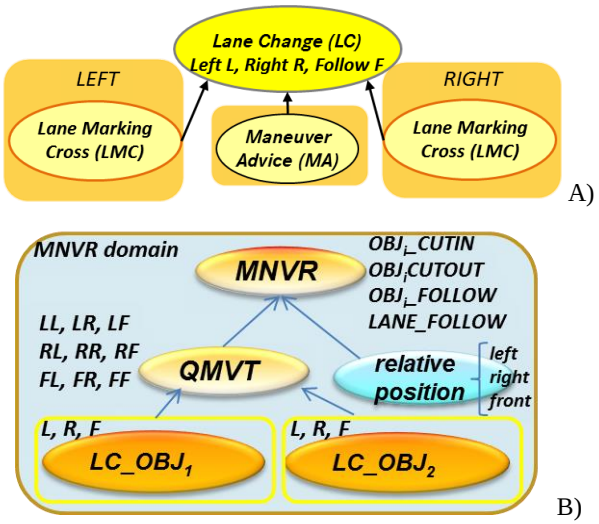

Figure 13. The object classes: LANECHANGE and Maneuver (denoted as MNVR)

We analyzed the results of the statisticsl evaluation and grouped the faults, based on causes with special attention to wrong classifications; and derived ideas for improvement of recognition performance for Lane-Follow and Object-Follow situations. We identified some *measured/percepted features* as "*special evidence* (SE_i)", which represent road topology and driving behavior in relation to other vehicles (which are present or not) on the same lane. These SE_i features extend the model of Figure 13.B) and are modeled with five blue nodes, while their influence on LC – with the yellow nodes, see Figure 14. Thus, they fuse the information for recognition of a lane change, where SE1 and SE2 consider the *lateral* and *longitudinal* relation between each pair of vehicles.

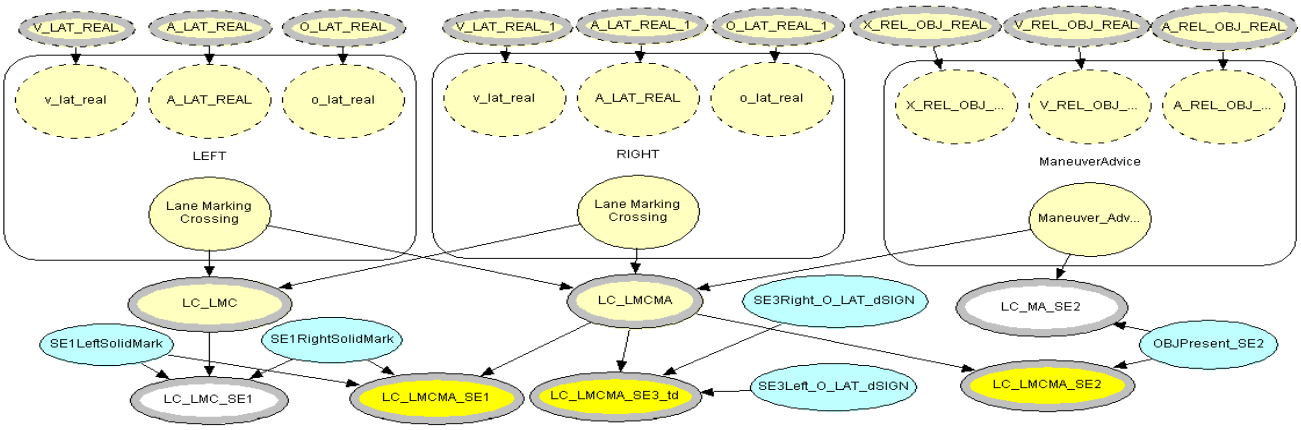

Figure 14. Information fusion at level LC of the extended OOBN model, including "special evidence" nodes to reduce false positive.

SE1: If one vehicle is approaching another vehicle moving on the most left (or most-right) lane, then no matter, if the longitudinal dynamics suggest LC to the left (or right) lane, this is not realizable due to natural lane boarders, i.e., there is no free space to execute any LC LEFT (or RIGHT) maneuver. This is incorporated in the road topology features *solid lane markings*: *SE1_LeftSolidMark, SE1_RightSolidMark.* It reduces the number of false positives (FP/wrongly classified) for OBJCUTOUT and the number of false negative (FN/not recognized) for FOLLOW maneuvers by 36% (from 11 to 7) even in the ORIG model.

SE2: If a vehicle is driving without any vehicle in front of it (possible even due to reduced perception reliability or out of sensor reach), then it has no reason to change the lane, unless an obstacle has been detected. This is incorporated in the model (Figure 14) by *SE2 OBJPresent (yes/no)*. This is represented by the logic rule: *If No Front Car detected, then both lateral and longitudinal dynamics classes* (Figure 4) - *LMC (LaneMarkCross) and REL_DYN - are set to Follow.*

SE3: Change of variable sign for lateral offset O_LAT. Due to the used coordinate system, the values of variables are positive only inside the current driving lane and change to negative, while changing to an adjacent lane. This is incorporated as features *SE3Right_O_LAT_dSIGN* and *SE3Left_O_LAT_dSIGN* in the extended structure of the BNs, Figure 14. The special evidence is present in the labeled data file and introduced in the models at the LC (Figure 14) and similarly at the maneuver MNVR (Figure 4) level.

5.4 Deployed classifiers

To study the effect of different model configurations on recognition, we have defined three static classifiers (ORIG; STATTR; STAT) and one dynamic classifier DBN; see Table 1. The ORIG classifier uses the Original OOBN (see Kaper *et al*, 2011, 2012; Kasper, 2013). "Y" shows which BN fragment is included in the corresponding classifier. All static classifiers use hypotheses LE and OCCGRID, while only ORIG and STATTR use TRAJ (Figure 4). The hypotheses "free space" FS ={OCCGRID and SRD} for the lateral and longitudinal relative dynamic respectively (Figure 4) remain static BN fragments for the purpose of satisfying the requirements on computation time and memory. The DBN fragments for the relative dynamics for the lateral and longitudinal motion are LE_DBN and REL_DYN_DBN. The developed static and DBN modelling fragments were generated as c-code and deployed by use of the divide-and-conquer (D&C) approach for probability update on the target Linux platform of the car – for details see (Weidl *et al*, 2017).

Table 1. Deployed classifiers on the Linux platform, see Figure 4.

	BN fragment				
Classifier	*LE (lateral relative dynamics)*	*TRAJ (trajectory)*	*OCCGRID OBJ1-OBJ2 (free space)*	*REL_DYN (longitudinal RD=relative dynamics)*	*SRD (free space/ safety)*
ORIG	Y	Y	Y	-	-
STATTR	Y	Y	Y	Y	Y
STAT	Y	-	Y	Y	Y
DBN	LE_DBN	-	Y	RD_DBN	Y

6 Evaluation and Analysis

Data sets used in the evaluation: The dataset has been acquired while driving in typical highway traffic. The raw data amounts to Terabytes. They are acquired by radar and stereo camera, which are fused to obtain the data objects with their characteristic features. In order to be able to analyze and use these data, they must be cleaned. The data preparation has involved: i) Visual examination of data quality for all collected sequences

in the prototype vehicle; ii) Statistical evaluation of all wrongly classified as well as not recognized maneuvers; iii) Data labelling and generation. Steps ii) and iii) have been automated. As a result, we have a total of 336 sequences consisting of 236 lane-change sequences and 100 lane-follow sequences. Quality measures of the recognition results have been selected for the performance evaluation of all developed classifiers. They include: the confusion matrix for the relevant (lane change) and irrelevant (follow or not present in the data) maneuvers; precision, recall; time gain for earlier recognition; and runtime performance of all classifiers. The statistical evaluation module establishes how big the time gain is relative to the labelled maneuver. The last is defined by the actual moment of lane marking crossing (LMC) by the midpoint of the car front bumper.

The confusion matrix for all deployed classifiers (Table 1) as performing on all evaluated driving sequences is shown in Table 2. The BN fragment TRAJ increases the accuracy, but the used gear angle is difficult to measure. The modeled special evidence has been successfully tested to contribute with a reduction of false positives (FP), thus increasing the accuracy. This has improved the performance on the Linux platform for deployment on the prototype car. We have made a proof, based on the performance of the ORIG classifier, by using all sequences and the statistical evaluation module, that the recognition accuracy of OOBN is not affected by the D&C approach and its implementation.

Table 3 shows the time gain for all maneuver classes for vehicle pairs. The average time gain for all deployed classifiers is about 1 second ahead of LMC. Moreover, dependent on the traffic situation and object perception, even earlier maneuver recognition is feasible. 36 of the tested sequences show earlier recognition with time gains of 1.5s – 6.72s (seconds). Test drives in real highway confirm, that traffic scenarios with "longitudinal relative dynamics" are recognized as a "need for lane change" before a vehicle is initiating a maneuver due to the recognition of a slower moving vehicle in front on the same lane. Therefore, the recognition by DBN classifier (visualized in Figure 15-17 with blue arrow) is earlier than the one by ORIG (visualized with red arrow). Figure 15 shows recognition of EGOCUTOUT, where DBN is 3.24s earlier than the actual lane marking crossing (LMC) and 2.46s earlier than ORIG. The recognition of OBJCUTOUT (Figure 16) is 4.62s earlier by DBN than LMC and 3.9s earlier than ORIG.

The driving sequence with the best recognition performance is shown in Figure 17, where OBJCUTIN maneuver is recognized by DBN 6.72s earlier than LMC and 5.88 s earlier than ORIG. The parallel D&C implementation has been deployed for all classifier alternatives (ORIG, STAT, STATTR, DBN, see Table 1.) on the automotive Linux platform for maneuver recognition. Table 4 shows between 22% and 40% gain in runtime performance for all deployed classifiers (using c-code on the Linux platform) due to the parallel D&C approach with "special evidence SE". A time performance of 1-4 milliseconds (ms) is still far from the target value of 0.15 milliseconds. One should note here, that these numbers are for the Linux prototype platform of the car and thus hardware dependent. The optimization of the parallel D&C method on a dedicated Linux computer allowed even better results with optimized time performance, coming very close to the initially set requirement of the target platform, see (Weidl *et al*, 2017).

Table 2. Performance comparison of the deployed classifiers with "special evidence" (index _SE). Column Nr.: 1: TP of OBJCUTIN; 2: TP of OBJ CUTOUT; 3: TP of EGOCUTIN; 4: TP of EGOCUTOUT; 5: TP (=as labeled); 6: FN (not recognized); 7: FP (wrong classified); 8: All (TP+FN) Maneuvers

Classifier	1	2	3	4	5	6	7	8	precision	recall
Label*	29	83	67	57	236	0	0	236		
ORIG	25	82	67	57	231	5	11	236	95.5%	97.9%

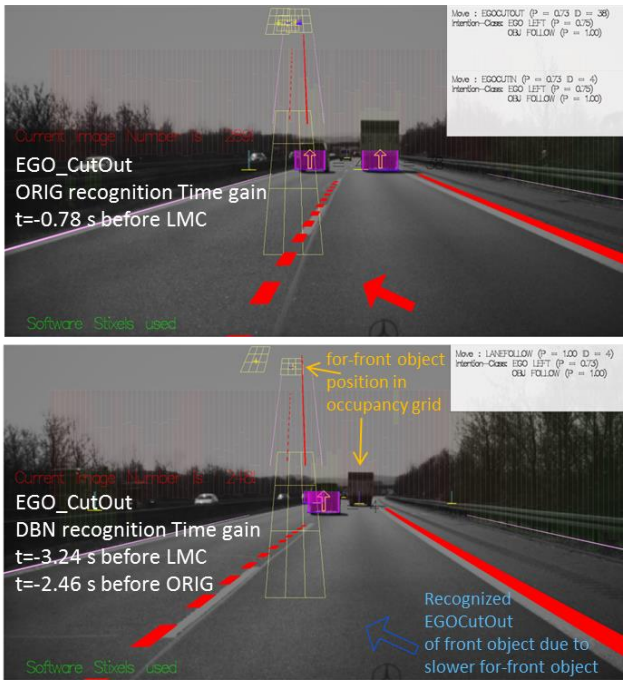

Figure 15. Highway demonstration with REL_DYN showing the classifier performance for EGOCUTOUT: DBN is 3.24s earlier than actual LaneMarkingCrossing (LMC) and 2.46s - than ORIG.

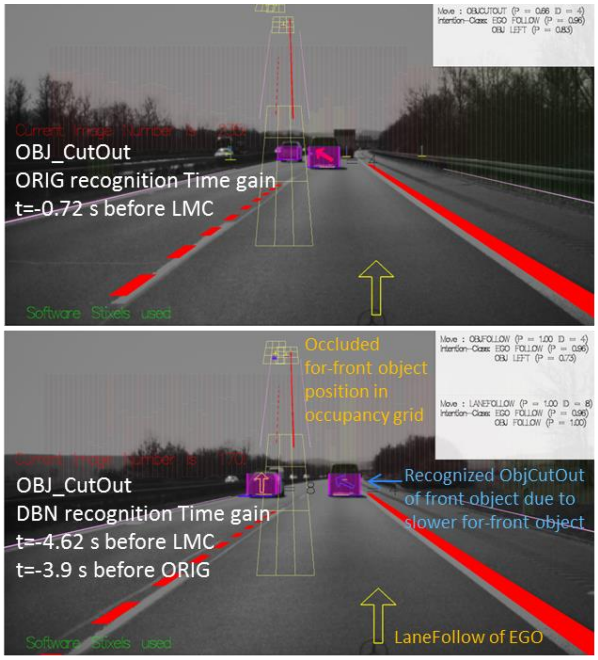

Figure 16. Highway demonstration with REL_DYN showing the classifier performance for OBJCUTOUT: DBN is 4.62s earlier than actual LMC and 3.9s earlier than ORIG.

7 Discussion of Results and Outlook

A Bayesian network has been designed and parameterized for lane change maneuvers. The advantage of our approach is that only measured features for lateral and longitudinal dynamics of the vehicles are necessary, without map data. The limitation is that lane markings are required to compute the features and some wrong classifications cannot be resolved for cases when the prediction horizon of a lane curvature does not reach the percepted front vehicle and thus the vehicle orientation inside the lane cannot be computed.

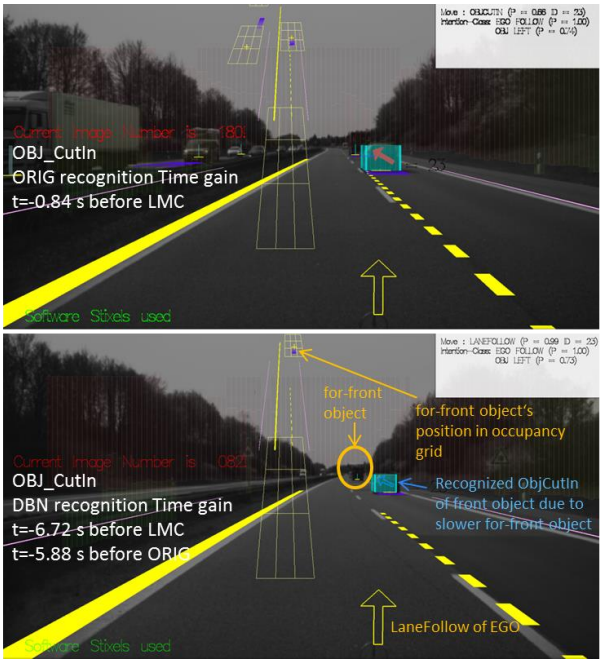

Figure 17. Highway demonstration with REL_D YN showing the classifier performance for OBJCUTIN: DBN is 6.72 s earlier than actual LMC and 5.88 s earlier than ORIG.

The introduced "special evidence" reflects road topology and vehicles relations, thus improving the recognition accuracy of lane-follow and reducing the false positives of lane-change maneuvers. The solution has been successfully tested for all classifiers. With the system deployment on the prototype vehicle, we have collected more data, which will be further divided to use for testing, and for learning of models' parameters of the lateral and longitudinal relative dynamics, together with their safety aspects. Here the hand tuned expressions will serve as an initial guess to improve further the recognition accuracy by use of machine learning techniques (Lauritzen, 1995), which have shown promising results.

In addition, we have analyzed the effect of parallelization of computations based on divide-and-conquer strategy (D&C). We describe in (Weidl *et al*, 2017) the implemented parallel D&C realization, allowing resolving the requirements on computation time (0.15 milliseconds) and memory for deployment on a prototype vehicle. This is an important step towards a scalable solution, meeting the hardware constraints of the automotive target platform. Future work will also focus on trend analysis for even more accurate and earlier maneuver recognition.

Abstract

Monitoring of water quality should not be solely based on laboratory samples. Such activity, although producing reliable results, cannot provide an accurate enough temporal coverage for water quality monitoring. The Finnish Environment Institute, SYKE, has therefore established numerous online water monitoring stations that continuously monitor water quality. The problem with the automatic monitoring, however, is that the recorded values are not reliable as such and need to be subject to quality control and uncertainty estimation. Here, as the main contribution, we present a computational service that we have implemented to automate and integrate the water quality monitoring process. We also present a case study regarding the river Väänteenjoki and discuss the obtained uncertainty results and their implication.

Keywords: environmental measurements, quality control, uncertainty estimation, computational service, river

1 Introduction

The Finnish environmental authorities have regularly monitored water quality variables such as total suspended solids (TSS) and total phosphorus (TP) concentrations in major Finnish rivers since 1960s. The aim is to get general idea on the amounts of substances transported into the Finnish lakes and coastal areas and to detect possible trends. Presently, water quality and flow are monitored at 29 downstream monitoring stations of Finland's major rivers discharging into the Baltic Sea. There are also numerous inland river monitoring sites included, for instance, in the Finnish Eurowaternet (Niemi and Raateland, 2007). Annually, 13 to 22 water samples are taken and analyzed for TSS and TP (The Finnish Ministry of Environment, 2014) in addition to other substances.

SYKE has published quality recommendations for laboratories producing and delivering environmental monitoring data for registers of water quality in Finland (Näykki et al., 2013). Examples of the recommended limits of quantification (LOQ) and expanded measurement uncertainties (MU) are given in Table 1. The challenge in automating water quality monitoring is that the measurement data have not only significant seasonal variation but also erroneous values. Thus, without proper quality control and reliable uncertainty estimation, the data has little value. Thus far, this activity has been performed manually by environmental researchers.

Table 1. Recommended LOQ and MU (k=2) values for the measurement of TSS, TP and turbidity in monitoring of natural waters in Finland (Näykki et al., 2013).

Parameter	Unit	LOQ	Range	MU
TSS	mg/l	2	2-3	± 0.5
			> 3	± 20%
TP	µg/l	3	3-10	± 1.5
			> 10	± 15%
Turbidity	NTU (or FNU)	0.5	0.5-1	± 0.2
			>1	20 %

As a solution, we have implemented a computation service based on an Enterprise Service Bus Architecture. The service provides means for online quality control and integration of uncertainty estimation. It automates the sequence of operations performed earlier by the researchers; thus, providing more reliable results in a scalable and extensible manner. The service also enables reliable monitoring of the changes in water quality and flow over shorter periods of time.

2 Materials and Methods

The river Väänteenjoki was used here as the measurement site. A turbidity sensor was assembled at the Väänteenjoki site in the Karjaanjoki River Basin (2046 km^2) in southern Finland, shown in Figure 1, as a part of the sensor network

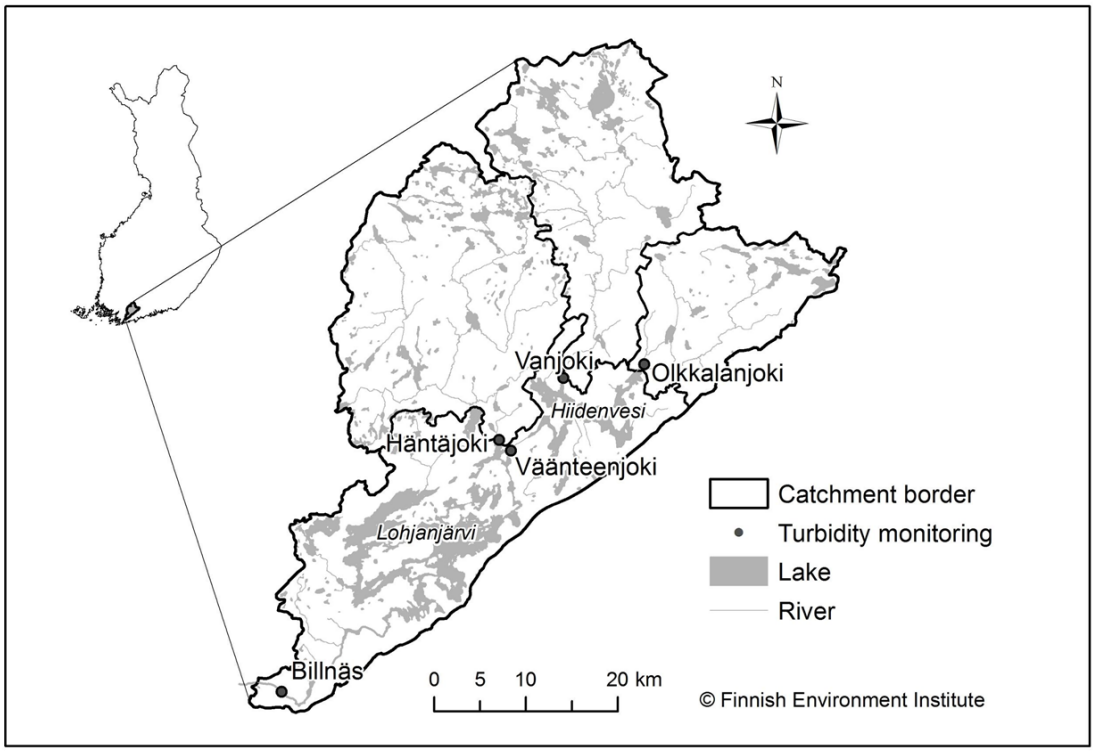

Figure 1. Location of the Väänteenjoki measurement site in the middle of the Karjaanjoki river basin.

established during the years 2007 and 2008 in the Soil-Weather project (Kotamäki et al., 2009). The river basin is mainly covered by forest (60%), the rest of the area being agricultural land (13%), lakes and rivers (12%), and population centers (9%). The Väänteenjoki measurement site is located between the two major lakes of the Karjaanjoki basin. From the lake Hiidenvesi (area 29 km2, mean depth 6.7 m), waters flow via the river Väänteenjoki into the lake Lohjanjärvi (area 92 km2, mean depth 12.7 m).

The monitoring process of the Väänteenjoki site is depicted in Figure 2. In the Väänteenjoki case, an OBS3+ sensor by Campbell Scientific was used. It emits a near-infrared light into the water, measures the light that scatters back from the suspended particles, and transforms this information into turbidity values (in Nephelometric Turbidity Units, NTU). The sensor collects and transmits the data to a server as SMS messages. The received messages are decoded as measurements with timestamps. The measurements are stored into a HydroTempo database maintained by SYKE.

Laboratory samples are collected once in a month. More frequent sampling can also be carried out during the high water runoff seasons. Laboratory turbidity measurement is carried out according to the international standard ISO 7027 (International Organization for Standardization, 1999). Turbidity is measured nephelometrically; the instrument measures the scattered light using the detector angle of 90 degrees from incident light. Instrument is calibrated with formazine standard solutions, and the turbidity of the tested water sample is expressed in Formazine Nephelometric Units (FNU). Note that FNU equal to NTU. TSS are determined at laboratory according to the standard EN 872 (European Committee for Standardization, 2005a), where water samples are filtered with GF/C glass fibre filter and dried at 105 ^{o}C. The mass of the residue retained on the filter is determined by weighing. Measurement of TP is based on standard EN ISO 15681-2 (European Committee for Standardization, 2005b) and recommendations of the analyzer manufacturer. Phosphorus is converted to orthophosphate by an acid-persulfate digestion prior measurement, where orthophosphate reacts in an acid solution containing molybdate and antimony forming an antimony phosphomolybdate complex. Reduction of the complex with ascorbic acid forms a strongly coloured molybdenium blue complex which is measured at the wavelength of 880 nm.

In a previous study (Koskiaho et al., 2015), turbidity recorded by an OBS3+ sensor at the Väänteenjoki site was calibrated against the turbidity determined from water samples taken near the sensor. Calibration equation, shown in Table 2, was determined according to linear regression between the values of the water samples and the simultaneous values recorded by the sensor. Because turbidity does not denote the content of substance in water, it cannot be directly used in calculations of material fluxes. Thus, correlations of turbidity with the concentrations of

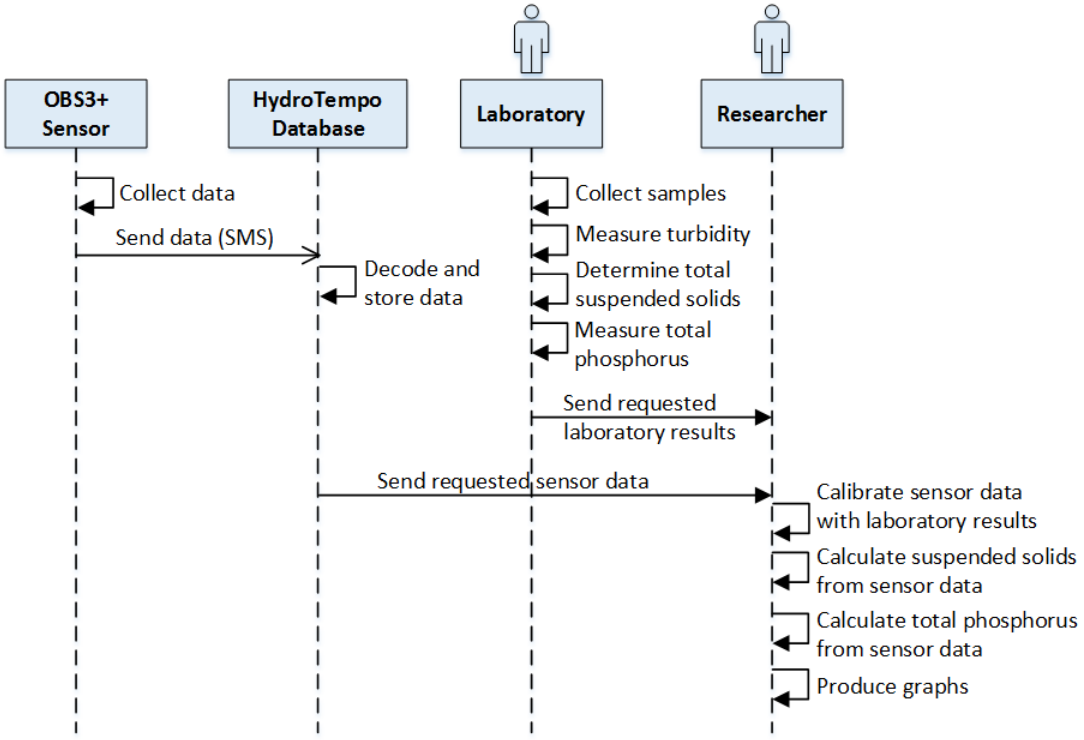

Figure 2. The monitoring process of the Väänteenjoki site.

TSS and TP were determined from the 2009–2012 water sample data collected at Väänteenjoki to convert the sensor-based, calibrated turbidity data to hourly concentrations of TSS and TP. The conversion equations based are presented in Table 2.

It should be noted that there may be events where turbidity jumps into the maximum (e.g. 250 NTU) and stays there for some hours. In some cases such events have lasted a day or two. The events could be caused by a storm followed by rapidly increasing water flow. In a previous study (Koskiaho et al., 2015), these events were manually checked, removed, and replaced with interpolated values before further processing. In (Koskiaho et al., 2015), however, measurement uncertainty was not estimated.

We have implemented a computational service that automates and integrates uncertainty estimation to the sequence of operations depicted earlier in Figure 2. The service architecture, shown in Figure 3, uses an Enterprise Service Bus (ESB) to connect different subsystems and to relay data between the subsystems. When the researcher inquires TSS for a specific river, ESB is used to acquire relevant measurement data and laboratory results. That data is passed to an online computational subservice. It computes TSS and TP for the river based on turbidity measurements. It also computes (combined) measurement uncertainty for the result.

In the computation, the calibration equation and related conversion equations are used as discussed earlier in Table 2. The computation results obtained by using these linear regression equations are then subjected to uncertainty estimation as discussed in (Ellison and Williams, 2012; Barwick, 2003). The results regarding the amount of TSS, including the linear regression equations, are then delivered to the researcher along with the (total) measurement uncertainty. The measurement uncertainty is a reliability estimate and can be used to compare the measurement results among each other or with reference values (JCGM, 2008).

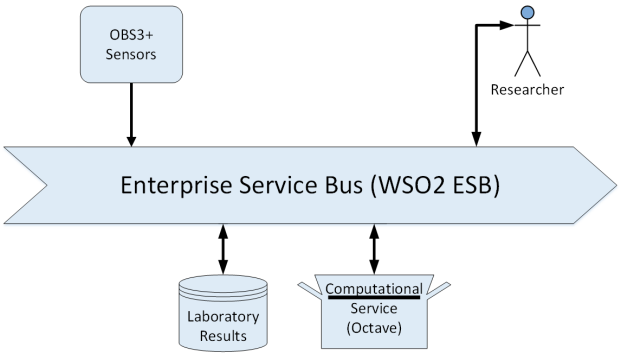

Figure 3. ESB based architecture implementing the service for computing TSS and TP along with measurement uncertainty estimation.

The combined measurement uncertainty includes contribution from the laboratory reference measurement and the performance of the measurement models, i.e. how well the measured values fit in the model, and how repeatable the online measurements are. The laboratory reference uncertainty is estimated according to the Nordtest approach (Magnusson et al., 2012) and ISO standard 11352 (International Organization for Standardization, 1012), where

Table 2. Calibration equations and coefficients of determination (r^2) derived from the relation between the sensor recordings and water samples, and equations to convert the calibrated turbidity to TSS and TP concentrations.

Calibration equation	Conversion equation for the concentration of	
	TSS [mg/l]	TP [µg/l]
y = 2.8 + 2.12x; r^2=0.86	z = 1.6 + 0.78y; r^2=0.74	z = 14.3 + 1.76y; r^2=0.82

where x = recorded turbidity (NTU, raw data)
y = calibrated turbidity (NTU, final data for further calculations)
z = TSS or TP concentration determined from clibrated turbidity

Table 3. Uncertainty budget for the turbidity, TP and TSS concentration measurements.

	Turbidity (25 FNU)	TP (60 µg/l)	TSS (20 mg/l)
Laboratory analysis	10 %	7.5%	7.5%
Turbidity sensor measurement model	7.8%	7.8%	7.8%
Phosphorus/solids measurement model		7.7%	11.9%
Combined standard uncertainty	12.8%	16.4%	17.4%
Expanded uncertainty (k=2)	25.6%	32.9%	38.0%

combined standard uncertainty consists of two main components: the within-laboratory reproducibility and the uncertainty due to possible bias. The quality recommendation for reporting measurement results and uncertainties does not include the uncertainty due to sampling (Näykki et al., 2013). The uncertainty of the linear regression measurement models, u_{c_0} , is estimated with help of (Ellison and Williams, 2012):

$$u_{c_0} = \frac{S}{B_1}\sqrt{\frac{1}{p}+\frac{1}{n}+\frac{(c_0-\bar{c})^2}{S_{xx}}} \qquad (1)$$

where S is the residual standard deviation of the measurement model, B_1 is the slope of the measurement model, p is the number of replicate measurements in the determination of the concentration c_0, n is the number of replicate measurements in the determination of the mean calibration value $\bar{c}$, and S_{xx} is the standard deviation of the measured values and the mean calibration value. The uncertainty related to the repeatability of the measurements is included in Equation (1).

3 Results and Discussion

Hourly time series of the calibrated turbidity measured by sensors (curves) together with turbidity analyzed from water samples (dots) are presented in Figure 4. As suggested by the equality of sampled and sensor-based values, calibration of the sensors was successful.

The turbidity curve of the river Väänteenjoki, also shown in Figure 4, differed strongly from those of the other measurement sites dealt with in (Koskiaho et al., 2015), which showed clearly sharper general form and higher peak values. The difference was claimed to be a consequence of the retention effect of the lake Hiidenvesi and the close proximity of the Väänteenjoki measurement site to the lake. In other measurement sites, the distance to the upstream lakes was much longer, or the lakes were small.

The uncertainty components are listed in Table 3. In this example, a typical value for the turbidity is 25 FNU, for the TP is 60 μg/l, and for TSS is 20 mg/l. The standard uncertainty (k=1) of the laboratory analysis is 10% for the turbidity in the range $>$1 FNU, and 7.5% for the TP and TSS in the ranges of $>$10 μg/l and $>$3 mg/l, respectively. Using Equation (1), we obtain the standard uncertainty estimates for the turbidity sensor calibration, 7.8%, and for the TP and TSS measurement models, 7.7% and 12%, respectively. The TP and TSS contents are determined based on turbidity, so the calibration of the turbidity sensor must be included. The combined standard uncertainty is calculated as a square sum of the individual, uncorrelated components (JCGM, 2008). Figure 5 demonstrates the expanded uncertainty (in content) as a function of measured turbidity, TP and TSS. The measured values presented are between the minimum and maximum values of the data set of our example.

It can be seen that all the uncertainty components, laboratory analysis and the measurement models, are of the order of the same magnitude. The linear regression models are based on the whole dataset 2009 – 2012. In this case, there is no significant difference in terms of uncertainty whether the model is fitted based on the whole dataset or on yearly basis.

Using the presented measurement models practically doubles the measurement uncertainty as compared with the laboratory analysis, but on the other hand the online monitoring provides more representative and frequent information in the water quality. In Figure 6, this is illustrated by presenting the relative standard error of the mean for TP in different variation levels, calculated based on the two different monitoring processes and their measurement uncertainties presented in Table 3.

The more frequent data of online monitoring (24 samples per day) enables following the trends in daily basis with low estimation error, whereas infrequent laboratory

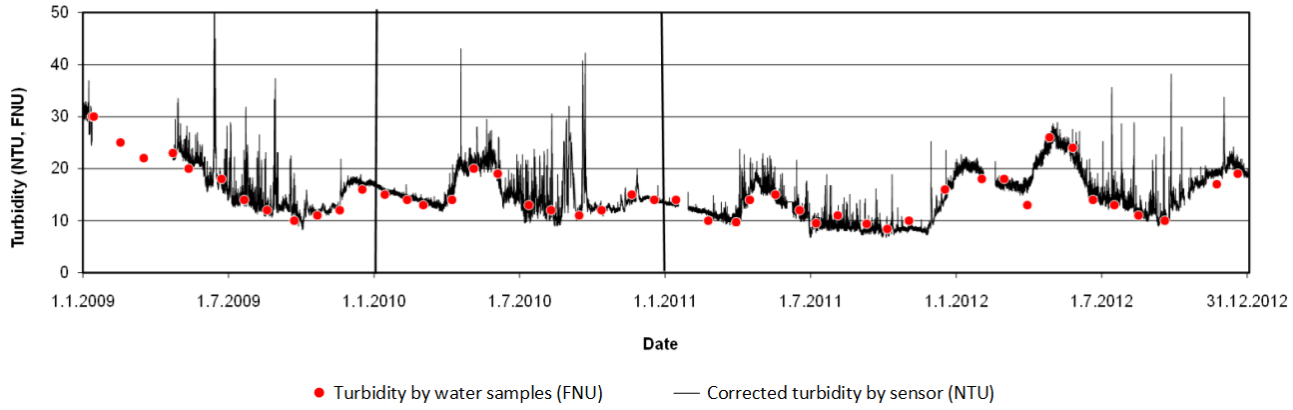

Figure 4. Hourly time series of the corrected turbidity measured by sensors (NTU) together with turbidity analyzed from water samples (FNU) in Väänteenjoki measurement site.

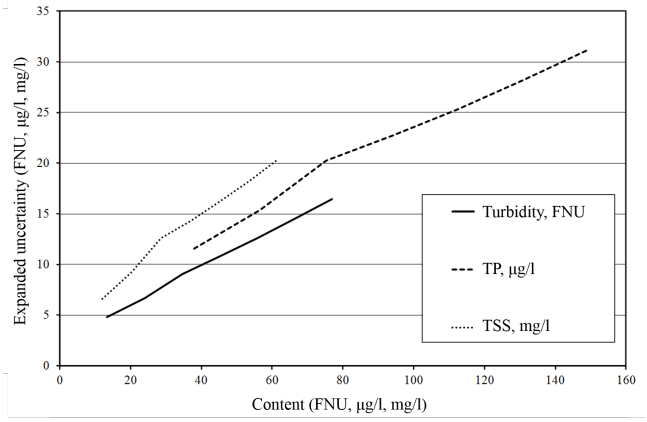

Figure 5. Expanded uncertainties of turbidity (FNU, solid line), TP(μg/l, dashed line) and TSS (mg/l, dotted line) as a function of content.

measurements (1 sample per month) is only suitable for estimating yearly averages with a comparable estimation error.

As compared with the quality recommendations in Table 1, the uncertainty of the laboratory analysis is equal to the recommendation for turbidity and TP. For TSS, the quality recommendation is 20%, and in this case 15%.

For the measurement models, the total number of measurement data points is 45 for turbidity and 46 for TP and TSS. The coefficients of determination for the measurement model equations are 0.86, 0.82 and 0.74 for the turbidity, TP and TSS measurement models, respectively. The coefficient of determination of 0.90 would result in uncertainties of 6.5%, 6.0% and 7.7% for turbidity, TP, and TSS, respectively. With the present laboratory analysis uncertainties, these uncertainties would produce respective expanded uncertainties of 24%, 31% and 32%. If the coefficient of determination is 0.95, the turbidity sensor measurement model would result in 4.5% standard uncertainty. This would result in 22% expanded uncertainty in turbidity, 29% in TP, and 31% in TSS measurement model.

However, the coefficient of determination of 0.90 would be obtainable by using an outlier detection algorithm. This would require removal of two most deviating points from turbidity model, five from TP model and ten points from the TSS model. Even the coefficient of determination of 0.95 is obtainable, at least with turbidity measurement model. This would require removing 11 most deviating measurement points from the model. Reducing the size of the data set down to 34 points does not increase the uncertainty of the model significantly.

4 Conclusions

A computational service for monitoring TSS and TP was introduced in this study. The service also integrates measurement uncertainty estimation and delivers monitoring results with uncertainty information. The service was implemented by using a scalable and extensible architecture based on the use of an Enterprise Service Bus.

The monitoring results obtained for the river Väänteenjoki were presented and discussed. The results indicate that online monitoring does not fully fit within the recommended limits of quantification. The advantage of online monitoring, however, is that it is a continuous activity and it supports monitoring of quick events and changes in trends. This is something that would not be feasible by using laboratory sampling only. Thus, in together with laboratory sampling online monitoring provides a more accurate situation picture of the state and quality of Finnish rivers.

Abstract

This article deals with intra-ocular lens (IOL) power calculations during the cataract surgery. At present, IOL power calculated by formulas is usually able to provide acceptable results for the majority of the patients. The problem appears when any of input parameters have the value which is not normal in population distribution. Then the patient post-operative refraction result can inconsiderable deviate from intended target. This work describes approach how to preoperatively indicate which samples of a patient could be problematic in accurate IOL calculations by classification of Artificial Neural Networks (ANN). Small and long eyes are used to test the ability of ANN to classify input samples which are taken from pre-operative measurements to several groups which represent probable post-operative result. In our experiment, ANN classifies samples into two groups. The first group is for data samples with a probable result in positive ranges of diopter and second group is for negative ranges. The accuracy of ANN, in this case, is 94.1 %.

Keywords: intra-ocular lens (IOL) power calculation, artificial neural networks (ANN), cataract surgery, refraction result

1 Introduction

A cataract is present when the transparency of the eye lens is reduced to the point that the patient's vision is impaired. According to the latest assessment of World Health Organization, cataract is responsible for 51 % of world blindness which represents about 20 million people (2010). Fortunately, it can be surgically removed. Natural lens of the eye that has developed an opacification is replaced with an artificial IOL. Choosing the appropriate IOL power is a major determinant of patient satisfaction with cataract surgery. There are 3 main factors: accurate measurements (biometry), selecting appropriate calculations (formulas), and assessing the patient's needs and expectations to determine the postoperative refractive target (clinical considerations) (Henderson et al., 2014).

When the human lens is replaced with an intra-ocular lens, the optical status becomes a two-lens system (cornea and intra-ocular lens) projecting an image onto the fovea. The distance (X) between the two lenses affects the refraction as does the distance (Y) between the two-lens system and the fovea. X is defined as the distance from the anterior surface (vertex) of the cornea, which curvature is described by keratometry (K), to the effective principle plane of the intra-ocular lens in the visual axis. Y is defined as the distance from the principal plane of the intra-ocular lens to the photoreceptors of the fovea in the visual axis. It is easy to see in Figure 1 that X + Y is equal to the visual axis, the axial length of the eye (AL). Therefore, knowing X and A will allow the calculation of Y (Y = AL - X). Also to calculate the intra-ocular lens power (P), we must know the vergence of the light rays entering the cornea (refractive error (R)). For emmetropia, R is zero. The relationship of these factors (X, Y (AL-X), P, K, R) is such that a formula can be written to describe it. Knowing the values of any four of these variables will allow for the calculation of the fifth (Roger and David, 2010).

1.1 Calculation formulas

For appropriate intra-ocular lens power selection, the mathematical computing formulas are used. These formulas have been developed approximately from the sixties of the last century (Kuchynka, 2007). Over time, some trends have emerged regarding which formulas to use in general categories of patients:

- <22 mm: Hoffer Q
- 22-23 mm: Hoffer Q or Holladay 1
- 24-26 mm: Holladay 1
- >26 mm: SRK/T or Holladay 2

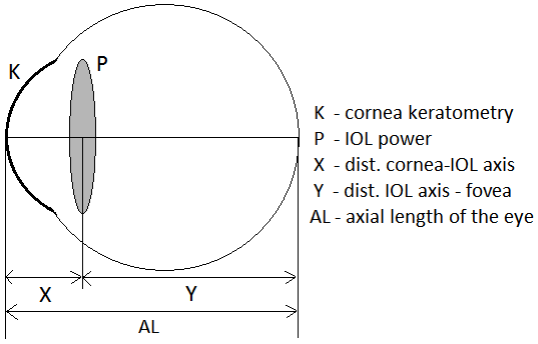

Figure 1. Ocular dimesions.

It is essential to use the appropriate power calculation constant (A constant, ACD-constant, surgeon factor) specified by the intra-ocular lens manufacturer for the specific formula, chosen intra-ocular lens style, and personalized as warranted by the surgeon (Henderson et al., 2014). These formulas usually work very well for the majority of the patients, but the problem may appear if any of input parameter has a value which is not normal in population distribution.

1.2 Calculation of Intra-Ocular Lens for Non-Normal Eyes

Many results and ways how to solve the problem of intra-ocular lens power calculation can be found in the present literature. The problem of accurate calculation is quite complex and depending on many pre and post-operative factors. Therefore needs to be divided into many parts.

One of many ways how to calculate intra-ocular lens power can be seen in (Abulafia et al., 2015). The accuracy of Holladay 1, SRK/T, Hoffer Q, Haigis, Barrett Universal II, Holladay 2, and Olsen formulas for eyes axial length longer than 26.0 mm is provided. SRK/T, Hoffer Q, Haigis, Barrett Universal II, Holladay 2, and Olsen methods are having a prediction error of $\pm$0.5 D in at least 71 % of eyes and $\pm$1.0 D in 93 % of eyes.

A calculation for 53 eyes of 36 patients with axial length more than 27.0 mm by the IOL Master is evaluated in (Bang et al., 2011) for the Holladay 1, Holladay 2, SRK/T, Hoffer Q and Haigis formulas. For eyes longer than 27.0 mm the Haigis formula is found to be most accurate followed by SRK/T, Holladay 2, Holladay 1 and in the last place Hoffer Q. All formulas predicted more myopic outcome than was the real result of the surgery.

Refractive outcomes for small eyes and calculation with Hoffer Q, Holladay 1, Holladay 2, Haigis, SRK-T, and SRK-II are observed in (Carifi et al., 2015). The Hoffer Q formula provides best refractive outcomes of which 39 %, 61 %, and 89 % of the eyes had a final refraction within $\pm$0.5 D, $\pm$1.0 D, and $\pm$2.0 D of the target, respectively.

The accuracy of Hoffer Q and Haigis formula according to anterior chamber depth in small eyes is evaluated in (Eom et al., 2014). 75 eyes of 75 patients with axial length less than 22.0 mm is included in the study. The difference between the predicted refractive errors of the Hoffer Q and Haigis formula increased as ACD decreased in short eyes. No significant difference is found when anterior chamber depth is longer than 2.4 mm.

Predictability of intra-ocular lens power calculation using Carl-Zeiss IOL Master and applanation ultrasound using SRK/T, SRK II, Holladay 1 and Haigis with an axial length longer than 25.0 mm is evaluated in (Wang et al., 2008). The mean axial length was significantly longer than in case of applanation ultrasound. The mean average errors calculated by the SRK/T, SRK II, and Holladay 1 formulas were comparable between both methods of measurement. The best results were provided by the IOL Master data in combination with the Haigis formula.

Refractive prediction of Holladay 1, Hoffer Q, Haigis and SRK/T intraocular lens power calculation formulas for eyes longer than 25.0 mm is evaluated and method for axial length optimization is proposed in (Wang et al., 2011). Refractive prediction errors with the Holladay 1, Haigis, SRK/T, and Hoffer Q formulas were evaluated in consecutive cases. Eyes were randomized to a group used to develop the method of optimizing AL by back-calculation or a group used for validation. Further validation was performed in two additional datasets. The proposed method of optimizing AL significantly reduced the percentage of long eyes with a hyperopic outcome. Updated optimizing AL formulas by combining all eyes from the two study centers are proposed.

Refractive outcomes of Haigis–L formula for calculation intraocular lens power in Asian eyes with axial lengths longer than 25.0 mm that had a previous myopic laser in situ keratomileusis or photorefractive keratectomy are evaluated in (Wong et al., 2015). The predictability of being within $\pm$0.5 D and $\pm$1.0 D of the target was 35.7 % and 63.1 %, respectively. 31.6 % and 60.5 %, respectively, in eyes with an AL less than 27.0 mm; and 39.1 % and 65.2 %, respectively, in eyes with an AL of 27.0 mm or longer.

Next interesting way how to calculate an intra-ocular lens power is provided by (Clarke and Burmeister, 1997). The accuracy of trained artificial neural network and Holladay 1 formula is compared. In 72.5 % of cases for artificial neural network and in 50.0 % of cases for Holladay 1 formula an error of less than $\pm$0.75 D is achieved.

2 Back ground of studies

As was described; many ways how to calculate intra-ocular lens power is being used at present. Many algorithms and calculation formulas have its own accuracy limits for example in the calculation for the unusual cases of eyes - eyes with long or short axial length or keratometry.

In the field of cataract surgery as well as in all health-care related fields patients demands and expectations to provided care are continuously increasing. Together with increasing prevalence of cataract surgery, this could be one of the main motivating factors to provide best possible postoperative refraction results to if possible the greatest amount of patients. Another factor which is no less important could be the economic side of re-operation or following refractive correction of the patient which has implanted bad calculated intra-ocular lens.

As was written in the previous section of this article. Our algorithm for intra-ocular lens power estimation is based on Artificial Neural Networks which are used as a classifier.

3 Artificial Neural Network

Artificial Neural Networks dominate by ability in immediate pattern recognition of input/output relations. This

differs ANN from expert systems which achieve excellent results in the sequence of logical operations and fuzzy logic methods and are characterized by the ability represent knowledge (Tuckova, 2009).

Artificial Neural Networks are inspired by biological neural networks. This property in some way determines that the Artificial Neural Network should be capable to behave well or at least like their biological patterns. Knowledge of Artificial Neural Network is stored in relations between neurons. These relations are strengthened during the learning process or penalized when the learning does not lead to better results. More about Artifical Neural Networks can be found in (Tuckova, 2009).

Our algorithm for intraocular lens power estimation is based on Artificial Neural Network which is used as a classifier. The base principal of our access is following:

1. Multi-layer Artificial Neural Network classifies input matrix compound from pre-operatively measured K, ACD and AL into several groups.
2. Each group has its own estimated post-operative refraction outcome.
3. Intra-ocular lens power is calculated using standard SRK/T formula.
4. Intra-ocular lens power calculated by SRK/T formula can be corrected by surgeonâĂŹs decision based on refractive outcome estimated by classification of Artificial Neural Network.

3.1 Real data

For the research purposes, specific patientâĂŹs data had to be collected from clinic database, then cleaned up and preprocessed.

3.1.1 Collected Data

- Implanted IOL manufacturer and type
- Pre operative ïňĆat meridian of the cornea - K1 [D]
- Pre operative steep meridian of the cornea - K2 [D]
- Pre operative anterior chamber depth - ACD [mm]
- Pre operative axial length of the eye - AL [mm]
- Implanted IOL power - P [D]
- Implanted IOL A constant - A
- Subjective post operative sphere - SfS [D]
- Subjective post operative cylinder - CyS [D]
- Subjective post operative spherical equivalent - SfES [D]
- Objective post operative sphere - SfO [D]
- Objective post operative cylinder - CyO [D]
- Objective post operative spherical equivalent - SfEO [D]
- Eye

3.1.2 Specification of Patients Data Selected for Collection

- Patient undergoing cataract surgery
- Indicated for monofocal intra-ocular lens
- Data from beginning of January 2012 till end of July 2015
- Both eyes
- Calculated for emetropia
- Pre operative ïňĆat meridian of the cornea between 30 and 55 diopters
- Pre operative steep meridian of the cornea between 30 and 55 diopters
- Pre operative anterior chamber depth between 1 and 5 millimeters
- Axial length of the eye between 15 and 21 or between 25 to 35 millimeters
- Post operative sphere between -10 and 10 diopters
- Post operative cylinder between -10 and 10 diopters
- No cases with previous corneal refractive surgery

3.1.3 Specification of Preprocessing Parameters

- SfCalc: post operative sphere calculated by SRK/T from K1, K2, AL, P and A constant.
- RDS: difference between SfCalc and SfS.

$$RDS = SfCalc - SfS \tag{1}$$

- RDO: difference between SfCalc and SfO.

$$RDO = SfCalc - SfO \tag{2}$$

- K: mean keratometry calculated from K1 and K2.

$$K = \frac{K1 + K2}{2} \tag{3}$$

- InputVector: matrix which is used as input for Artificial Neural Networks and is composed from AL, ACD and K vectors, which are normalized between 0 and 1.

$$ALn = \frac{AL - min(AL)}{max(AL) - min(AL)} \tag{4}$$

$$ACDn = \frac{ACD - min(ACD)}{max(ACD) - min(ACD)} \quad (5)$$

$$Kn = \frac{K - min(K)}{max(K) - min(K)} \quad (6)$$

- TargetVector: this variable separates InputVector into several groups and is used for Artificial Neural Network training and testing. Ranges of these groups are described in results section.

On the Figures 2, 3, 4 there can be seen dependence of RDS between AL, Kmean and ACD of tested data. Most significant dependency can be seen on Figure 2 where RDS grows with decreasing AL and conversely. Some other trends can be also find in Figure 3 or Figure 4.

These multifactorial dependencies are the main reason why we chose the Artificial Neural Networks as our main decision algorithm for intra-ocular lens power estimation improvement.

4 Results

We use the Feedforward-Pattern net with one hidden layer. Input vector (a compound from ACDn, ALn, Kn) contains 114 data samples from biometry measurements. Patients with three different monofocal intra-ocular lenses - BAUSCH & LOMB MI 60 (43 samples), CROMA ACR6D SE (55 samples), EYEOL UK LW 5752R (16 samples) were chosen.

4.1 Objective

To estimate whether the post-operative refraction based on ACD, AL and K values from preoperative biometry measurements will be larger or smaller than 0 diopters.

4.2 ANN training

Data were randomly divided into the three subsets (training set, validation set, testing set). ANN was trained on 80 samples, validated on 17 samples and tested on 17 samples causally chosen from InputVector with 114 samples.

ANN performance was calculated by cross-entropy which lot penalizes extremely inaccurate outputs and leads to good classifiers (Møller, 1993). Cross-entropy chart can be seen on Figure 5.

As a learning algorithm scaled conjugate gradient backpropagation was chosen. The data vector is fed to the input of ANN. After passing through the network the output of each neuron is calculated and the result is compared with the desired value. Mean squared error is calculated and previous layers and synaptic weights representing memory are corrected. This process repeats till minimum error between the real value and the desired value is reached. Scaled conjugate gradient backpropagation algorithm ensures rapid convergence of learning and using standard numerical optimization methods. More about this ANN learning algorithm can be found in (Tuckova, 2009; Pelusi, 2012).

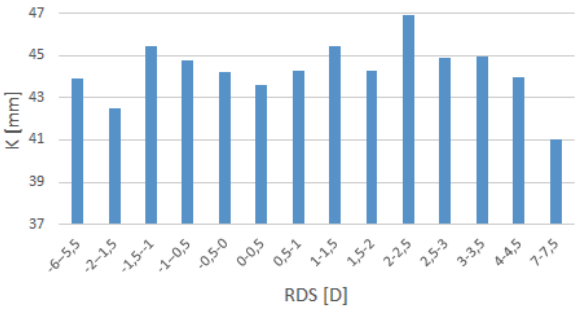

Figure 3. Relation of K between RDS (Sramka, 2015).

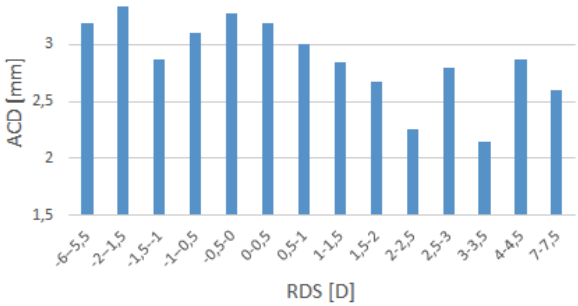

Figure 4. Relation of ACD between RDS (Sramka, 2015).

Algorithm for the best count of the hidden layer neurons was constructed and the ANN was tested for 1 to 50 neurons in the hidden layer. As can be seen in Figure 6 best performance was reached with 37 hidden layer neurons.

4.3 ANN settings

Following ANN settings which can also be seen in Figure 7 were used:

- Input neurons: 3
- Hidden layer neurons: 37
- Hidden layer transfer function: Hyperbolic tangent sigmoid
- Output layer neurons: 2
- Output layer transfer function: Soft max
- Number of training epochs: 16

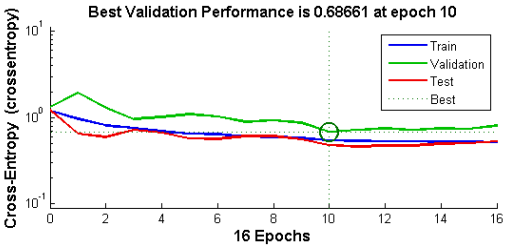

Figure 5. Relation between ANN performance and number of hidden layer neurons

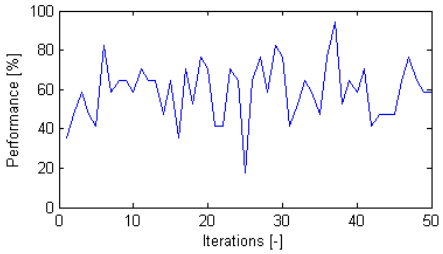

Figure 6. Relation between ANN performance and number of hidden layer neurons

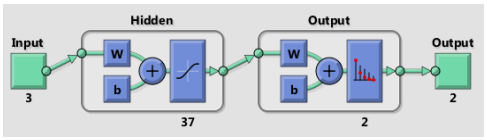

Figure 7. Scheme of Artificial Neural Network used in experiment

4.4 Results

On the Figure 8 there can be found that the overall accuracy of the testing is 94.1 %. Ten samples which represent 58.8 % of the testing set were correctly classified into Group 1 (Table 1). Six samples which represent 35.3 % of the testing set were correctly classified into Group 2 (Table 1). One sample which represents 5.9 % from Group 2 was incorrectly classified into Group 1.

5 Conclusions

This work deals with IOL power calculations during the cataract surgery. At present, intra-ocular lenses power is mostly being calculated by calculation formulas SRK/T, Holladay 1, Holladay 2, Haigis, Hoffer Q and others. All of these formulas using data measured by ultrasound or more often optical biometry and are able to provide acceptable results for the majority of the patients. This is based on fact that these formulas using constants which

Table 1. Group 1: Samples with Subjective Post-operative Refraction Larger than 0; Group 2: Samples with Subjective Post-operative Refraction Smaller than 0

Group 1	Group 2
SfS > 0	SfS < 0

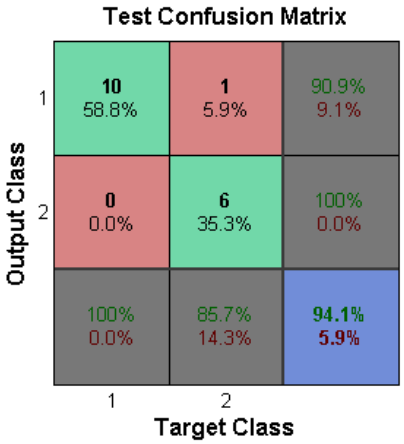

Figure 8. Test Confusion matrix. Green squares - samples correctly classified. Red squares - samples misclassified. Grey squares - Accuracy of each group. Blue square - overall accuracy (Sramka, 2015).

was derived by regression analysis. In the moment when any of input parameters has a value which is significantly unusual a problem can appear. In such a cases patient post-operative refraction can significantly deviate from intended target.

This work describes approach how to preoperatively compensate or indicate which samples of patients could be problematic in accurate intraocular lens calculations by classification of Artificial Neural Networks. Small and long eyes are used to test the ability of Artificial Neural Networks to classify input samples which are taken from pre-operative measurements to several groups which represent the probable post-operative result. In our experiment, Artificial Neural Network classifies samples into two groups. The first group is for data samples with a probable result in positive ranges of diopters and second group is for negative ranges. The accuracy of Artificial Neural Network, in this case, is 94.1 % and Artificial Neural Network seems like the instrument which has potential to improve an intra-ocular lens power calculation accuracy.

Based on the experiment Artificial Neural Networks seems to be the good solution for intra-ocular lens power compensation for non-standard eyes.

6 Future work

We will focus how to reach better accuracy in compensation inaccurate calculations by classification to more groups. Target is that each classification group would have an increment by 0.5 diopters, what is also a dioptric increment of IOL power usually given by manufacturers. Then could be inaccurate calculation compensate very exactly. Artificial Neural Network training could be tested for each IOL type and surgeon. Artificial Neural Network formula

selection could also be tested for the special cases. The special algorithm for compensation calculations for the patient with previous corneal refractive surgery could be designed.

Abstract

Genetic manipulation is increasingly used to fine tune organisms like bacteria and yeast for production of chemical compounds such as biofuels and pharmaceuticals. The process of creating the optimal organism is difficult as manipulation may destroy adaptation and compensation mechanisms that have been tuned by evolution to keep the organisms fit. The continued progress in synthetic biology depends on our ability to understand, manipulate, and tune these mechanisms. Concepts from control theory and control engineering are very applicable to these challenges. From a control theoretic viewpoint, *disturbances rejection* and *set point tracking* describe how adaptation mechanisms relate to perturbations and to signaling events. In this paper we investigate a set regulatory mechanisms in the form of biochemical reaction schemes, so-called controller motifs. We show how parameters related to the molecular and kinetic mechanisms influence on the dynamical behavior of disturbance rejection and set point tracking of each controller motif. This gives insight into how a molecular controller motif can be tuned to a specified regulatory response.

Keywords: bioengineering, *biological systems*, *adaptation*

1 Introduction

1.1 Homeostasis, Disturbance Rejection and Set Point Tracking

Homeostasis is described as the mechanism behind the observed adaptation of an organism in a changing environment (Cannon, 1929; Langley, 1973). From a control theoretic point of view homeostasis can be described by the properties of disturbance rejection and set point tracking.

A physiological example of disturbance rejection is the intravenous/oral glucose tolerance test (IVGTT/OGTT), where the blood glucose concentration is measured at regular intervals after injecting/eating large amounts of glucose (Ackerman et al., 1964). If the blood glucose level is above a predefined level after a certain amount of time, the patient is often diagnosed as diabetic (Ame, 2014). Over the last half century, such disturbance rejection studies are reported in a vast number of publications, see e.g. (Larsen et al., 2003; Steele, 1959), and also a large number of mathematical models are made with the aim to capture the glucose and insulin dynamics, see e.g. the comprehensive review of (Ajmera et al., 2013). Both OGTT and IVGTT represent an impulse (or short time pulse) disturbance perturbation, whereas the chronic infusion of glucose (Topp et al., 2004) represent a stepwise disturbance. Another physiological example of adaptation to a stepwise perturbation change is the adaptation of light sensitivity of the eye, which includes both a compensatory change in pupillary size and an adaptation of the photochemical system in the rods and cones (Guyton and Hall, 2006).

Physiological examples where set point tracking is investigated are relatively rare, although set point determining mechanisms with respect to body temperature and metabolism have beed discussed (Briese, 1998; St Clair Gibson et al., 2005).

Regulatory mechanisms can today be synthetically modified or added to make organism better suitable for a specific job. Still, engineering of biochemical networks has not yet achieved the status and robustness as engineering of electrical and mechanical systems (Ang et al., 2010). From a synthetic biology perspective (Ang and McMillen, 2013; Ang et al., 2013), it is thus of vital importance to have insight into the biochemical mechanisms behind physiological regulatory systems. One possible way to gain such insight is to analyze both the disturbance rejection and set point tracking dynamics of such systems *in vivo*, as well as doing *in silico* studies based on different model candidates. The latter approach is a well known technique used in control engineering. We will in this paper start with the simplest form of biochemical networks with regulatory function and identify by model analysis and simulation how the dynamic response of such networks can be tuned.

1.2 Controller Motifs

A biochemical network with regulatory properties must in its simplest form include at least two components, i.e., state variables, one controlled component and a controller component. The controller component acts on the controlled component in a way that compensates for external disturbances. We have earlier presented a collection of simple two-component regulatory networks (Drengstig et al., 2012; Thorsen et al., 2013), and we have used the name *controller motifs* to describe them. These motifs consist of two chemical species, A and E,

both of them being formed and turned over. A may represent an intracellular compound which is subject to disturbances in the form of e.g. uncontrolled diffusive transport of A in and out of the cell, and E may represent a membrane bound compound such as a transporter protein as shown in Figure 1. Like many cellular compounds which is subject to strict regulation (due to e.g. toxicity if present in large amount), the concentration of A should not exceed or be less than some limits. By connecting the compounds A and E through cellular signaling events such as activation and inhibition, species A becomes the controlled variable, while species E becomes the manipulated variable.

Based on the direction of the E-mediated flow, the motifs fall into two categories termed *inflow* and *outflow* controllers. The complete set of possible inflow and outflow controller motifs are shown in Figure 2, and the *steady state* properties of these controllers were presented in (Drengstig et al., 2012). Based on the *type* of E-mediated inflow or outflow, the controllers are further divided into *activating* (inflow 1/3 and outflow 5/7) or *inhibiting* (inflow 2/4 and outflow 6/8) controller type, indicated by grey and white background in Figure 2, respectively.

In the following we will show how the parameters of the controller motifs, i.e. rate constants, Michaelis-Menten constants, activation constants and inhibition constants, influence on the dynamic performance, and show how it is possible to adjust the system's response similar to the tuning of industrial control systems.

2 Results

2.1 Dynamic Properties of Controller Motifs

The dynamic properties of a two component biochemical system (second order system) can be described in terms of the undamped natural frequency ω_n and the damping ratio ζ. To illustrate how these two parameters relate to the regulatory mechanisms in Figure 2, we use outflow controller 5 as an example. For unique identification, we

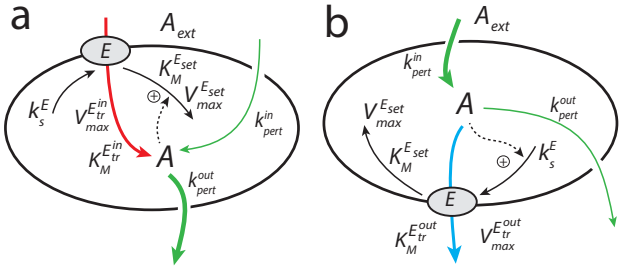

Figure 1. Illustration of a cell with a compound A being under homeostatic control by an inflow controller (panel a) or an outflow controller (panel b). Panel a: An inflow controller compensate for outflow perturbations, k_{pert}^{out} (thick green line), in A by adding more A through an E-mediated inflow (red line). Panel b: An outflow controller compensate for inflow perturbations, k_{pert}^{in} (thick green line), in A by removing excess of A through an E-mediated outflow (blue line).

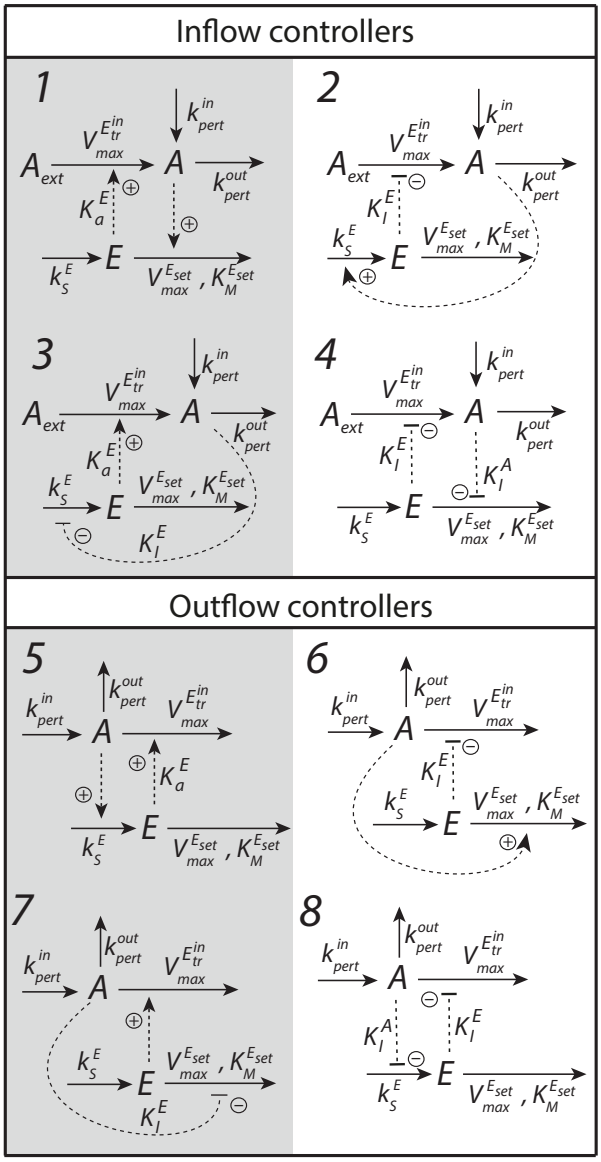

Figure 2. Set of two-component homeostatic controller motifs (Drengstig et al., 2012) classified as inflow and outflow controllers, where grey or white background indicate activating or inhibiting controller types, respectively.

apply subscript $_5$ on the appropriate parameters and variables, and hence, the nonlinear rate equations for an outflow controller 5 are given as (Drengstig et al., 2012):

$$\dot{A} = k_{pert}^{in} - k_{pert}^{out} \cdot A - V_{max}^{E_{tr},5} \cdot A \cdot \frac{E_5}{\left(K_a^{E_5} + E_5\right)} \tag{1}$$

$$\dot{E}_5 = k_s^{E_5} \cdot A - \frac{V_{max}^{E_{set},5} \cdot E_5}{\left(K_M^{E_{set},5} + E_5\right)} \tag{2}$$

As discussed in (Drengstig et al., 2012), the set point $A_{set}^{out,5}$ is found by assuming ideal (theoretical) conditions, i.e. $K_M^{E_{set},5}=0$ in (2), to give $A_{set}^{out,5}=\frac{V_{max}^{E_{set},5}}{k_s^{E_5}}$. Once the theoretical set point is established, we re-assume realistic conditions and reorganize (2) into the integral control law

equation $\dot{E}_5 = G_{i,5} \cdot (A_{set}^{out,5} - A_{meas})$. This allows us to identify the integral controller gain $G_{i,5}$ and the measurement signal A_{meas} as:

$$\dot{E}_5 = \underbrace{-k_s^{E_5} \cdot \frac{E_5}{K_M^{E_{set,5}} + E_5}}_{G_{i,5}} \cdot \left(\underbrace{\frac{V_{max}^{E_{set,5}}}{k_s^{E_5}}}_{A_{set}^{out,5}} - \underbrace{A \cdot \frac{K_M^{E_{set,5}} + E_5}{E_5}}_{A_{meas}} \right)$$

Note that the measurement signal A_{meas} actually includes information about the control signal E_5 which is not common in industrial control engineering. Note also that as long as $K_M^{E_{set,5}} > 0$, the actual value of A will be less than the theoretical set point $A_{set}^{out,5}$. Nevertheless, the set point tracking properties are good since the control error e, calculated as:

$$e = (A_{set}^{out,5} - A_{meas}) \tag{3}$$

is zero. The difference between the actual level of A and the theoretical set point A_{set} is termed *inaccuracy* (Thorsen, 2015). A general result valid for all controller motifs is that both rate constants for synthesis and degradation of E, i.e. k_s^E and $V_{max}^{E_{set}}$, are a part of the set point A_{set} (Drengstig et al., 2012). At the same time, one of these rate constants is also a part of the integral controller gain G_i.

In order to identify the parameters $\omega_{n,5}$ and ζ_5, we once again assume ideal conditions, i.e. $K_M^{E_{set,5}} = 0$, and continue by linearizing the model in (1) and (2) around an arbitrary working point A_{ss} and $E_{5,ss}$. Since the set point consist of two individual parameters, i.e. k_s^E and $V_{max}^{E_{set}}$, we select $V_{max}^{E_{set}}$ to be our input. We then find the closed looped transfer function from the Laplace transformed input $\Delta V_{max}^{E_{set,5}}(s)$ to the Laplace transformed output $\Delta A(s)$ as:

$$M(s) = \frac{\frac{\left(\left(k_{pert}^{out} + V_{max}^{E_{tr,5}} \right) \cdot V_{max}^{E_{set,5}} - k_{pert}^{in} \cdot k_s^{E_5} \right)^2}{V_{max}^{E_{set,5}} \cdot K_a^{E_5} \cdot V_{max}^{E_{tr,5}} \cdot k_s^{E_5}}}{s^2 + \frac{k_{pert}^{in} \cdot k_s^{E_5}}{V_{max}^{E_{set,5}}} \cdot s + \frac{\left(\left(k_{pert}^{out} + V_{max}^{E_{tr,5}} \right) \cdot V_{max}^{E_{set,5}} - k_{pert}^{in} \cdot k_s^{E_5} \right)^2}{V_{max}^{E_{set,5}} \cdot K_a^{E_5} \cdot V_{max}^{E_{tr,5}}}}$$

Using that $V_{max}^{E_{set,5}} = k_s^{E_5} \cdot A_{set}^{out,5}$, we find $\omega_{n,5}$ and ζ_5 as:

$$\omega_{n,5} = \frac{\sqrt{k_s^{E_5}} \cdot \left(\left(k_{pert}^{out} + V_{max}^{E_{tr,5}} \right) \cdot A_{set}^{out,5} - k_{pert}^{in} \right)}{\sqrt{K_a^{E_5} \cdot V_{max}^{E_{tr,5}} \cdot A_{set}^{out,5}}} \tag{4}$$

$$\zeta_5 = \frac{k_{pert}^{in} \sqrt{K_a^{E_5} \cdot V_{max}^{E_{tr,5}}}}{2 \cdot \sqrt{V_{max}^{E_{set,5}}} \cdot \left(\left(k_{pert}^{out} + V_{max}^{E_{tr,5}} \right) \cdot A_{set}^{out,5} - k_{pert}^{in} \right)} \tag{5}$$

From (4) and (5) we see that, depending on the perturbation levels (inflow versus outflow perturbations), it is possible to obtain negative values for $\omega_{n,5}$ and ζ_5. These negative values correspond to circumstances where the perturbation levels are such that the controller breaks down (Drengstig et al., 2012). Breakdown occurs when the net inflow perturbation is larger than the capacity of the outflow controller, i.e., greater than the maximum of the compensatory flow. In this case there is no stable equilibrium in the system and A integrates towards infinity. Such a state is unwanted and may very likely be toxic for the cell. In this case the values of $\omega_{n,5}$ and ζ_5 are invalid and have no physical meaning. Table 1 gives a summary of ω_n and ζ for the four inflow and four outflow controllers, together with the expression for each set point A_{set}.

Note that there is a close relationship between the expressions for ζ and ω_n for each controller, and thus, it is not possible to specify *both* ζ and ω_n independently.

Since controller 5 is an outflow controller, the inflow perturbation $\Delta k_{pert}^{in}(s)$ is considered the main disturbance, and the transfer function characterizing the disturbance rejection properties is:

$$N(s) = \frac{s}{s^2 + \frac{k_{pert}^{in} \cdot k_s^{E_5}}{V_{max}^{E_{set,5}}} \cdot s + \frac{\left(\left(k_{pert}^{out} + V_{max}^{E_{tr,5}} \right) \cdot V_{max}^{E_{set,5}} - k_{pert}^{in} \cdot k_s^{E_5} \right)^2}{V_{max}^{E_{set,5}} \cdot K_a^{E_5} \cdot V_{max}^{E_{tr,5}}}}$$

As expected, this transfer function has a zero in the origin, implicating homeostatic behavior and perfect adaptation (Drengstig et al., 2008).

2.2 Tuning of Individual Controllers

As shown in (Drengstig et al., 2012), the *steady state* performance of the individual controllers were found to be identical, given a certain set of parameter values. A related issue is to determine whether it is possible to tune the controllers to obtain identical *dynamical* performance using the theoretical design parameters in Table 1. Such tuning will be useful in synthetic biology. Also on a more fundamental level, if such tuning is possible it implies that it is impossible to infer the underlining network structure, i.e., the particular controller motif, responsible for an observed adaptive process by measuring the dynamical properties of the controlled variable alone.

We have selected to use the rate constants of the synthesis and degradation of the controller species, k_s^E and $V_{max}^{E_{set}}$, together with the rate constant of the E-mediated compensatory flow $V_{max}^{E_{tr}}$, as our tunable parameters. These parameters are relatively easy to tune from the perspective of synthetic biology and offer a greater tunable range than the parameters associated with the nonlinearities in the model (K_a^E, K_I^A, and K_I^E). To discuss one of the tunable parameters, the rate constant for synthesis of E, k_s^E, can in practice be modified by altering the promoter of the gene coding for E. One way to do this is a fixed tuning of the promoter itself, e.g. the *Cu*-dependent promoter of the CUP1-gene of *Saccharomyces Cerevisiae* can be modified by mutations to show wide range of different induction ratios (Thiele and Hamer, 1986). Another option is to use a dual mode promoter, a type of promoter who's regulation

Table 1. The set point A_{set}, natural undamped frequency ω_n and damping ratio ζ for controller motifs 1-8 in Figure 2 under theoretical conditions, i.e. $K_M^{E_{set}}=0$. For each controller we have added a subscript to the parameters for unique identification.

$A_{set}^{in,1}=\frac{k_s^{E_1}}{V_{max}^{E_{set,1}}}$	$\omega_{n,1}=\frac{\sqrt{V_{max}^{E_{set,1}}}\left(k_{pert}^{in}-k_{pert}^{out}A_{set}^{in,1}+V_{max}^{E_{tr,1}}A_{ext}\right)}{\sqrt{K_a^{E_1}V_{max}^{E_{tr,1}}A_{ext}}}$	$\zeta_1=\frac{k_{pert}^{out}\sqrt{K_a^{E_1}V_{max}^{E_{tr,1}}A_{ext}}}{2\sqrt{V_{max}^{E_{set,1}}}\left(k_{pert}^{in}-k_{pert}^{out}A_{set}^{in,1}+V_{max}^{E_{tr,1}}A_{ext}\right)}$
$A_{set}^{in,2}=\frac{V_{max}^{E_{set,2}}}{k_s^{E_2}}$	$\omega_{n,2}=\frac{\sqrt{k_s^{E_2}}\left(k_{pert}^{out}A_{set}^{in,2}-k_{pert}^{in}\right)}{\sqrt{K_I^{E_2}V_{max}^{E_{tr,2}}A_{ext}}}$	$\zeta_2=\frac{k_{pert}^{out}\sqrt{K_I^{E_2}V_{max}^{E_{tr,2}}A_{ext}}}{2\sqrt{k_s^{E_2}}\left(k_{pert}^{out}A_{set}^{in,2}-k_{pert}^{in}\right)}$

$A_{set}^{out,6}=\frac{k_s^{E_6}}{V_{max}^{E_{set,6}}}$	$\omega_{n,6}=\frac{\sqrt{V_{max}^{E_{set,6}}}\left(k_{pert}^{in}-k_{pert}^{out}A_{set}^{out,6}\right)}{\sqrt{K_I^{E_6}V_{max}^{E_{tr,6}}A_{set}^{out,6}}}$	$\zeta_6=\frac{k_{pert}^{in}\sqrt{K_I^{E_6}V_{max}^{E_{tr,6}}}}{2\sqrt{k_s^{E_6}}\left(k_{pert}^{in}-k_{pert}^{out}A_{set}^{out,6}\right)}$
$A_{set}^{out,7}=\frac{V_{max}^{E_{set,7}}K_I^A}{k_s^{E_7}}-K_I^A$	$\omega_{n,7}=\frac{\sqrt{k_s^{E_7}}\left(\left(k_{pert}^{out}+V_{max}^{E_{tr,7}}\right)A_{set}^{out,7}-k_{pert}^{in}\right)}{\sqrt{\left(A_{set}^{out,7}+K_I^A\right)V_{max}^{E_{tr,7}}K_a^{E_7}A_{set}^{out,7}}}$	$\zeta_7=\frac{k_{pert}^{in}\sqrt{\left(A_{set}^{out,7}+K_I^A\right)V_{max}^{E_{tr,7}}K_a^{E_7}}}{2\sqrt{k_s^{E_7}A_{set}^{out,7}}\left(\left(k_{pert}^{out}+V_{max}^{E_{tr,7}}\right)A_{set}^{out,7}-k_{pert}^{in}\right)}$
$A_{set}^{out,8}=\frac{k_s^{E_8}K_I^A}{V_{max}^{E_{set,8}}}-K_I^A$	$\omega_{n,8}=\frac{\sqrt{V_{max}^{E_{set,8}}}\left(k_{pert}^{in}-k_{pert}^{out}A_{set}^{out,8}\right)}{\sqrt{\left(A_{set}^{out,8}+K_I^A\right)V_{max}^{E_{tr,8}}K_I^{E_8}A_{set}^{out,8}}}$	$\zeta_8=\frac{k_{pert}^{in}\sqrt{\left(A_{set}^{out,8}+K_I^A\right)V_{max}^{E_{tr,8}}K_I^{E_8}}}{2\sqrt{V_{max}^{E_{set,8}}A_{set}^{out,8}}\left(k_{pert}^{in}-k_{pert}^{out}A_{set}^{out,8}\right)}$

of protein production depends on two activators. One activator would be the control variable A and another would be a chemical compound that can be meticulously added to the growth medium to achieve a certain level of gene transcription and production of E, represented in the model as the value of k_s^E. One such promoter controlled by Testosterone and IPTG (isopropyl β-D-1-thiogalactopyranoside) has recently been developed (Mazumder and McMillen, 2014).

In order to best tune the parameters we have to know about the operational limits of the system. For this purpose, we define as in (Drengstig et al., 2012) an upper limit for the maximum compensatory flux, $j_{A,max}=10$, corresponding to a maximum level of $E_{max}=15$ for the activating controllers 1, 3, 5 and 7, and corresponding to $E_{min}=0$ for the inhibiting controllers 2, 4, 6 and 8. We assume further that the set point of A is $A_{set}=1.0$, the external concentration is $A_{ext}=2$. The kinetic constants for activation and inhibition are chosen to avoid saturation effects: $K_a^E=2$, $K_I^A=0.1$ and $K_I^E=1.0$. Moreover, the working point of perturbations is specified as $k_{pert}^{in}=2/k_{pert}^{out}=5$ for inflow controllers and $k_{pert}^{in}=5/k_{pert}^{out}=2$ for outflow controllers. Given these overall system parameters, the tuning procedure of each individual controller motif is based on specifying ζ (or ω_n, but not both) in a similar way as the pole placement method, and determine the last three parameter values of each motif, i.e. $V_{max}^{E_{tr}}$, $V_{max}^{E_{set}}$ and k_s^E.

To illustrate, we specify *two* different dynamical responses in the concentration of A for a step in A_{set}, i.e. one critically damped ($\zeta=1$) and one underdamped ($\zeta=0.2$ corresponding to 50% overshoot) response. A strongly underdamped system overshoots when adapting a change in set point, but shows considerably better disturbance rejection than a critically damped system. Thus, tuning for the latter may be of interest in many biological systems.

We illustrate the procedure in detail by continuing on the outflow controller 5 example, and start by considering the rate expression for the compensatory flux, j_A, from (1):

$$j_A=V_{max}^{E_{tr,5}}\cdot A\cdot\frac{E_5}{\left(K_a^{E_5}+E_5\right)} \tag{6}$$

By setting $j_A=j_{A,max}=10$ and inserting $E_5=E_{5,max}=15$, $A=A_{set}^{out,5}=1$ and $K_a^{E_5}=2$ into (6), gives $V_{max}^{E_{tr,5}}=11.33$. Using the mathematical expressions for $A_{set}^{out,5}$ and ζ_5 tabulated in Table 1, we find $V_{max}^{E_{set,5}}=2.04$ and $k_s^{E_5}=2.04$ for

ζ_5=1 and $V_{max}^{E_{set},5}$=51.0 and $k_s^{E_5}$=51.0 for ζ_5=0.2, see Table 2.

Table 2. The parameters $V_{max}^{E_{tr}}$, $V_{max}^{E_{set}}$, k_s^E and the integral controller gain G_i (in grey) for each controller motif specified for critical damped response ζ=1 and underdamped response ζ=0.2. The other parameters are defined in the main text.

		$V_{max}^{E_{tr}}$	$V_{max}^{E_{set}}$	k_s^E	G_i
Critically damped, ζ=1	Inflow 1	5.67	2.04	2.04	2.04
	Inflow 2	5.00	6.94	6.94	-6.94
	Inflow 3	5.67	2.24	24.68	2.04
	Inflow 4	5.00	84.03	7.64	-6.94
Under-damped, ζ=0.2	Inflow 1	5.67	51.0	51.0	51.0
	Inflow 2	5.00	173.6	173.6	-173.6
	Inflow 3	5.67	56.1	617.1	51.0
	Inflow 4	5.00	2100.7	191.0	-173.6
Critically damped, ζ=1	Outflow 5	11.33	2.04	2.04	-2.04
	Outflow 6	10.00	6.94	6.94	6.94
	Outflow 7	11.33	24.68	2.24	-2.04
	Outflow 8	10.00	7.64	84.03	6.94
Under-damped, ζ=0.2	Outflow 5	11.33	51.0	51.0	-51.0
	Outflow 6	10.00	173.6	173.6	173.6
	Outflow 7	11.33	617.1	56.1	-51.0
	Outflow 8	10.00	191.0	2100.7	173.6

This corresponds to an integral controller gain of $G_{i,5}$=−2.04 and $G_{i,5}$=−51.0, respectively, and a response time of T_r≈0.8 seconds ($\omega_{n,5}$=2.5) and T_r≈0.1 seconds ($\omega_{n,5}$=12.5). The simulation results shown as black curves in panels **c**, and **d** in Figure 3, verify the tuning specifications, both with respect to overshoot and response time.

In order to compare the individual performance of each controller, the above described tuning specifications are applied for all controllers, and the results are shown in Table 2 and verified by simulation in Figure 3.

Note the identical values for G_i (greyed out in Table 2) for all the activating (inflow 1/3 and outflow 5/7) and all the inhibiting (inflow 2/4 and outflow 6/8) controllers, respectively. Note also the opposite signs for activating and inhibiting inflow and outflow controllers, respectively, which is due to the combination of controller type (*activating/inhibiting*) and controller configuration (*inflow/outflow*).

The responses in Figure 3 clusters into two groups, where the first group is the E-activating inflow controllers 1/3 (black and red curves in Figures 3**a** and 3**b**) and the E-inhibiting outflow controllers 6/8 (blue and green curves in Figures 3**c** and 3**d**). The second group is the E-inhibiting inflow controllers 2/4 (blue and green curves in Figures 3**a** and 3**b**) and the E-activating outflow controllers 5/7 (black and red curves in Figures 3**c** and 3**d**). The reason why equally tuned controllers behaves slightly different is due to the nonlinearity of each individual controller combined with a relative large set point step change.

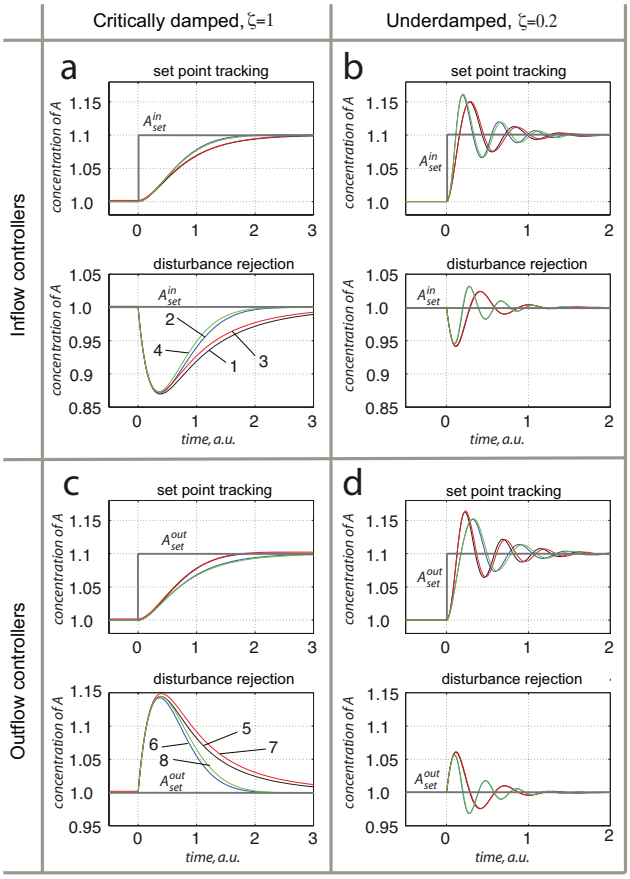

Figure 3. Dynamic properties of inflow and outflow controllers showing the response in concentration of species A. The color codes for the different inflow controller are: 1=black, 2=blue, 3=red and 4=green, and the color codes for the different outflow controllers are: 5=black, 6=blue, 7=red and 8=green. For the *set point tracking* curves, the set point changes from A_{set}=1.0 to A_{set}=1.1 at t=0. For the *disturbance rejection* curves, the disturbance is a unit step change from 5 to 6 at t=0 in k_{pert}^{out} for inflow controllers and in k_{pert}^{in} for outflow controllers. Panels **a** and **b**: Set point tracking (upper) and disturbance rejection (lower) responses for inflow controllers tuned for critically damped (ζ=1) and underdamped (ζ=0.2) responses, using the parameters shown in Table 2. Panels **c** and **d**: Set point tracking (upper) and disturbance rejection (lower) responses for outflow controllers tuned for critically damped (ζ=1) and underdamped (ζ=0.2) responses, using the parameters shown in Table 2.

From Table 1 we see that the inflow and outflow perturbations come into the expressions of ω_n and ζ in different ways. To visualize the effect of varying level of perturbation, Figure 4 shows dynamic responses of inflow controller 3 for k_{pert}^{out}={3,5,7} (Figure 4**a**) and outflow controller 6 for k_{pert}^{in}={5,7,9} (Figure 4**b**). The effect of increased k_{pert}^{out} for inflow controller 3 is slower dynamics with less damped response. On the other hand, outflow controller 6 shows faster dynamics together with more underdamped response at increased k_{pert}^{in} levels.

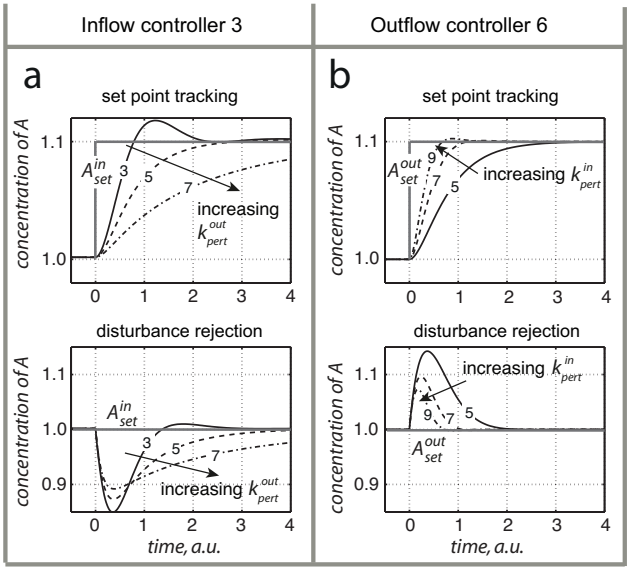

Figure 4. Set point tracking (upper) and disturbance rejection dynamics (lower) of species A using inflow controller 3 (panel **a**) and outflow controller 6 (panel **b**) at different level of outflow and inflow perturbations, respectively. The set point change is a step from A_{set}=1.0 to A_{set}=1.1 at t=0 and the disturbance is a step increase of 1 from original value at t=0. In panel **a** the labeling on the curves corresponds to outflow perturbations of $k^{out}_{pert} \in \{3,5,7\}$. In panel **b** the labeling on the curves corresponds to inflow perturbation of $k^{in}_{pert} \in \{5,7,9\}$.

3 Conclusions

We have shown how a set of homeostatic controller motifs can be tuned, in a similar way as in industrial control systems, to exhibit a specified dynamic response with respect to overshoot δ and response time T_r. We have also shown analytically and through simulations how *i*) the level of inflow/outflow disturbances and *ii*) the values of different rate constants influence on the set point tracking properties. The corresponding disturbance rejection properties is also studied through simulations using a unit step input signal in the disturbance.

An important implication of the fact that all controller motifs can show identical dynamic responses is that one cannot postulate a specific controller motif based on measurement of disturbance rejection and/or set point tracking alone. The motif type, i.e. inflow or outflow, activating or inhibiting, rest on how the molecular mechanisms behind the controller interact and not on the system's ability to show a specific response. The specific response of physiological regulatory system is a result of tuning the system's kinetic parameters and the strength of the perturbation.

There is a great effort going on in both academia and industry to genetically manipulate organisms to produce useful bioproducts. One of the landmark studies published in Science last year was the implementation of the complete biosynthesis of opioids in yeast (Galanie et al., 2015; Service, 2015). Opioids like morphine are the primary drugs used for treatment of severe pain and pain management, and production depends on the cultivation of opium poppies. While the implementation of opioid biosynthesis in yeast is a tremendous achievement, it still requires an improvement in overall yield by a factor of $7 \cdot 10^6$ to compete with poppies (Galanie et al., 2015). Great improvements are expected (Galanie et al., 2015), but this will require an intricate tuning of the different parts of the biosynthesis pathway.

From a synthetic biology point of view, the work in this paper creates a basis one can use to identify which and how properties of a reaction and participating proteins/enzymes contributes to the dynamical response. For instance, the natural undamped frequency ω_n, which is important for the swiftness of a controller motif, will for outflow controller 5 increase if we by some means manage to increase the production of E (increase k^E_s) by e.g. increasing the expression of mRNA coding for E (as shown in Table 1, a change in k^E_s will also change the set point). A related example of such is reported in (Ang et al., 2010), where a two promotor network system is constructed *in silico* from realizable parts within the bacterium *Escherichia coli*. The network includes both basal rates and activated/repressed regulatory inputs, and hence, the network share similarities with inflow controller 2 in Figure 2. Two requirements were used as tuning criteria for the network, i.e. ζ=1 (critically damped) and large ω_n indicating a response time T_r as short as possible. In order to obtain the necessary approximate zero order degradation of the repressor R (corresponding to our species E), two effectors I_1 and I_2 are included in order to force the repressor to work at saturated conditions, i.e. corresponding to the theoretical conditions, $K^{E_{set}}_M$=0, used in this paper.

An alternative approach to tuning is given in (Ang et al., 2013), where the tuning is related to the so-called *response curves*. These are steady state relationships between an input and an output variable, e.g. the molecular concentration of a transcription factor protein and the expressed protein, respectively, and not time dependent tuning as discussed in this paper. However, variations in kinetic parameter values results in different steady state relationships.

Abstract

Future biorefineries will work according to the principles of Nature, using microbes and enzymes for valorizing wastes and other biomass into biofuels, other bioenergy substances, organic platform chemicals, and organic fertilizers. A mobile biorefinery pilot plant was engineered and manufactured in Finland and tested in Finland, Poland and Sweden with various biowastes within ABOWE project. The main purpose of the ABOWE Biorefinery pilot plant tests was to give a reliable "proof of concept" on the industrially important substances producible in a sustainable way. This goal was achieved successfully, and several overall difficulties were overcome during the testing in three countries.

Keywords: bioprocess, biorefinery, biowaste, consolidated bioprocessing, undefined mixed cultures, anaerobiosis

1 Introduction

Biotechnology deals with processes that are based on naturally occurring phenomena. Bastin and Dochain (1990) define bioreactor as a tank in which several biological reactions occur simultaneously in a liquid medium. The biological reactions which are involved in the process can be classified as microbial growth reactions/microbiological reactions and enzyme catalyzed reactions/biochemical reactions. The growth of the microorganisms (bacteria, yeasts, etc.) proceeds by consumption of appropriate nutrients or substrates such as carbon, nitrogen and oxygen. Preferably environmental conditions (temperature, pH, etc.) are optimized. The cell growth is associated with the enzymatic reactions in which some reactants are transformed into products through the catalytic action of enzymes. (Bastin and Dochain, 1990)

Favorable environmental conditions for microorganisms should be maintained all the time. Exceeding boundary values regarding conditions leads to slowing of the production rate, and there is often no other way than to readjust or restart. The failure of the process does not always require even crossing the threshold, but this may also happen due to circumstances in which some of the harmful microbes take over.

To process control and automation the multiple variables in a mixed microbial culture set high demands. Parameters in terms of automation are, *e.g.*, pH, temperature, sugar balance, dissolved oxygen and gas mixtures. Each of the above-mentioned variables has its own control and adjustment aspects. This is the so-called multivariable system, in which there are dependencies between parameters. Each parameter's effects on microbial activity should be understood in order to get the optimal outcome from the automation and process design. The principles of fuzzy logic might be needed. Temperature control alone is already a challenging thing, because the process itself generates heat, which should be predicted. Not to mention the other variables. The phenomena are very unstable and cross-effects are common. For control engineering and process control these are demanding cases to adjust and measure the variables in order to reach the desired outcomes.

Processes cannot be adjusted only with traditional methods used in heavy industry but events have to be controlled with a technique called bioautomation. In addition to the physical sensors there is information required that might not even be possible to get with concentration analysis measurements. There is a need to go deeper into the events even at the cellular level for which micro- and nanotechnology bring along new opportunities.

Knowledge of processes is very important in automation engineering. Microbiology often deals with more difficult phenomena than regular process chemistry does. The problems are almost impossible to be solved otherwise than through close cooperation between experts from various fields.

Future biorefineries will work according to the principles of Nature, using microbes and enzymes for valorizing wastes and other biomass into biofuels, other bioenergy substances, organic platform chemicals, and organic fertilizers. The concept of 'waste' will become unnecessary in industries, communities, agriculture and forestry as all materials are being refined and recycled. The ABOWE (Implementing Advanced Concepts for

Biological Utilization of Waste, 12/2012-12/2014) project, led by Savonia University of Applied Sciences, and its two pilot plants, have paved the way for this industrial revolution. ABOWE project belonged to the EU Baltic Sea Region Programme 2007-2013. (Jääskeläinen and Hakalehto, 2015)

The novel biorefinery concept, innovated and developed by Adjunct Professor Elias Hakalehto, (Finnoflag Oy and University of Eastern Finland), was one of the two platforms of the ABOWE project. The second platform was biogas production with the dry digestion technology piloted under the supervision of Ostfalia University of Applied Sciences, Germany. ABOWE was an extension project for REMOWE project (Regional Mobilization of Sustainable Waste to Energy Production 9/2009-12/2012) to continue with these two promising technologies to piloting phase. (Hakalehto *et al*, 2016a)

Savonia University of Applied Sciences invested in the ABOWE project in a mobile biorefinery pilot plant. In this biorefinery plant biodegradable wastes are valorized to valuable chemical and energy products with the aid of microbes and their enzymes, in the same way as in the natural environments.

The pilot plant engineering team consisted of Finnoflag Oy experts and Savonia's engineering teachers, project engineers and engineering students. The project team was built so that teaching was integrated as widely as possible already at the planning stage of the process. Versatile knowledge of process and instrumentation, layout, mechanical, electrical, automation, IT, environmental and manufacturing was combined for the pilot plant engineering and manufacturing during 2013.

Savonia manufactured the pilot plant in front of its educational workshop. In the pilot plant manufacturing, several locally operating industrial enterprises were participating as component suppliers. Also many trainees from Savo Vocational College, Finland, participated in the manufacturing of the pilot plant. Altogether over 50 persons were involved in the pilot plant engineering and manufacturing in Finland. There was not much available model, and practical experience about effects of various functions was mostly lacking. Savonia's personnel instructed the project, brought engineering know how to the project and performed equipment purchases. (Jääskeläinen and Hakalehto, 2018)

The biorefinery pilot plant was completed in January 2014 and was tested in Finland with waste water treatment sludge at a fluting factory, in Poland with potato waste from chips factory and in Sweden with chicken manure and slaughterhouse waste during 2014.

2 Materials and Methods

Objectives of the ABOWE project regarding the mobile biorefinery pilot plant were to test

- Effective pretreatments and hydrolysis of various biodegradable wastes.
- Enhanced natural microbial bioprocess for the upstream production of fuels and chemicals.
- Preliminary planning of the simultaneous product collection.

The goal of the ABOWE project and the mobile pilot plant was to provide "proof of concept" on the ways, how biomass waste materials could be used as raw materials. The products were biofuels, bioenergy, organic platform chemicals and organic fertilizers. These should be produced in an economically feasible way, with the help of micro-organisms. (Hakalehto *et al*, 2016b)

The biorefinery process is novel in terms of improved productivity, low initial investment costs and versatile product opportunities. The production exploits results from the research conducted in the Finnoflag laboratory since 1997 with the PMEU enhanced cultivation unit (Portable Microbe Enrichment Unit), and in larger vessels. As various products are produced faster, the production plant size reduces enabling lower investment. Moreover, the total duration of the process can be shortened and end product concentrations increased. (Hakalehto *et al*, 2016b)

There are four main tanks in the mobile biorefinery pilot plant's process (Hakalehto *et al*, 2016b):

1. HOMOGENIZER is the first main tank. Attached to it is a biomass crusher and the tank has an effective mixer. Water content can be adjusted partially in Homogenizer from a water tap. Homogenizer is also one of the three recycled and modified tanks in the pilot plant used for the upstream bioprocess. In Homogenizer various biomasses are mechanically broken in micro- and macroscale. Their dry weight is measured in the on-site lab room and the total masses of solid and liquid substrates are measured with a weighing sensor installed in the leg of the tank.

2. HYDROLYZER is a reactor with thermostat and pH control for producing, maintaining and adjusting the optimal conditions for chemical and/or enzymatic hydrolysis of the macromolecules in the substrate biomasses. Main operating parameters are the water content, fill in level, temperature (can be lifted up to 80 degrees Celsius), pH of the biomass, viscosity and the hydrolysis time. Hydrolyzer temperature is controlled with a control sequence whose parameters can be set from the control room. The purpose of the sequence is to perform the hydrolysis of the raw material and to kill harmful microbes so that the batch would be ready to be fed in the Bioreactor. Also pH is started to be adjusted for the coming process phases.

3. BIOREACTOR is the sole entirely novel big tank in the pilot plant. It has been manufactured by (Brandente Oy, Kuopio, Finland) according to the instructions of the innovator (Finnoflag Oy, Siilinjärvi, Finland) and Savonia. The patented design is based on numerous bioprocess runs in Finnoflag Oy's laboratory projects preceding the ABOWE project. Different homogenized and hydrolyzed biomasses are processed in adjustable gas conditions in the Bioreactor in order to produce biofuels, biogases and biochemicals by the metabolic activities of bacteria and other micro-organisms. The volume of the tank is around 300 liters of which effective volume is around 200 liters.

An optimal gas mixture is introduced to the Bioreactor from gas bottles and air compressor via a gas mixer. Typical gases besides the air are carbon dioxide and nitrogen depending on the specific requirements of the microbial culture. An optimal mixture is introduced via aeration discs and rings from two layers in the Bioreactor. The gas flow is at the same time performing the airlift principle in the Bioreactor mixing. There is not any mechanical stirring system, *e.g.*, to avoid shear forces in the process broth.

There is a two-step process for producing the microbiological inocula: first in the PMEU equipment (Portable Microbe Enrichment Unit) (Samplion Oy, Siilinjärvi, Finland), and then in the seed fermenters connected to the Bioreactor. In PMEU it is possible to get homogenous cultures into same active growth phase in a few hours of cultivation (Hakalehto and Heitto, 2012). Besides ABOWE version, the PMEU has been productized earlier for environmental, clinical, food, and other hygienic control purposes (Hakalehto, 2012).

Additional substances and pH adjustment chemicals are fed to a circulation from the Bioreactor back to the Bioreactor, run by a circulation pump. Thus substances can easier be mixed with the mass and local higher concentrations are not occurring in the Bioreactor. At the same time it is possible to take necessary samples from this circulation. Circulation velocity or the reference value for flow speed (l/min) can be set from the control room.

During the process runs pH, dissolved oxygen, temperature, total volume (biomass input and process fluid outflow), as well as the gas mixing and measurement are adjusted by the process control system together with real time operating activity by the personnel on site and via 3G connection to the pilot plant. The gaseous products are recorded from the volatile outflow of the Bioreactor prior to the stabilization.

A schematic drawing of the Bioreactor is presented in Figure 1.

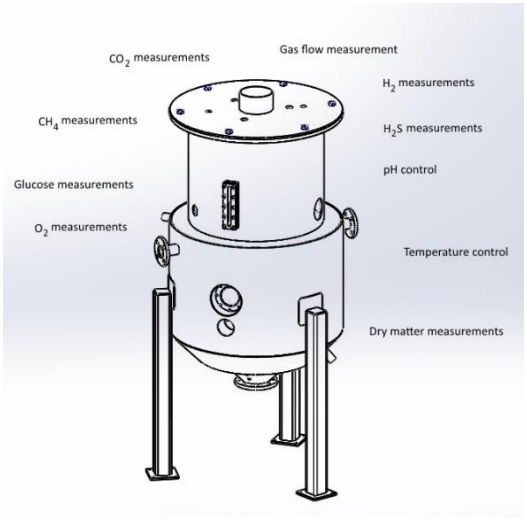

Figure 1. Schematic drawing of ABOWE Bioreactor with indication of various measurement parameters. Lecturer Anssi Suhonen, Savonia based on instructions from Adj. Prof. Elias Hakalehto, Finnoflag Oy.

4. STABILIZER was modified from a food industry boiling tank into a cooled collection unit of the bioprocess fluid containing liquid and possibly solid products of the pilot plant. In Stabilizer the temperature is decreased to 15-18 degrees Celsius from the usually much higher production temperatures in order to avoid losses in the product concentrations after the process.

The process fluid was further analyzed with Nuclear Magnetic Resonance (NMR) by Professor Reino Laatikainen at the University of Eastern Finland in Kuopio (Laatikainen *et al*, 2016). Ostfalia University of Applied Sciences in Germany provisionally experimented the downstream processing of some of the bioprocess products, under the supervision of Professor Thorsten Ahrens.

The original idea of the piloting experiments was to study the combination of gaseous, liquid and solid phases in the Bioreactor in order to produce biofuels and bioenergy, organic platform chemicals and organic fertilizers, or their raw materials. Breaking the biochemical process into bits and pieces could form this basis for any experimentation in the future. (Hakalehto *et al*, 2016b)

3 Results and Discussion

3.1 Tests in Finland

The first ABOWE testing site was Powerflute Oyj Savon Sellu fluting factory's waste water treatment plant in Kuopio, in Eastern Finland during February-March 2014. The climate conditions with temperatures between -25°C and -30°C were harsh so the functions of the pilot plant were put straight into a real "climate test". Liquids tend to get frozen in the pipes during their pumping into the pilot plant. Also the substrate for the tests, the dried sludge from the waste treatment plant

was rapidly cooling down in the piles where it was collected from the activated sludge pools. Another raw material for the experiments was the incoming waste water. In the factory there are actually two separate systems, namely the pulp factory and the corrugated carton board (fluting) machine. Waste waters from both machines arrive to the waste water treatment plant. The original raw material wood chips are treated with many chemicals during the production process. (Hakalehto *et al*, 2016b; Hakalehto *et al*, 2016c)

Products and services from the test runs at Savon Sellu were:

- Ethanol, Butanol
- 2,3-butanediol
- Organic acids
- Hydrogen
- Fertilizer biomass
- Biogas
- Purified waste water
- Decreased waste treatment expenses
- Lesser environmental and climatic load

The initial break-in test runs and international training period were carried out during the testing at Savon Sellu waste water treatment plant in January and February 2014. The first 3-4 runs were targeted for pretreating the available substrate in the pilot plant process. Both anaerobic and aerobic test runs were accomplished. In all cases, regardless of the hygienization during the hydrolysis step, the natural microflora from the activated sludge treatment process pools, especially the sulfur bacteria, contaminated the Bioreactor process broth. They were then restricted by the inoculated *Klebsiella*/*E.coli* strains which were preincubated in the Bioreactor as a nutrient bed type of inoculum. This same strategy was later used in the two anaerobic cultivations with *Clostridium sp.* (Hakalehto *et al*, 2016b) An example of the process development at the Finnish testing site is presented in Table 1.

Table 1. Description of process development outlines in the Finnish runs at the Savon Sellu fluting factory site (Hakalehto *et al*, 2016b)

	General problem	**Practical solution**	**Potential solution**
1.	Diffusion limitation	Gas flow adjustment Homogenisation with effective hydrolysis	Improved Bioreactor design for full scale plants
2.	Disturbing organisms	Speeded up inoculations Nutrient beds Hygienization of waste	Consolidated Bioprocessing
3.	Productivity problems	Mixed wastes	Simultaneous downstreaming for blocking biological down regulation
4.	Too low raw material concentration	Process fluid circulation Nutrient beds	Better pumps and valves

Microbiologically one of the most influential process chemical addition is the use of sulfuric compounds in the Savon Sellu factory process, which eventually led to the enrichment of H_2S liberating bacteria into the gas emission flow from the Bioreactor when the sludge was used as substrate. As one of the precautions for this liberation of the toxic gas flow, a specific alarm system was installed. All gases, however, were directed out of the pilot plant which completely prevented their accumulation inside, and thus the formation of occupational hazards. The general safety of the unit had been discussed beforehand with North Savo Regional Rescue Services and the authorities were satisfied with the pilot plant and the plans for its short testing period. (Hakalehto *et al*, 2016c)

The H_2S formation was on a very high level in most of the test runs. Consequently, the fed-batch function of the pilot plant was not possible to get tested during the short time-window at the Savon Sellu testing site. Furthermore, a major part of the planned time was needed for adjustments of the heating and cooling system as three of the four main process tanks were purchased as recycled industrial equipment and modified for the bioprocess use with the principle of sustainability. (Hakalehto *et al*, 2016c)

Despite the very short time schedule for the start-up phase, promising results were obtained. The primary purpose of the first tests in Finland was mainly to get familiar with the relatively complicated system of the equipment with computer control, numerous measurements, as well as temperature, pH and gas adjustments. Several sensors proved to be useful with secondary screens in the process room, besides the process control system in the control / laboratory room. (Hakalehto *et al*, 2016c)

The basic principles for steering the pilot plant were learnt, and their implementation gave promises for the potential of future bioprocess development. In the start-up phase any result from the biological multi-variable process is giving valuable information for future experiments. Improvement of the pilot plant equipment is still needed, one target being such pumps that are capable to move raw material with dry weight higher than 10-15%. Increasing this value would uplift also the yield and productivity of various biochemicals. (Hakalehto *et al*, 2016c)

On the bioprocess side, the non-aseptic principle was tested, because it could at best lower the investment costs of the process equipment to one tenth in the large production units. Therefore, the natural microflora from the waste water pools and the activated sludge caused many problems and produced overgrowth which almost took over the Bioreactor in the beginning of the experimentation. Measures for abating the background flora were attempted, but these trials were not completed during the short experimentation period. However, the nutrient bed approach with inoculation of the production

organisms prior to the major substrate addition seemed to be the correct way to tackle most of the problems caused by the background flora. (Hakalehto *et al*, 2016c)

One significant result was the production of the hydrogen gas from the waste sludge, observed earlier in the Finnoflag Oy's laboratory, which could provide 150-300 kWh of electricity daily from the Savon Sellu fluting factory's waste waters. This value was estimated from the preliminary results without any continued optimization or process development. The generation of molecular hydrogen was taking place parallel to the production of liquid chemicals, whose production levels were subjected to improvement due to the preliminary nature of the testing. The diminishment in the environmental load of Savon Sellu waste water was already comparable to the biogas process, and actually the biorefining for chemical products could be combined with cascading biogas production for the highest decrease in the climatic effects of the waste water treatment. This gas emission could be combined with methane from another reactor system in order to obtain hytane (hydrogen plus methane) gas mixture for energy production. (Hakalehto *et al*, 2016c)

3.2 Tests in Poland

The testing site in Poland was the waste management center of ZGO Gać Ltd near Wrocław, in Lower Silesia during May-early July 2014. The main substrates were potato peels from a chips factory and separately collected biowaste from households and restaurants. These substances were rather easily degradable. The potato starch had been readily degradable source of hydrolysable biomass in the experiments preceding ABOWE, carried out by Finnoflag Oy in Finland (Hakalehto *et al*, 2013). Then record levels of 2,3-butanediol productivities had been achieved (8 g/l/h). This degradative process was based on the studies with the members of Enterobacteriaceae family of facultatively anaerobic bacteria, particularly of the genus *Klebsiella* (Hakalehto, 2013; Hakalehto *et al, 2008*).

In the tests participated 24 students and six experts from Wrocław University of Technology together with Finnoflag Oy. The substrate was of a "carboxylic platform" type (den Boer *et al*, 2016a). In the experiments with sole Polish potato waste (consisting mainly of potato peels), ethanol was the principal product, besides the high amounts of hydrogen produced from the waste. Hydrogen measurement was limited to 10 000 pm due to calibration of the gas measurement unit. The hydrogen production exceeded 10 000 ppm for long periods during each run. It should be taken into account that this flow of volatiles was produced into a carrier gas flow which was not diminished in the calculations. Consequently, the levels of biohydrogen production could be considered as promising ones. (Hakalehto *et al*, 2016b)

In the beginning of the Polish testing period, heterogeneous composition of sorted biowaste was believed to disturb the process set up and control. However, this did not turn out to be a considerable problem. Instead, adding miscellaneous food waste to the process clearly boosted the production of various organic chemicals which reached a few percent of the total volume, and 15-20% of the dry weight. During these experiments the highest yields were not achieved or even tried to get achieved due to time limitations. In the future, efforts should be made to concentrating the feedstock into adequately high substrate concentrations. However, with more time and some technical upgrading of the pilot plant equipment, still much higher levels and productivities could be achieved with optimized processes. This is deducible also from the amount of unused substrate in the process residues. However, even by the current experimentation several industrial levels of biochemical productions were obtained. (Hakalehto *et al*, 2016b)

The analysis results from on-site Gas Chromatography (GC) and the Nuclear Magnetic Resonance (NMR) studies, the latter conducted by Prof. Reino Laatikainen, School of Pharmacy, University of Eastern Finland, produced somewhat different results. In some runs the levels were about 2-3 times higher in the former than the latter. This could be due to the storing of samples for the NMR in cold and transportation them to Finland, where they were analyzed much later on. It is then quite obvious that some changes could occur. Otherwise the NMR gave clear identification of the substances whereas the GC seemed to give some peaks close to each other which caused difficulties in the identification of the compounds. This was the case especially with 2,3-butanediol and valeric (pentanoic) acid. The latter was not expected to come out in the fermentation in large quantities but it was produced in high amounts. This organic acid was probably resulting from the condensation of acetic acid (two carbon molecule) and propionic acid (three carbon molecule). Both 2,3-butanediol and valeric acid could be valuable chemicals for producing butadiene (a raw material for plastics, synthetic rubber) and in cosmetic products (called also "2,3-butylene glycol"). (Hakalehto *et al*, 2016b)

Otherwise GC turned out to be a rather reliable method and it was successfully used in the pilot plant tests in Finland, Poland and Sweden. In all sampling and sample treatments it was important to separate the solids quickly enough for preventing any bacteriological activity caused degradation. The amount of products bound to the precipitating solid fraction could not be analyzed, so in future applications separation of the products in the liquid forms needs to be taken into consideration. In any case, the Polish testing period

indicated clearly the biorefinery concept's potential for producing soluble chemicals for industrial raw materials. Likewise it indicated the potential to produce hydrogen in these processes. In fact, the hydrogen production started quickly, and it was produced on remarkable levels even though this flow was integrated into the carrier gas. (Hakalehto *et al*, 2016b)

Two microbe species were applied in the Polish biorefinery process runs as additional inocula to the process broth, namely *Klebsiella mobilis* and *Escherichia coli*. These strains had been reported to metabolize glucose into organic acids, ethanol and 2,3-butanediol as a result of joint activities of their mixed cultures where a symbiotic relation between the strains developed (Hakalehto *et al*, 2008). The initial five runs were performed using potato waste as the single substrate. In these tests ethanol and acetic acids were main products. Among the gaseous products, hydrogen formation took place at elevated levels. Potato waste, however, seemed not to contain sufficient microelements to maintain generation of high level, longer chain products. It seems probable that the nitrogen and calcium levels could be limiting factors for the microbes. A significant improvement could be obtained when the kitchen biowaste were used as the initial raw material. With NMR analyses the presence of such substances as butyric acid, propionic and valeric acid at elevated levels were confirmed. Especially in the Polish Runs 7 and 8 high conversion rates to carboxylates, 0,75 and 0,81 mol/mol glucose respectively, to longer chain carboxylic acids were measured. Compared to C2–C4 carboxylic acids, longer chain carboxylic acids are superior in terms of energy content and hydrophobic nature, facilitating the downstream processing (Spirito *et al*, 2014). The results confirmed, that the biorefinery processes offer a clear advantage over conventional biowaste treatment technologies in terms of useful products which can be generated. (den Boer *et al*, 2016a)

3.3 Tests in Sweden

During the Swedish tests the pilot plant was located at a chicken farm Hagby Gård in Enköping. The farm produces roughly 800 chickens a week for slaughter (2014). The slaughterhouse, as well as their own store, is located in Västerås. (Hakalehto *et al*, 2016a; Schwede *et al*, 2017)

Finnoflag Oy led the Swedish tests which were organized by experts from Mälardalen University together with the Hagby Gård and also Savonia University of Applied Sciences. During the tests at Hagby farm, some 30% of chicken slaughterhouse waste was mixed with other biomass. The latter were chicken manure from the farm, some saw dust used as litter in the bird shelters, and occasionally some waste apples available at the farm. As additives were occasionally also used some potato flour, sugar or blueberry soup. Considerable problems emerged during the testing due to the pumps' inability to operate with the sticking feathers and the small stones originating from the bird digestion. The pumps got easily stuck with these miscellaneous particles or substances even though they had enough capacity for forwarding the biomass. Therefore, the final density and dry mass content was too low for higher product yields. However, the proof of concept was clearly demonstrated, and valuable products formed within the limits of the raw material offered. A tedious mixture of protein and lipid wastes was possible to convert first into yellowish milky broth were no particles were detected practically in overnight, and further to a solution of organic acids and alcohols. This could happen without significant loss in the dry weight of the soluble substances. (Hakalehto *et al*, 2016b)

The slaughterhouse located some 40km from the testing site so the chicken inner organs and other remaining parts were cooled for transportation. This cooling was probably not effective enough, which provided time for the mixed flora in the wastes to develop too far for the optimal substrate use in the biorefinery. In order to boost the biochemical production after the hygienization (in Hydrolyzer), strains of *Clostridium acetobutylicum* and *Clostridium butyricum* were inoculated. It is noteworthy that, even though they are generally considered as obligate anaerobes, these bacteria have been reported to withstand some oxygen occasionally. They also could stay active under 100% oxygen flow (Hell *et al*, 2010). This was used as a selective factor during the experimentation. Earlier it had been reported that the clostridial growth was boosted also by CO_2, which has been exploited for the rapid start of growth (Hakalehto, 2015; Hakalehto and Hänninen, 2012). In some runs, subsequent inoculations seemed to initiate the production of some chemicals which is implying to some quarum sensing type of signaling in the bacterial cultures. Also, addition of blueberry soup into some test runs clearly had a positive boosting effect which indicates the need for some trace elements and minerals for the best production levels. (Hakalehto *et al*, 2016b)

The expected products were short-chained organic acids, like acetate, propionate and butyrate that, if there had been more time for the test runs, could have been reduced to alcoholic and aliphatic substances. Other expected products were hydrogen and some 2,3-butanediol. Further, analysis by the NMR in Finland revealed some additional products such as valeric (pentanoic) acid and amyl alcohol. The latter was probably produced partially from the apple waste, but could get obtained also without the apples. Acetate and propionate derived from the bacteriological activity, can react with each other to form valeric acid, which also is a valuable product with a price 2-3 times of 2,3-

butanediol. (Hakalehto *et al*, 2016a; Hakalehto *et al*, 2016b)

The results show that products have been obtained both in the aerobic and anaerobic experiments. Production rates are higher when easily accessible carbohydrates and sugars are available. The highest levels of ethanol, acetic acid, propionic acid and 2,3-butanediol were obtained in the second test. Easy accessed carbohydrates in the added sugars and potato flour might explain this. Also the first run where sugar was also added showed somewhat higher product levels than later runs. (Hakalehto *et al*, 2016a)

Due to the glucose limitation of the raw material, *Klebsiella* was not effective for 2,3-butanediol production in this setting. Higher glucose levels could be facilitated by pump and mass transfer improvements, which could make it possible to gain industrial levels. Several organic acids were produced in high quantities. Improved pretreatments and elevated small carbon molecules would increase the yield also in their production.

During intensive bacteriological activity periods hydrogen production was rather high, which could give leads to development of biohydrogen production from the organic wastes, such as the animal or plant residues from the agriculture. (Hakalehto *et al*, 2016a)

Surprisingly, ABOWE tests in Sweden produced significant amounts of organic chemicals regardless of the low carbohydrate concentrations in the beginning of the experiments. This indicated the use of proteins and fats as substrates by the microbes. The microflora consisted of the natural microbiota and the added industrial strains which were managed to get function relatively well together. The yields and productivities could be increased by improvements to the process and to the equipment. (Hakalehto *et al*, 2016a; Schwede *et al*, 2017)

In an overall consideration, the Swedish testing period gave a proof of concept on a reasonable method to deal with tedious wastes from slaughterhouse and bird farm within a short time-window. This approach could serve as a significant model for the activities in many countries, where the chicken litter forms a considerable environmental problem. (Hakalehto *et al*, 2016b)

3.4 Technical Functioning of the Mobile Biorefinery Pilot Plant

During the project many challenges were faced in the designing and construction of the mobile pilot plant which would be both a real production process as well as a research laboratory. For instance, temperature and pH control for a process that is run by living organisms, brought along many questions to be solved.

The weighing of Homogenizer did not function well enough so the amount of solid matter could not be properly measured. Moreover water and other substances were added to the process from other ways than through measurements. This complicated the testing operations and the analysis thereof, as the amounts of raw materials were not always reliably known.

A lot of heat energy was needed for the hydrolysis and in the pilot plant the heating of hydrolysis functioned well. Using warm water, from a hot-water tank, as an energy source was a good solution. In an industrial scale production plant this should be recovered in cooling and used for treatment of new raw material. This means that for a viable treatment the process needs to be a continuous one and energy has to be transmitted with a heat exchanger always to new raw material. In this pilot plant this efficient energy consumption could not be implemented.

In the following figures, there are presented the measured temperature and pH values from Hydrolyzer and Bioreactor during a selected test run from all three countries. The time axis is the same in the figures of Hydrolyzer and Bioreactor.

In Figures 2 and 3 the temperature and pH measurement data from Hydrolyzer and Bioreactor during the final test run in Finland are presented.

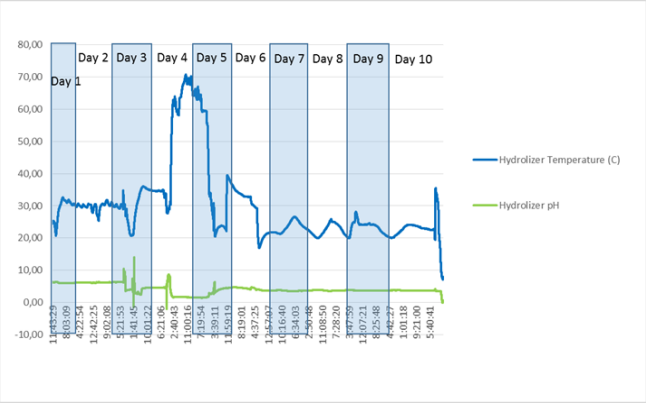

Figure 2. Hydrolyzer Temperature and pH during the Finnish Run 6 (24.3.2014 – 3.4.2014).

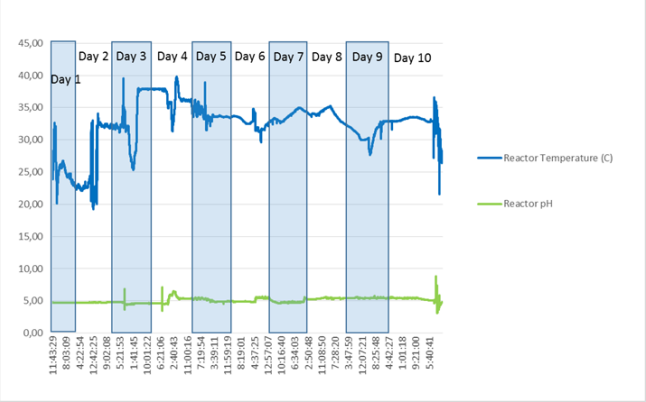

Figure 3. Bioreactor Temperature and pH during the Finnish Run 6 (24.3.2014 – 3.4.2014).

In Figures 4 and 5 the temperature and pH measurement data from Hydrolyzer and Bioreactor during Run 7 in Poland are presented.

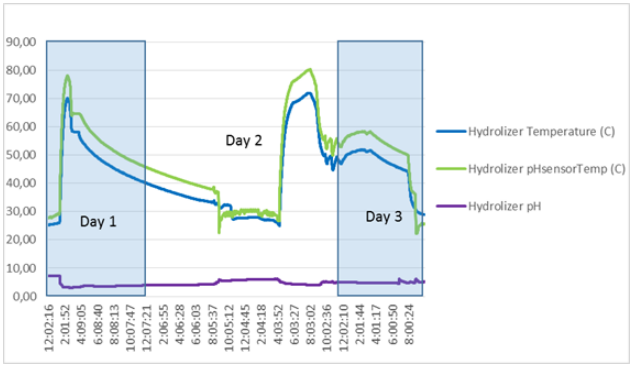

Figure 4. Hydrolyzer Temperature and pH during the Polish Run 7 (23.6.2014 – 25.6.2014).

In the Polish example, first the temperature of the Hydrolyzer had been risen up to 80°C for hygienization purposes and after that the substrate has been pumped to the Bioreactor in which the temperature had been kept as 35°C. In addition, Hydrolyzer heating had been started again, simultaneously with a bioprocess run in the Bioreactor (Day 2).

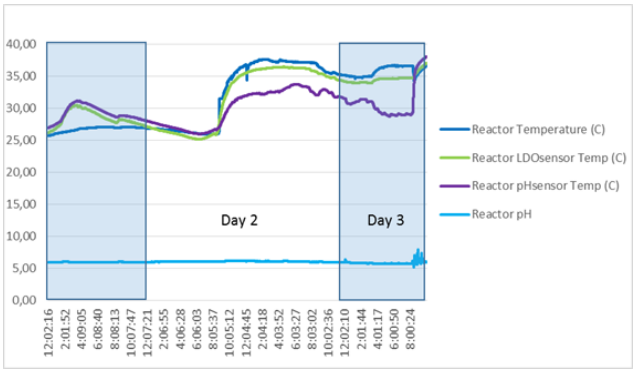

Figure 5. Bioreactor Temperature and pH during the Polish Run 7 (23.6.2014 – 25.6.2014).

In Figures 6 and 7 the temperature and pH measurement data from Hydrolyzer and Bioreactor during the final test run in Sweden are presented.

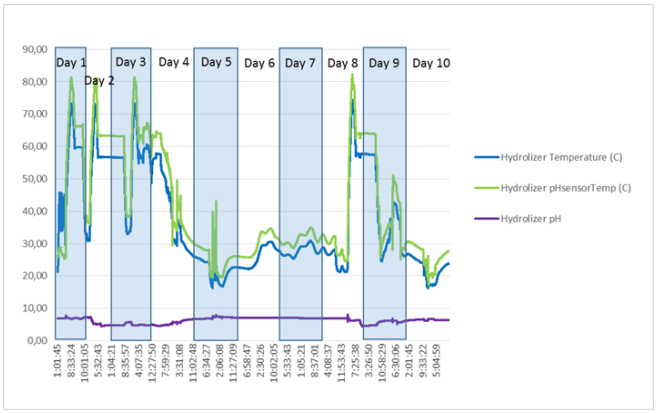

Figure 6. Hydrolyzer Temperature and pH during the Swedish Run 4 (22.9.2014 – 2.10.2014).

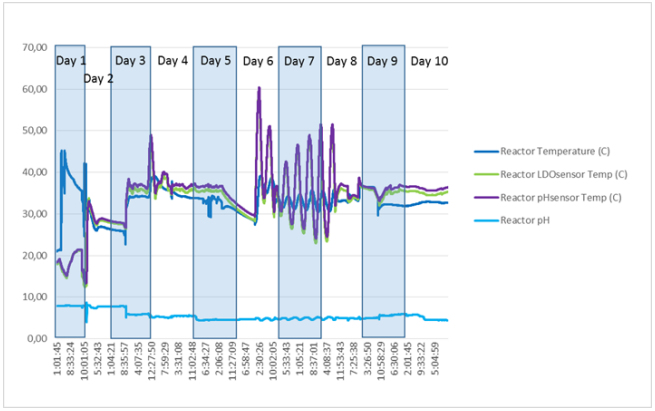

Figure 7. Bioreactor Temperature and pH during the Swedish Run 4 (22.9.2014 – 2.10.2014).

The Bioreactor was manufactured of stainless steel and for the temperature control it has a water jacket which reaches about half of the height of the Bioreactor. To the water jacket it is possible to introduce either hot water from the hot-water tank or cold water from the cooler. The objective was to gain a wide surface for the heating and cooling so that point-form high surface temperatures would not kill or hamper the bacterial strains. For the Bioreactor's temperature control these brought challenges as in principle a simple heating process changed into a process that includes two time constants. It can be concluded that the water jacket around the Bioreactor is unnecessary large, which caused too much delay for the temperature control. By speeding up the temperature measurement of exiting heating or cooling water it is possible to improve the cascading structure of the adjustment.

The Bioreactor's temperature sensor is located in the bottom where temperature cannot change very rapidly. Bioreactor mixing with airlift does not always reach the lower parts of the Bioreactor. Dissolved oxygen electrode and pH-electrode locate in the middle part of the Bioreactor and they both contain a temperature sensor. The temperature sensor of pH-electrode, however, is faster to react than the temperature sensor of

the dissolved oxygen electrode. pH-electrode has a considerably smaller mass and in addition, the tip of the electrode, in which the temperature sensor is locating, is narrow. Hence the values that these two temperature sensors are showing might differ from each other.

PH adjustment of the Bioreactor was known to be challenging and even more efforts should have been put to that control. However, pH has remained surprisingly stable. Temperature compensation of the pH electrode rectifies the change of the current from pH electrode that is due to temperature, but also the pH of a substance is changing as temperature changes and that change is not linear.

The emptying of the Bioreactor did not function well. Continuous recovery of products was not tried because the Stabilizer was not insulated and the risk of emitted H_2S from the process broth could not be handled.

4 Conclusions

A lot of challenges were faced in ABOWE because of the very tight time schedule for engineering and construction of the mobile biorefinery pilot plant. Besides, there were only two months available for test runs in each of the three countries. There came out some problems which probably were due to insufficient time to implement all planned settings before the test runs had to be started. Planned systems were not always put completely into operation because of their deficiencies or because there were not time for training. This led to situation where the major parts of the system were operated manually although automatic functions had been designed.

From the microbiology side, the combinations of the natural microbial flora with some added microbial strains should be further tested in future. It would be necessary to continue the experiments with the cellulosic waste in order to demonstrate the full potential of the biorefinery principle. It could then also be possible to combine the control with the activities of the natural flora into an overall bioprocess steering.

In ABOWE Polish tests pure cultures of microbes were used. However, volatile fatty acids (VFA) can be produced from various organic wastes also with mixed cultures under anaerobic conditions (Agler *et al*, 2011). According to Agler *et al.* (2011) and Spirito *et al.* (2014), undefined mixed cultures (or unrestricted microbiomes) offer a clear advantage over pure cultures because open microbiomes can, due to the metabolic flexibility, tolerate the complexity and variability of substrates. Moreover, sterilization and aeration can be eliminated in many cases since undefined mixed cultures can grow under non-aseptic conditions and often in anaerobiosis, too. (den Boer *et al*, 2016b)

More test runs would be needed for fully optimizing the effects of various parameters to further improve the yield of the biorefining. Gaining and maintaining the optimal conditions for bioprocesses is demanding as many raw materials and their concentrations or the products can affect even radically to the process and its velocity. From the adjustment technology point of view it is the question of a multi-parameter process and in addition the events are nonlinear.

It is possible to compile a mathematical model of the Bioreactor that can be simulated. The parameters have to be known as well as the interrelations between parameters. Based on measurement data, the Bioreactor operations could be modelled and transfer functions could be gained. Then various adjustment solutions should be simulated with a numerical computing program. For example, it would be possible, with logging data from automation system with regular intervals, to further model the temperature behavior of the Bioreactor such as temperature measurement and adjustment as well as to try cascade adjustment. To calculate heating and cooling power there should be, in addition to temperature measurement, also flow measurement in place. In measurements-based modelling, the adjustment should be done manually so that the effect of steering would be seen in the responses from the measurements reliably enough.

Implementation of degradative and recycling function of the Nature's microbiota into industrial applications is the leading principle in the Finnoflag Oy's biorefinery technology. This requires understanding of the interactions between the biomass (whose composition is subjected to variations), its natural flora, and the added strains and enzymes. The main purpose of the biorefinery pilot plant experiments was to give a reliable proof of concept on the industrially important substances producible in a sustainable way. This goal was achieved successfully, and several overall challenges were overcome during the testing in three countries. (Hakalehto *et al*, 2016b)

According to the analysis on the climatic impacts of the biotechnological processes, a combined production strategy including both 1. biorefining of chemicals from biomasses and 2. biogas process based on its residues could add value, if technologies were applied together with a cascading principle. This approach could also bring along an effective solution for eliminating the waste problems. In this case the biorefining and the preliminary hydrolysis should take place preferably in a consolidated bioprocess (CBP) where the waste macromolecules would be hydrolyzed simultaneously with the actual upstream process (Hakalehto, 2015). In case of the pilot plant the hydrolysis was partially going on also after the transfer of the pretreated substrate from the Hydrolyzer into the Bioreactor. Fast moving of the broth, from where the biochemicals were collected using the CBP principle, with a subsequent transfer of the biomass from the biorefinery into a biogas production unit, could optimally contribute in the

lowering of any climatic effect of the waste treatment. Then the biogas process could be boosted by the remaining organic acids in the solid fraction. Also the uplifted biochemical and gas production levels after optimization of the piloting and scale up trials would produce improvements in greenhouse gas reduction. (Hakalehto, 2015; Hakalehto *et al*, 2016b)

den Boer *et* al. (2016b) define some potential configurations of the biorefinery process in the waste management system and synergies of co-location with other waste handling plants. Scenario 1 is a biorefinery combined with a municipal incineration plant for residual waste. Separate collection and treatment of biowaste improves the calorific values of residual waste. Building biorefinery, as a central biowaste recycling plant next to an incineration plant would enable heat generated in the incineration to be utilized for heating up the biorefinery process. Scenario 2 co-locates a biorefinery with a biogas plant within one regional biowaste treatment plant. The biorefinery would add value in the pretreatment of separately collected biowaste by first processing high value commercial products from it. The residual biodegradable fraction of biorefinery process could be further fed to a biogas plant in order to produce energy. The benefit from combining the biorefinery and biogas plant is that the excess heat of the biogas plant could be used to heat up the biorefinery process. Scenario 3 considers locating biorefinery in combination with an industrial wastewater treatment plant. Biorefinery technology could be implemented at a range of food processing industries such as a potato chips and snacks factory. Nowadays, the large quantities of biowaste that the industry generates need to be transported to a remote biogas plant. The benefit would be to include the biorefinery process directly on-site, which saves in the transportation costs. The plant would also benefit from diversification of products they generate and options for new business. For the treatment of the residues of the biorefinery process, the optimal solution would be to utilize existing wastewater treatment plant. Food industry plants normally generate large amounts of wastewater which needs to be treated directly on-site. The most common method to treat wastewater sludges is wet digestion. Here, the co-digestion of wastewater sludges and residues from the biorefinery process would be the most beneficial solution. The heat generated in the digestion plant could be again utilized for the biorefinery process. Stabilized sludges from the wet digestion could be used as high quality fertilizer to close the natural cycle of nutrients. (den Boer *et al*, 2016b)

Acknowledgements

The ABOWE project was funded by the European Union (European Regional Development Fund). Construction of the mobile biorefinery pilot plant was co-funded by the Ministry of Employment and Economy in Finland and the Regional Council of Pohjois-Savo, Finland.

Modelling of Target-Controlled Infusion of Propofol for Depth-of-Anaesthesia Simulation in Matlab-Simulink

Gorazd Karer

Faculty of Electrical Engineering, University of Ljubljana, Slovenia, gorazd.karer@fe.uni-lj.si

Abstract

Total intravenous anaesthesia (TIVA) is an anaesthesiologic technique, where substances are injected intravenously. The anaesthesiologist adjusts the injection of intravenous anaesthetic agents regarding the depth of anaesthesia. In the paper, we present a model of an anaesthetic agent, namely propofol, influencing the depth of anaesthesia. The influence of propofol is linked to the concentration of the drug in the appropriate compartment. First, the modelling of pharmacokinetics of propofol is introduced. The 3-compartmental model and the effect-site model are presented, the relevant model parameters are given. Next, the model is verified by comparing the simulation results to the data file that was recorded by the Orchestra Base Primea infusion workstation during a medical procedure, which lasted about 40 minutes. The simulation results are presented and the predictive quality of the model is evaluated.

The presented model for Matlab-Simulink provides a basic tool for further researching the dynamics of anaesthetic depth. Despite the fact that more data must be obtained in order to properly validate the model, the presented model provides a basis for running simulations and testing various scenarios of propofol administration and is usable for developing and testing closed-loop control approaches for automatic control of depth of anaesthesia.

Keywords: target-controlled infusion, Propofol, depth-of-anaesthesia, Matlab-Simulink

1 Introduction

To perform a general anaesthesia, it is necessary to use substances, which enable deep unconsciousness, analgesia, amnesia and muscle relaxation, all required for performing a surgery or a diagnostic procedure. General anaesthesia and related dynamic activities in the human body is a complicated process, which includes pharmacokinetic and pharmacodynamic mechanisms, which have not been fully studied yet.

During the general anaesthesia, the anaesthesiologist needs to monitor the patient's vital functions and maintain the functions of vital organs. To achieve anaesthesia, substances are introduced in different manners into the patient's body. In clinical practice, the most commonly used methods are the intravenous induction of an anaesthetic agent, i.e., injection of the anaesthetic into a vein, and inhalation induction of anaesthesia, whereby the patient inhales the substance from the breathing mixture. Total intravenous anaesthesia (TIVA) is an anaesthesiologic technique, where substances are injected intravenously.

The anaesthesiologist needs to adjust the dosage of anaesthetic to maintain the appropriate depth of general anaesthesia according to pharmacokinetics and pharmacodynamics of the anaesthetic agent and considering the type of procedure. Inadequate depth of anaesthesia is manifested with the activation of sympathetic nerves or in the most unlikely event with the patient awakening. Too deep anaesthesia is manifested with a drop in blood pressure level and heart rate frequency as well as slow postoperative awakening of the patient from general anaesthesia. In modern clinical practice, the depth of anaesthesia is determined by assessing the relevant clinical signs (iris, sweating, movements), by interpreting hemodynamic measurements (Potočnik et al., 2011) and by estimating the depth of anaesthesia from EEG signals, for which several established measurement systems already exist, e.g. BIS index, Narcotrend, Scale Entropy and Response Entropy. BIS index measurement is a non-invasive method, where a BIS monitor is connected to electrodes on the patient's head. By measuring the EEG signals the bispectral index is defined, representing the depth of anaesthesia. The BIS monitor provides a single dimensionless number, which ranges from 0 (equivalent to EEG silence) to 100. A BIS value between 40 and 60 indicates an appropriate level for general anaesthesia, whereas for long-term sedation due to head injuries a value below 40 is appropriate. The reference can thus be set to the applicable value; the manner and speed of approaching the reference value depend on the specific characteristics of the procedure and the pharmacokinetics and pharmacodynamics of the substance in the patient's body.

The problem of modelling the effect of propofol is described in literature in various ways. For such purposes, pharmacokinetic and pharmacodynamic models have been developed, such as in (Marsh et al., 1991; Schnider et al., 1998, 1999; Kataria et al., 1994; Schüttler and Ihmsen, 2000; Kenny and White, 1990). The models typically define the basic structure of the dynamic operating system of propofol and the parameters depend on individual patients. The values of model's parameters are affected by the patient and his characteristics (weight, height, age, sex etc.) as well as individual sensitivity to propofol and the

ability to excrete propofol.

Several developed pharmacokinetic models are used in certain infusion pumps for target controlled infusion (TCI), where the pump sets the proper flow of the medication with regard to the model. The problem with these models is that they often do not reflect the real dynamics, which also depends on individual sensitivity of the patients to the substance, therefore such approaches, based on open-loop induction, often do not yield the best performance.

In the paper, we present a dynamical model of propofol influencing the depth of anaesthesia, which is connected to the concentration of the drug in the appropriate compartments. The paper is organized as follows. First, modelling of pharmacokinetics of propofol is introduced. The 3-compartmental model and the effect-site model are presented, the relevant model parameters are given. Next, the model is verified by comparing the simulation results to the data file of an actual anaesthetic application of target-controlled infusion of intravenously administered propofol, which was recorded by the Orchestra Base Primea infusion workstation during a medical procedure that lasted about 40 minutes. The simulation results are presented and the predictive quality of the model is evaluated. Finally, we give some concluding remarks.

2 Modelling the pharmacokinetics of propofol

2.1 The 3-compartmental model

The pharmacokinetics of the derived model is based on the Marsh model (Marsh et al., 1991). The dynamic relations are based on a well-established 3-compartmental model structure, as shown in Figure 1.

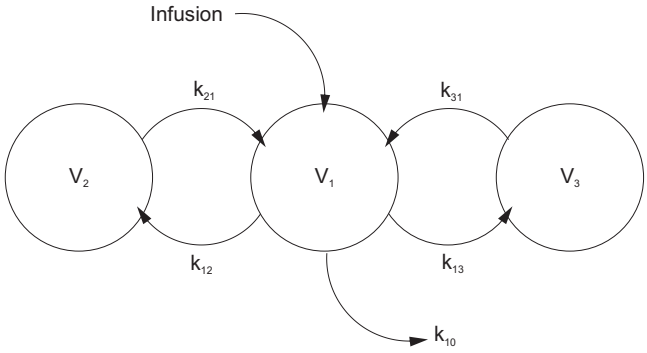

Figure 1. The pharmacokinetics of the 3-compartmental model.

The 3-compartmental model can be described as follows:

- The drug (namely *propofol*) is injected intravenously into the central compartment (V_1), representing the blood (or plasma) in the body - contained primarily in the arteries and veins and the directly influenced tissues and organs, such as brain, heart, liver, kidney etc.

- The second compartment (V_2) represents the group of tissues that are indirectly affected by the amount of drug in the central compartment, i.e., mainly the muscles. The exchange of the drug with the central compartment is denoted by k_{12} and k_{21}.

- The third compartment (V_3) represents the group of tissues that can store a certain amount of drug, but the exchange with the central compartment is rather slow, i.e., mainly the fat. However, the amount of drug in these tissues influences the amount of the drug in the central compartment in the long run. The exchange of the drug with the central compartment is denoted by k_{13} and k_{31}.

- The drug is eliminated from the body with a rate denoted by k_{10}.

The internal dynamics of the model can be formulated by using

$$\frac{dx_1}{dt} = \phi - k_{12}x_1 - k_{13}x_1 - k_{10}x_1 + k_{21}x_2 + k_{31}x_3 \quad (1)$$

$$\frac{dx_2}{dt} = -k_{21}x_2 + k_{12}x_1 \quad (2)$$

$$\frac{dx_3}{dt} = -k_{31}x_3 + k_{13}x_1 \quad (3)$$

where the variables x_1, x_2, and x_3 represent the amount of the drug in compartment V_1, V_2, and V_3. respectively. The infusion flow rate is denoted as ϕ. As noted above, the parameters k_{12}, k_{21}, k_{13}, and k_{31}, represent the partition coefficients that determine the speed at which the drug goes from one particular compartment to another. Finally, k_{10} is the rate of elimination of the drug from the body.

Note that the concentration in the central compartment is often referred to as plasmatic concentration.

2.2 Effect-site concentration model

The effect site for the drug propofol is basically the central nervous system. The effect site is thus part of the central compartment, but the effect of the drug is subject to some dynamics with regard to the (theoretical) concentration in the central compartment. This is mainly due to transportation delay as the drug concentration in the central compartment is not homogenous, which is evident especially during the transient response, i.e., when the amount of the drug in the central compartment is changing rapidly. The effect-site concentration is therefore a representation of a volumeless 4th compartment, where the drug is active. This compartment is virtually linked to the central compartment.

Therefore, a 1st order model has been used to describe the effect-site concentration dynamics, as given in

$$\frac{dx_e}{dt} = -k_{e0}x_e + k_{e0}x_1 \quad (4)$$

where the virtual link between the central and the effect-site compartment is characterised by the coefficient k_{e0}, which is actually the inverse time constant of the dynamic system describing the connection between the plasmatic concentration and the effect-site concentration x_{e0}.

The schematics explaining the effect-site concentration dynamics are presented in in Figure 2.

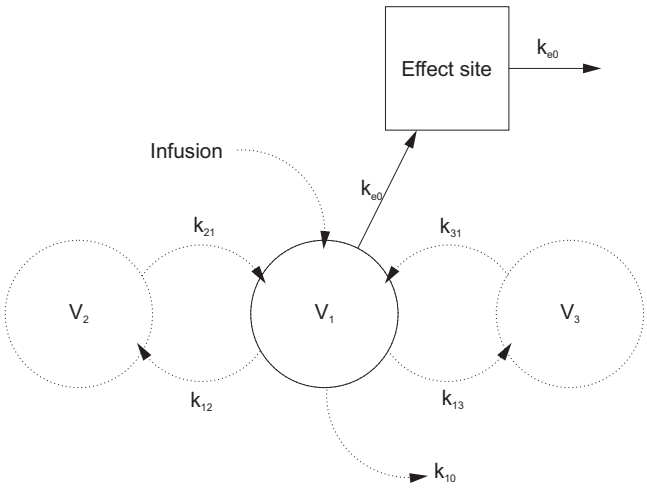

Figure 2. The effect-site concentration dynamics.

2.3 Model parameters

The parameters of the model are taken from (Marsh et al., 1991) and (Orc). The values are given in Table 1.

Table 1. Parameter values.

Parameter	Value
V_c	0.228 l/kg
k_{10}	0.119/min
k_{12}	0.112/min
k_{13}	0.0419/min
k_{21}	0.055/min
k_{31}	0.0033/min
k_{e0}	1.21/min

When developing the model in Matlab-Simulink we have to consider the units and the dilution factors of the drug. For example, the parameters expressed in min^{-1} have to be converted to s^{-1}. Furthermore, the input flow of propofol is typically expressed in ml/h, and the dilution is $10mg/ml$, i.e., 1%. The output concentration (plasmatic and effect-site) are expressed in $\mu g/ml$.

3 Model verification

The Marsh model is also used in the infusion workstation *Orchestra Base Primea* (produced by *Fresenius Kabi*) (Orc). We obtained a textual output data file of an actual anaesthetic application of target-controlled infusion of intravenously administered propofol, which was recorded by the Orchestra Base Primea infusion workstation during a medical procedure that lasted about 40 minutes. The data recorded in the output file are as follows:

- The infusion flow of propofol.
- The predicted plasmatic concentration of propofol c_p.
- The predicted effect-site concentration of propofol c_e.
- Important events (alarms, occlusions, syringe changes, target-value changes).
- Patient data:
  - age (43 years),
  - weight (78 kg),
  - height (177 cm), and
  - gender (male).

A Matlab-based parser was developed, which is able to processes the textual output data files recorded by the Orchestra Base Primea infusion workstation so as to obtain suitably formatted time-stamped data arrays. In such a manner, the obtained data arrays can easily be used in the Matlab-Simulink environment.

4 Simulation results

4.1 Propofol inflow

We used the presented model for simulating the system behaviour with regard to the response to the inflow of propofol influencing the depth of anaesthesia through plasmatic concentration and effect-site concentration of propofol. The simulated inflow of propofol was adjusted according to the data recorded by the Orchestra Base Primea infusion workstation.

The inflow-signal of propofol $\phi_{propofol}$ was parsed from the recorded data and is shown in Figure 3.

Note that first a bolus-dose is administered so as to rapidly increase the concentration of propofol in the body. This phase is called the induction of anaesthesia and results in the patient losing consciousness. Later, a suitable dose of propofol is continuously administered in order to keep the proper anaesthetic depth. A close-up of the second transient phase is shown in Figure 4.

The presented Matlab-Simulink model was fed the propofol-inflow signal $\phi_{propofol}$ and the resulting trajectories of propofol concentration in the central compartment and in the effect-site compartment (c_p and c_e, respectively) were compared to the data recorded by the Orchestra Base Primea infusion workstation.

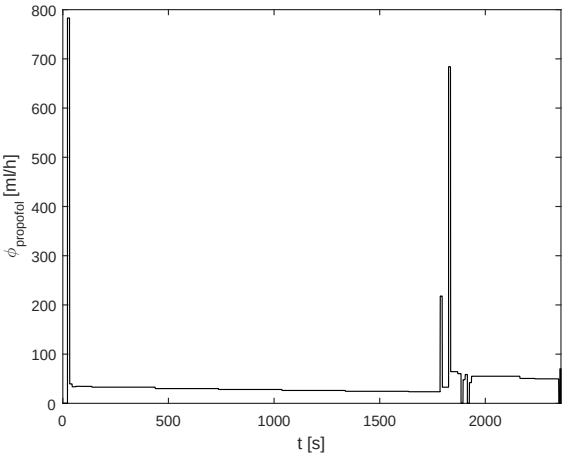

Figure 3. The inflow of propofol $\phi_{propofol}$.

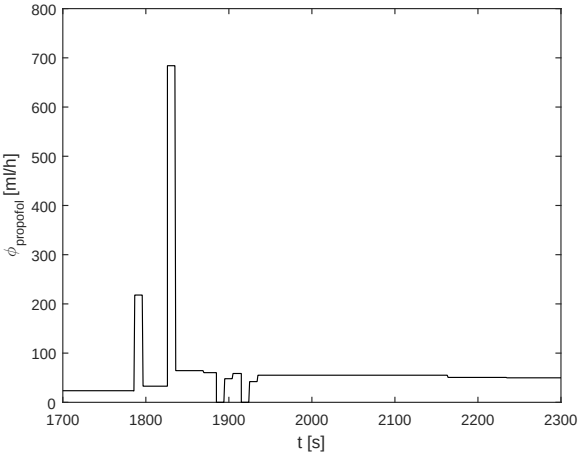

Figure 4. The inflow of propofol $\phi_{propofol}$ (close-up).

4.2 Plasmatic concentration

The simulated plasmatic concentration of propofol $c_{p,sim}$ trajectory is shown in Figure 5. The simulated results are compared to the parsed data from the Orchestra Base Primea infusion workstation data file $c_{p,data}$. A close-up of the second transient phase is shown in Figure 6.

4.3 Effect-site concentration

Similarly, the simulated effect-site concentration of propofol $c_{e,sim}$ trajectory is shown in Figure 7. The simulated results are compared to the parsed data from the Orchestra Base Primea infusion workstation data file $c_{e,data}$. A close-up of the second transient phase is shown in Figure 8.

4.4 Evaluation of the predictive quality of the model

In order to evaluate the predictive quality of the model, the simulated results are compared to the parsed data from the Orchestra Base Primea infusion workstation data file. Some established quantitative measures for predictive

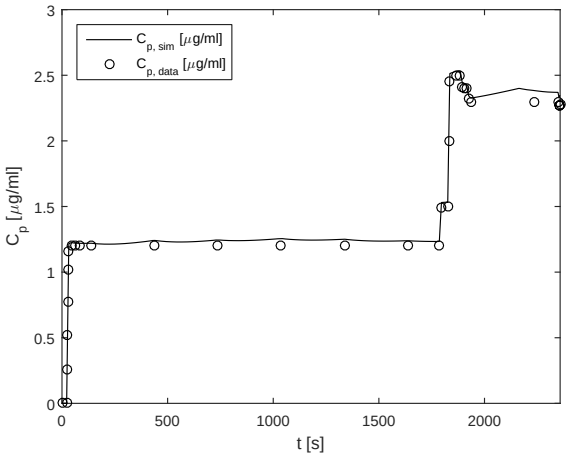

Figure 5. The simulated plasmatic concentration of propofol $c_{p,sim}$ compared to the parsed data $c_{p,data}$.

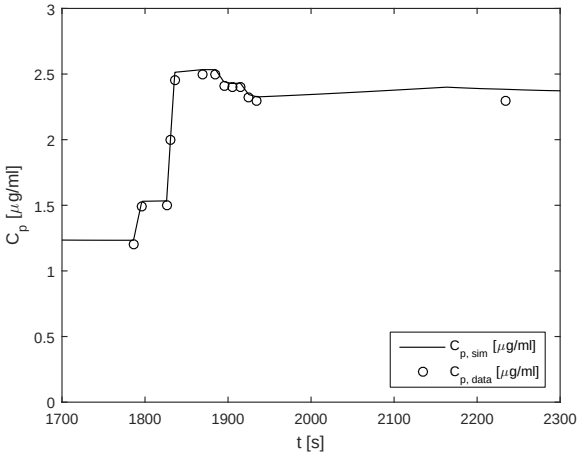

Figure 6. The simulated plasmatic concentration of propofol $c_{p,sim}$ compared to the parsed data $c_{p,data}$ (close-up).

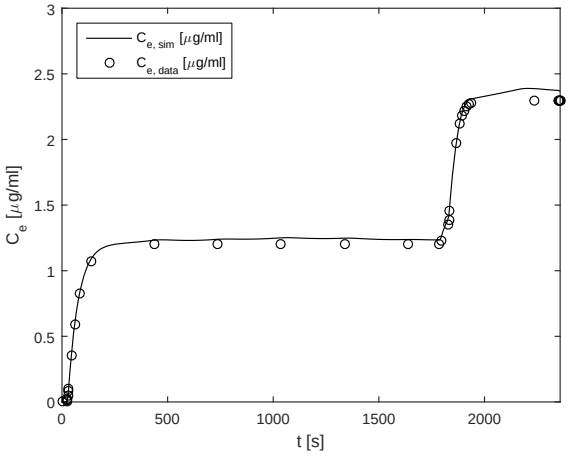

Figure 7. The simulated effect-site concentration of propofol $c_{e,sim}$ compared to the parsed data $c_{e,data}$.

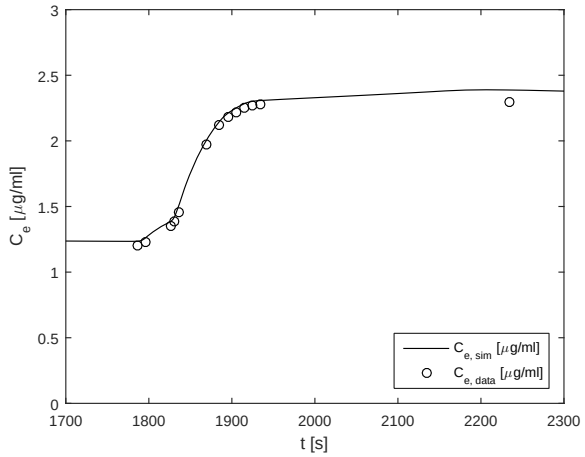

Figure 8. The simulated effect-site concentration of propofol $c_{e,sim}$ compared to the parsed data $c_{e,data}$ (close-up).

quality are *prediction mean square error* (PMSE), *median performance error* (MDPE), and *median absolute performance error* (MDAPE) (Mertens et al., 2003). The aforementioned measures are calculated as defined in

$$PMSE_x = \frac{1}{N}\sum_{i=1}^{N}(x_{i,sim} - x_{i,data})^2 \quad (5)$$

$$MDPE_x = median\{\frac{x_{i,data} - x_{i,sim}}{x_{i,sim}} \cdot 100\%\}_{i=1,\ldots,N} \quad (6)$$

$$MDAPE_x = median\{|\frac{x_{i,data} - x_{i,sim}}{x_{i,sim}}| \cdot 100\%\}_{i=1,\ldots,N} \quad (7)$$

where x_{sim} and x_{data} stand for the simulated and the "measured" data, respectively, and N is the number of data points in the data set.

In our case, the values of the aforementioned measures are presented in Table 2.

Table 2. Predictive quality measures.

Signal x	$PMSE_x$	$MDPE_x$	$MDAPE_x$
C_p	$2.21 \cdot 10^{-3}$	-1.67%	2.00%
C_e	$1.62 \cdot 10^{-3}$	-2.35%	2.78%

As the Orchestra Base Primea infusion workstation suffers from some error when logging the propofol-flow data $\phi_{propofol}$, it is sensible to take into account the final cumulative amount of the administered drug. In this case, the total amount of propofol used was 25.5 ml, whereas the simulated consumption was 26.2 ml. It is clear that the simulated propofol concentration signals, both plasmatic and effect-site, are influenced considerably by the aforementioned error.

In general, the propofol-flow $\phi_{propofol}$ error is generally not uniformly distributed. Nevertheless, the simulation results can be improved by simply pondering the simulated propofol inflow by a factor of $\frac{25.5ml}{26.2ml}$. The newly simulated results are again compared to the parsed data from the Orchestra Base Primea infusion workstation data file in Figures 9 and 10 for plasmatic and effect-site concentration trajectories, respectively.

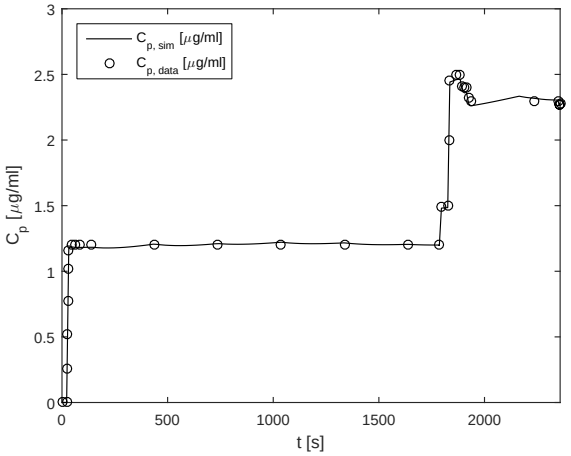

Figure 9. The newly simulated plasmatic concentration of propofol $c_{p,sim}$ compared to the parsed data $c_{p,data}$.

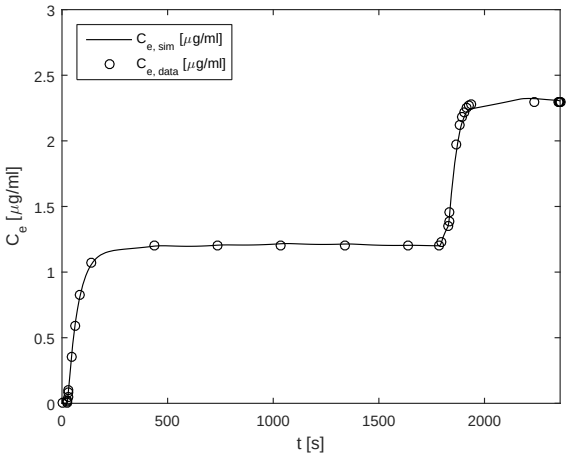

Figure 10. The newly simulated effect-site concentration of propofol $c_{e,sim}$ compared to the parsed data $c_{e,data}$.

In this manner, the predictive quality measures are improved by a considerable amount, as shown in Table 3.

Table 3. Predictive quality measures (modified).

Signal x	$PMSE_x$	$MDPE_x$	$MDAPE_x$
C_p	$0.65 \cdot 10^{-3}$	1.16%	1.38%
C_e	$0.32 \cdot 10^{-3}$	0.324%	1.14%

5 Conclusions

The developed model for Matlab-Simulink provides a basic tool for further researching the dynamics of depth of

anaesthesia. The model enables improvement and refinement of model quality for propofol for assessment of the dynamic properties of anaesthetic depth. However, more data must be obtained in order to properly validate the model. We will work with the anaesthesiologic team of the University clinical centre in Ljubljana in order to reach this goal. In addition, the measured data from real medical procedures will enable further refinement of the model parameters and possibly a structural improvement of the considered dynamical relations.

That said, the presented model provides a basis for running simulations and testing various scenarios of propofol administration that could lead to better administration protocols due to a deeper insight of the mechanisms of depth of anaesthesia.

Finally, the model is usable for developing and testing closed-loop control approaches for automatic control of anaesthetic depth, which will be the main direction of our joint future research in collaboration with the anaesthesiologic team of the University clinical centre in Ljubljana.

Development of a Genetic Algorithms Optimization Algorithm for a Nutritional Guidance Application

Petri Heinonen[1] Esko K. Juuso[2]

[1]Nutri-Flow Oy, Finland, petri.heinonen@nutri-flow.fi
[2]Control Engineering, Faculty of Technology, University of Oulu, Finland, esko.juuso@oulu.fi

Abstract

Personalized easy to follow nutritional guidance is getting more important, since lifestyle related health problems are increasing. To gain a healthy balanced diet usually requires knowledge of a licensed nutritionist. There is a Fuzzy Expert System (FES) which applies knowledge of nutritionists, health data of an individual, personalized nutritional recommendation, and a meal diary with food composition data to balance a diet. FES generates a set of foods and beverages which should be altered in the diet with information on the direction and importance of the change. This paper presents a selection and a development of an optimization algorithm to be integrated with FES to provide easy to follow nutritional guidance. The selection process is carried out as a literature review. The development of selected Genetic Algorithms (GA) is carried out as an integrated part of Nutritional Guidance application, Nutri-Flow®, since FES generates the search space, and is an important part of a Fitness Function of the optimization algorithm. The selection of the design parameters, are described and the test results are presented. Validation of the overall model is carried out with an expert analysis and comparison of the nutrient intake from the initial diet and recommended diet.

Keywords: genetic algorithms, optimization, nutritional guidance

1 Introduction

Personal dietary guidance is an important tool for achieving global and national targets of the battle on non-communicable diseases caused by lifestyle habits on diet and physical exercise (Heinonen, 2009). Micronutrient malnutrition due to eating habits is getting common while non-nutrient dense energy rich foods are getting common in diets (IFPRI, 2016).

The Internet is filled with calorie calculators and other similar applications which calculates energy and nutrient intake levels according to a meal diary. Average consumers cannot balance their diets by knowing which micronutrients should be added to balance the diet. Traditionally, a licensed nutritionist is needed to convert the nutrient level information into foodstuff level information as a meal plan. (Heinonen, 2009)

Nutri-Flow® Software gives personalized dietary guidance on the foodstuff level as foods and beverages by applying a national food composition database, national nutritional recommendations with personal health data and eating habits. Fuzzy logic handles the uncertainty and imprecise values, and the mapping from the nutrient level to foodstuff level is carried out with Fuzzy Expert System (FES), which contains licensed nutritionists' knowledge in a rule base. (Heinonen et al., 2009)

Optimization in Nutri-Flow® Software is needed to find a level of change for a set of foodstuffs to reach a more balanced diet. A type of an optimization problem usually defines which optimization methods are applicable within the problem domain. (Heinonen, 2009)

Direct search is one approach to solve optimization problems which have non-differentiable or discontinuous objective functions. Most traditional optimization methods require gradient or higher derivatives from the objective function to work properly. (Kolda et al., 2003)

Heuristic search is a set of optimization methods with rules to guide the optimization process towards to the global optimum. Genetic Algorithms (GAs) belongs to the heuristic search group. The theory was invented in 1975 and GA implements the concept from Darwinian principle of natural selection (Darwin, 1859). The terminology in GA is closely adapted from natural genetics (Holland, 1975). A solution is called a chromosome, which has locus bind variables. The solution can be coded in a binary form, but with many real world problems high precision makes chromosomes very long, and it gets inefficient. (Davis, 1991)

A set of solutions or a population is put in a competitive environment where each chromosome has a fitness value evaluated by an objective function (Holland, 1975), (DeJong, 1993). In every iteration round, GA operators are applied to the population. A crossover operator combines genetic materials of selected chromosomes creating a new population. Mutation operation makes random variation in the population to prevent the optimization process from stopping at local minimums. (Holland, 1975) Since the theory was published, several GA operators have been

developed with variations according to the current optimization problem (Goldberg, 1989a)

This paper presents the GA optimization model developed for the Nutri-Flow® Software.

2 Selecting an Optimization Method

The type of optimization problem is the key to selecting an optimization method. In this study, the optimization problem has a large amount of variables and there are several solutions which are almost equally good.

To form a mathematical function in this problem domain is challenging and time consuming. It is possible to calculate gradients at certain points, however the system is not continuous due to its nature. Based on this, traditional optimization methods are not selected for testing.

Direct search can be used with an optimization problem domain where is no gradient or higher derivative available. It works also with non-continuous problem space. (Kolda et al., 2003) In the optimization problem of this study, it might be possible to use direct search to find a single solution. This needs further testing.

A real-coded GA has solutions available as a set of comparable solutions. After evolving a population - the set of solutions - the set of the best options is available in the solution domain already without a mapping function. (Man et al., 1999)

The stochastic nature of GA with crossover, mutation, and elitism operators the optimization process is not easily stopped at local minimums. It is argued that real-coded GA does not always reach the best result. However, the real-coded GA is widely used with real word optimization problems. One example of this is represented in (Le and Kim, 2011).

There are also other Evolutionary Programming algorithms, e.g. differential evolution, which could be used in the optimization problem domain of this study.

3 Genetic Algorithms

Genetic algorithms are based on processing of a population of coded solution alternatives.

3.1 Chromosome Coding

A chromosome in GA represents a possible solution for the optimization problem. The size of search domain and accuracy level of result are used when evaluating if the coding should be done in the binary or real-value domain. (Goldberg, 1989a)

Real-value coding is used widely with practical real world optimization where the search domain is usually large and required high accuracy, where the binary coding would be inefficient with extremely long chromosomes. The solution domain is applied in real-value coding thus no result mapping is needed. It has been argued that the real-value coding does not always yield good results. (Man et al., 1999)

3.2 Population

A population is a term for a set of chromosomes. The best solution should be found by evolving the population by applying GA operators. In this process, the size of the population has an effect on convergence speed and reaching the global optimum. The population size can be fixed or it can vary throughout the optimization process. (Goldberg, 1989b)

Too small a population does not have enough diversity to evolve towards the global optimum. Longer the chromosome, bigger the population should be. (Goldberg, 1989b) When the population size is too big, the evolving needs more iteration rounds to reach the best solution. This affects the computing time with a slow convergence rate. (Affenzeller et al., 2007) There are statistical methods for generating the initial population, however it is usually generated randomly (Reeves and Rowe, 2002).

3.3 Crossover

Crossover operators evolve population towards better solutions by distributing good genetic matter between generations. Crossover starts with selecting parents by using a selection method, usually by the roulette wheel selection method (Sorsa et al., 2008) or by the tournament selection method (Goldberg, 1990).

Good genetic material is found into mating pool by selection methods since probability for selecting the fittest parents from the population is higher than for the worse ones. This is the basis how better solutions are found on every iteration round. (Sorsa et al., 2008)

The tournament selection method is based on randomly selected chromosomes from the population, and the chromosome with the best fitness value is selected. The tournament size k defines how many chromosomes will be selected from the population. Typically, value for it is 2. (Goldberg, 1990)

After a mating population is formed by a selection method, a crossover operator is applied. A design parameter for the crossover operator is crossover probability p_c, which determines if the current parent chromosomes are combined with the crossover operator or if they are moved directly to the offspring population. (Man et al., 1999)

With real-value coded chromosomes, uniform and non-uniform crossover operators can be applied. Where uniform operators act in the similar way in every generation, and non-uniform operators work depending on the age of the population. Two offspring from two parents are formed by an arithmetic operator as follows:

$$y_i^1 = \alpha_i x_i^1 + (1-\alpha_i) x_i^2, \quad (1)$$

$$y_i^1 = \alpha_i x_i^2 + (1-\alpha_i)x_i^1,$$

where α_i are uniform random numbers. α can vary in non-uniform crossovers, and is constant in uniform crossovers. (Sorsa et al., 2008). New crossover operators are developed actively (Gegúndez et al., 2007).

3.4 Mutation

Mutation is a GA operator which creates a random variation in the population. It maintains the population diversity by generating new genetic material. With correct design parameters, mutation prevents GA from stopping at local minimums. (Sorsa et al., 2008)

Uniform and non-uniform mutation operators can be used with real-coded chromosomes. The uniform mutation operator can be applied for each gene in a chromosome using the same mutation probability where initial population is $x_i^t = \langle v_1, \ldots, v_n \rangle$, after a mutation operation with 1≤n it becomes $x_m^t = \langle v_1, \ldots, v'_k, \ldots, v_n \rangle$. The random value for v'k is in a feasible range for the locus k. (Michalewicz, 1996)

One of the most commonly used non-uniform mutation operator is the Michalewicz's non-uniform mutation (Michalewicz, 1996), where the mutated element v'k is calculated by

$$v'_k = \begin{cases} v_k + \Delta(t, u_k - v_k), \text{if a random digit is 0} \\ v_k + \Delta(t, v_k - l_k), \text{if a random digit is 1} \end{cases}, \quad (2)$$

where

$$\Delta(t, y) = y\left(1 - r^{\left(1-\frac{t}{T}\right)^b}\right). \quad (3)$$

Mutation probability p_m controls the mutation operations. When using too big values for pm, good genetic material can be lost and the convergence rate slows down. With very low values, there is little or no effect on the population.

3.5 Elitism

When altering the genetic pool of a population with GA operators, there is a possibility to lose the best solution of an iteration round. The elitism operator is designed to save the best chromosome and transfer it to the next generation. This is done usually by replacing the worst chromosome from the new population with the best chromosome from previous population. (Man et al., 1999)

4 Genetic Algorithms in Domain of Dietary Optimization

In this study, the GA optimization is an interconnected module in Nutri-Flow® Software as represented in Figure 1. Nutri-Flow® Software has a database where personal dietary habits and personal health data are stored when filled in. A nutritional state of a diet is assessed and the guidance is mapped to foodstuff level, e.g. as foods and beverages. (Heinonen et al., 2009)

FES has two hierarchical levels representing main and sub-groups in the classification of foodstuffs in Nutri-Flow® Software database. The input consists of 30 nutrient variables and the output of FES has 129 variables, including 87 sub-groups of foodstuff classification and 42 foodstuff variables. The rule base in FES has 590 rules on the first hierarchical level, and 400 rules on the second level. (Heinonen, 2009) The expertise is introduced with the rules. Development of FES is presented more detailed in (Heinonen, 2009; Heinonen et al., 2009).

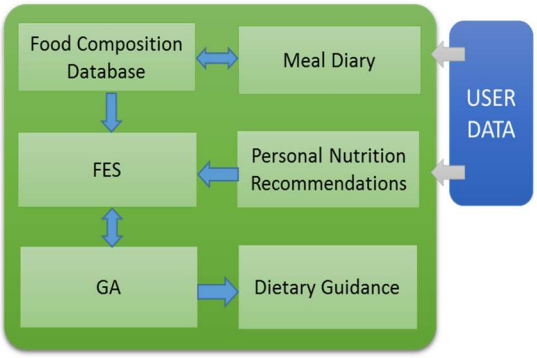

Figure 1. Schematic model of Nutri-Flow® software (Heinonen, 2009).

The output of FES is used to form a search space for GA. An initial population is generated randomly using the search space. A gene in a chromosome represents a foodstuff with recommended daily intake level. A chromosome represents a dietary recommendation in foods and beverages with their recommended daily intake levels.

An objective function is formed to analyze the fitness of the chromosomes. The recommendation takes into account also personal taste and allergies with the nutritional status.

A diagram of the GA optimization process is presented in Figure 2. Because the initial population is a random set, it is recommended to run GA optimization several times with a new initial population. GA in the Nutri-Flow® software is set to run 10 re-runs with a new initial population each time. All the best solutions of the last population of each GA re-run are stored, and the best of the best is used to form the dietary guidance. The selection of GA re-runs and other GA design parameters are described later on this paper.

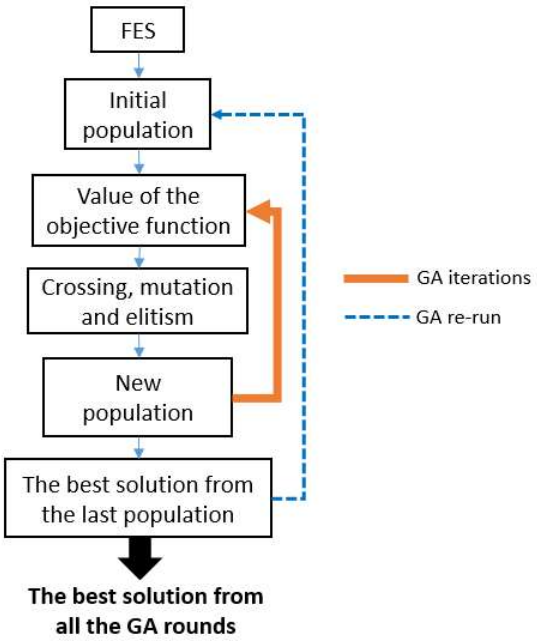

Figure 2. The GA Optimization process.

5 Developed Model

5.1 Search Space

The search space is formed according to the output of FES. The output stores the information about the foods to be added or reduced with the importance of the change. There are three different sets of foodstuffs in the output: "reduce", "no change" and "add".

There is a need to assess feasible ranges of daily intake levels for the foods, because the initial population is generated randomly within the given intake range for each food. The intake range for foods to be reduced is formed as [0, *i*], where *i* is the initial intake level. The foods, which have no need to be changed, will be kept at the original intake level, *i*. Foods to be added have a range with [*i, m*], where *m* represents a recommended maximum intake level, defined by licensed nutritionists. If no preset for maximum intake is present, the maximum value is evaluated from the initial intake level.

The search space has an effect on performance and calculation time of Nutri-Flow® software. If the initial population is biased due to infeasible range of intake levels of foods, is the convergence of the fitness value slow, and the global optimum might never be reached.

5.2 Objective Function

In this study, the objective is to minimize the fitness value. The objective function uses FES to determine the nutritional status of a solution. FES fuzzifies the nutrient and gives membership grades for each fuzzy membership function. The goal is to minimize "too little" and "too much" membership grades μ. The FES membership functions are represented in Figure 3.

Personal nutritional recommendations for 30 nutrients are used to tune the membership functions, data points A, B and C presented in Figure 3. The data points A, B and C represent Lower Intake level (LI), Recommended Intake level (RI), and Upper Intake level (UL), respectively (Heinonen, 2009).

There is no need to use normalizing function for each nutrient input levels since membership grades are already normalized to [0,1].

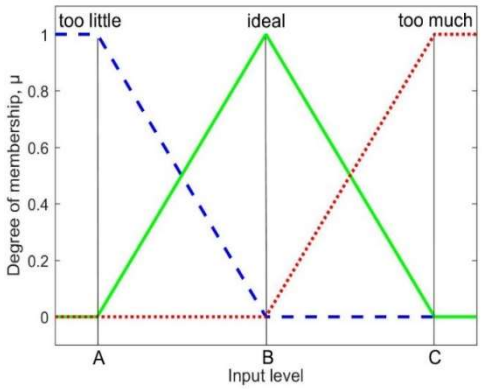

Figure 3. FES Input Membership Functions (Heinonen, 2009).

There are also other objectives to be minimized which are represented in the objective function as follows:

$$MIN(a\sum_{1}^{n}(l_n\mu_{l,n}+u_n\mu_{u,n})+b\sum_{1}^{m}|d_m|+c\sum_{1}^{p}k_p), \quad (4)$$

where a is weighting coefficient for nutrition status
l_n is weighting coefficient for importance of nutrient n at "too little" condition,
$\mu_{l,n}$ is membership grade for "too little" membership function for nutrient n,
u_n is weighting coefficient for importance of nutrient n at "too much" condition,
$\mu_{u,n}$ is membership grade for "too much" membership function for nutrient n,
b is weighting coefficient for level of change
d_m is distance from current diet for foodstuff m
c is weighting coefficient for importance level of other variables
k_p is other diet related variables.

The first term represents the difference between the recommended nutrient intake level and the current intake level in the fuzzy domain. According to licensed nutritionists, some nutrients are more important in keeping close to the recommendation level than others. The weighting factors l_n and u_n are used to emphasize the importance of the nutrient according to intake level. The weighting factors are tuned by licensed nutritionists. In this study, 30 nutrients are taken into account when assessing the individual nutritional state.

Smaller steps are usually easier to follow when changing eating habits. The second term is a measure how much a chromosome would change the initial diet.

It measures an amount of foodstuffs to be changed and the magnitude of the change. The weighting factor b is used to tune the level of change, and can be altered by a user through the user interface. If the value is set to 0, the magnitude of change is not taken into account.

The third term contains other measurable variables needed in dietary guidance, such as vegetable intake level and energy intake level. Other non-nutritional variables can be used too when these are used to fine-tune the recommendation. These should not have an advert effect on the nutritional status of the diet.

5.3 Coding

It was found out already in (Heinonen, 2009) that binary coding is not a good option to perform GA in this problem and solution domain, therefore the real-valued coding was selected. With real-valued coding, a gene stores a name of a foodstuff with a daily intake level: "a slice of rye bread", "20 g". The length of a chromosome depends on the variation of food beverage items in the meal diary during the period to be evaluated, therefore the length of the chromosomes is not fixed.

According to licensed nutritionists, with a recommended three to seven day period of meal tracking, there are average 20 different food items. Similar foods are combined when assessing daily intake levels. To confirm this, there is a need to do statistical evaluation on the meal diary database.

5.4 Population Size

While the chromosome size is not constant, the population size can vary throughout the different optimization run. In this study, the population size is kept constant at 100.

Population size has a strong effect on computing time when the size is too big as shown in (Heinonen, 2009). The effect on varying population size can be monitored through computing time, convergence rate, and the final result.

5.5 Crossover

Arithmetic crossover and tournament selection are used in this study. The design parameters for tournament selection are crossover probability p_c and tournament population size p_s. The selected arithmetic crossover is uniform.

Different values for p_c and p_s are tested while other GA design parameters kept fixed. The performance of the overall system is monitored via test parameters such as the convergence rate of the best and average solution, and fitness of the best solution.

5.6 Mutation and Elitism

The mutation and elitism operators are applied in this study to prevent the optimization process from stopping any local minimum. Elitism is used to prevent of loss the best solution during evolving the population.

Mutation probability m_p is evaluated with different value ranges while other parameters kept fixed. The overall system is monitored with the same parameters as crossover, the convergence rate of the best and average solution, and the fitness of the best solution.

Elitism is set to keep the best solution of the current population and replace the worst solution from the offspring population. In this study, the elitism operator replaces only one chromosome in the offspring population.

5.7 Additional Parameters

Each diet and goal are different when assessing personal dietary guidance. There is no way to set a global fitness value when the optimization process should be exited. The guidance should be able to follow without too drastic changes in the diet. Therefore, there are additional parameters in the objective function to make the guidance easier to follow.

There should be a certain exit point for the optimization process, which is executed using a counter for iterations. Too small a value for the counter would stop the optimization process too early with a poor result, and a too large number would just waste computing time. The optimum value for iterations can be found when the main design parameters are tuned first. The optimization process can be stopped when the best possible solution is not changing with a certain amount of iterations, but the average fitness value still evolves. In this study, the exit point for iterations is a fixed number, but in the future, the algorithm could analyze the convergence speed of the best solution vs. average solution and stop it when evolving for the best solution is not detected.

The initial population of GA is random. There is a possibility that the solution set has very bad fitness values or has too low a variation between the solutions. This could prevent GA to find the global optimum and cause a stop at a local minimum. This can be prevented to re-run GA with new initial population as presented in Figure 2. The rate of GA re-run should be set high enough. This multiplies the amount of iterations, thus has a direct effect on the computing time. A fixed value for the re-run rate is used in Nutri-Flow® software. The testing of the effect of rate on the re-runs requires a big set of meal diaries, hence it will be done later.

5.8 Java Genetic Algorithm Package

Nutri-Flow® software is currently written in Java and it applies JGAP – Java Genetic Algorithm Package library which provides the GA operators with all necessary design parameters.

Validating Nutri-Flow® software is done with data sets run in Nutri-Flow®, and in Matlab® model. The Nutri-Flow® software is working correctly if the same input generates the same output. GA needs a special focus, since optimization results with one input could

create several different outputs. Generally, there are several different ways to alter initial diet to achieve a certain balanced diet. Validation of GA module requires a large set of test runs with the statistical and nutritional analysis of the result set.

5.9 Data Acquisition

To keep the results comparable throughout the development work of Nutri-Flow® software, there is a set of individuals and data of their dietary habits. The test data represents different average dietary habits from fast food diet to vegan diet. The set of individuals contains male and female persons with different health profiles from athlete to pregnant women, and slim to fat inactive persons.

The used test data is suitable for testing GA optimization performance on the current problem domain. Data acquisition is done using Nutri-Flow® software. All the test variables of GA optimization process are saved to a text file and all the numerical data is analyzed with Excel or Matlab® which also provides a good platform for testing new calculation ideas.

6 Results and Discussion

6.1 Overall Performance of Nutri-Flow® software

Nutri-Flow® software provides the output as dietary guidance. Also the performance of GA is recorded separately to provide numerical data for analysis. The overall performance of the system is analyzed by licensed nutritionists.

When a person applies the recommended actions to the initial diet, the result must lead to a better state of nutrition. This can be analyzed numerically by comparing personal recommendations with the nutritional state of the recommended diet. The comparison should be done also in the fuzzy domain, since the values include uncertainty and imprecision. The formed dietary recommendation should be also feasible with recommended foods and their portion sizes and with level of change. For example, nobody would like to eat three tablespoons of cinnamon.

Results of the overall performance are promising. All the requirements are met numerically evaluated. However some of the recommended changes in diet were controversial, since there are expectations that some foods are healthier than others. Some healthy considered foods were recommended to reduce while some other foods were recommended to increase. After a review of licensed nutritionists, also the controversial guidance has been accepted, since the healthiness of a single foodstuff depends on the individual overall diet, not on the health claims on single food.

The tests revealed that, there are cases when GA is not working. Optimization with very limited diets with strong dietary limitations did not lead to any result. The reason is that, there was not enough variation in the population to find a feasible result. Other case was with very balanced diets. The initial diet was already so close to the recommendations that GA did not always find any better solution.

A statistical approach with a large set of individuals and meal diaries is needed to get more comprehensive data to analyze the performance of the overall system generally.

6.2 Population Size

According to previous contextual testing, the population size was set a fixed value, 100 individuals. There is a need to carry out more tests to show that selected population size is adequate for varying chromosome size. This could be done with the planned statistical testing for the overall system.

However, a population size more than 1000 will lead to longer computational time, which might affect the usability of the service. With current test data, global optimum is reached with current design parameters with all test cases.

6.3 Crossover

In this study, only uniform arithmetic crossover with the tournament selection method was analyzed. Parameters crossover probability p_c and tournament population size p_s are tested with population size 100. The best working values for the parameters are 0.8 and 2 for p_c and p_s, respectively. The test was run with the same data set as with the population test.

6.4 Mutation and Elitism

The same initial test data was applied also with testing mutation and elitism. The population size with this test was kept fixed at 100, and p_c and p_s to 0.8 and 2, respectively. Too big a value for mutation probability m_p slows the convergence rate as it affects the better genetic material more probably. The value 0.02 was selected. According to the data, the best value for m_p was 0.02.

Test runs show that running GA operators without elitism will lead us to lose some of the best solutions during the evolving of the population. This can be seen in Figure 4 where the trend line has peaks for both, the average fitness value and for the best fitness value.

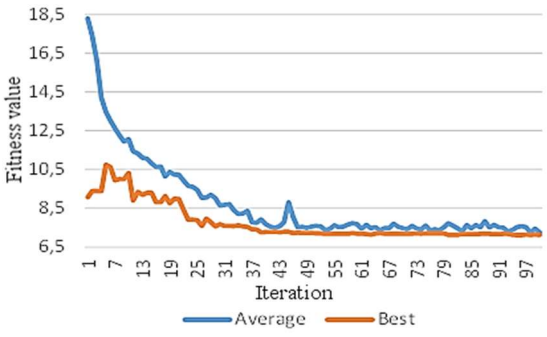

Figure 4. GA optimization without elitism operator.

6.5 Additional Parameters

According to the overall assessment with the numerical data of iterations, the best solution was reached with most of the test data within 100 iteration rounds. It is possible to create a self-monitoring feature to stop iterations when no better solutions are not found after a certain amount of iterations.

The initial population is created with random values within the given range. Sometimes it leads to a bad population which does not lead to the global optimum. GA should be run several times to find the global optimum. In Nutri-Flow® Software GA is run 10 times at the moment. This needs also further testing with a larger test set.

7 Conclusions

The nutritional guidance tool combines expertise with extensive food composition data through optimization. According to the overall assessment, the results are promising. All the requirements were met except two cases where no result was found at all. The real-coded chromosomes with GA operators such as crossover, mutation, and elitism can be used in the domain of dietary guidance when the search space is formed by FES. The objective function is crucial in comparing the results. When nutrient intake levels are handled in the Fuzzy domain, the imprecision and uncertainty can be taken into account, too.

The feasible result and a short computation time are essentials to make the Nutri-Flow® software usable. The validation of the system was carried out with expert knowledge, comparisons of nutritional status, and monitoring the key features of GA performance. There is a need to carry out more intensive testing with a large test data set. Also other optimization methods suitable for this problem domain will be tested.

Modular Model Predictive Control Concept for Building Energy Supply Systems: Simulation Results for a Large Office Building

Barbara Mayer[1] Michaela Killian[2] Martin Kozek[2]

[1]Institute of Industrial Management,FH Joanneum, Austria, {barbara mayer}@fh-joanneum.at
[2]Institute of Mechanics and Mechatronics, Vienna University of Technology, Austria, {michaela killian, martin kozek}@tuwien.ac.at

Abstract

The management of modern large buildings' energy supply systems (ESS) demands the maximal usage of renewable energy sources at minimum energy costs while meeting the energy demand of the consumption zone. Building ESS for heating and cooling usually consist of various supply circuits with several energy sources and different physical characteristics, possibly incorporating switching aggregates (heat pump, chiller) with latency times and stratified storage which change their operating state in a discontinuous fashion. Hence, these circuits can be seen as hybrid systems whose modelling as well as optimisation are demanding. Model predictive controllers (MPC) are an effective means for the optimisation of such problem formulations with divergent goals. The proposed modular predictive control concept (MPCC) is designed for a flexible usage in ESS building automation adding one appropriate MPC for each supply circuit including mixed-integer MPCs to the individual building's control structure. The resulting MPCC is capable of maximising the usage of renewable energy sources at minimum cost as well as efficiently managing switching aggregates with active storage. Suitable modelling of the linear and hybrid systems is demonstrated and validated on the example of a large office building in Austria. Furthermore, a simulation study shows the performance of the resulting MPC concept compared to a rule-based controller.

Keywords: building energy supply system, model predictive control

1 Introduction

Building control has become an important field since the building sector is responsible for about 40% of the total energy consumption in developed countries, (Pérez-Lombard et al., 2008). Therefore, an increasing effort has been put both on the development of energy saving building physical structure such as passive heating and cooling systems and on energy efficient building operation techniques. Model predictive control (MPC) has been proven as a promising technology for such building systems in recent years, (Širokỳ et al., 2011), with the ability of incorporating most influential quantities such as weather forecasts, (Oldewurtel et al., 2012), or occupancy information as well as technical constraints into the prediction. Moreover, the controller's optimisation target can include conflicting objectives expressed in thermal comfort and economic trade off. However, modelling of building systems is a crucial part for predictive building control, (Privara et al., 2013).

The efficient operation of large buildings' energy supply systems (ESS) aims at a maximal usage of renewable energy sources at minimum energy costs. Energy supply systems (ESS) of large buildings usually consist of various supply circuits of different physical characteristics, including heat exchangers and continuous pumps or additionally switching aggregates such as chillers or heat pumps with successive active energy storage, e.g. stratified storage tanks. Obtaining accurate models of latter systems is difficult, (Liu and Henze, 2004), since stratified storage is operated in either charging or discharging mode which is directly influenced by the state of the aggregate and its limitation of minimal up and down times. Due to the mixture of continuous and discrete variables hybrid models are suitable to approximate those systems. The efficient control of hybrid systems is challenging. For the optimisation within a predicitve controller with quadratic target this leads to a constrained mixed-integer quadratic problem (MIQP) at each time step. This can either be solved by a dual stage procedure where the storage tank operation mode profile is firstly fixed and the remaining QP solved in a second step, (Ma et al., 2009), or in a single step e.g. by using a branch and bound algorithm, (Mayer et al., 2016).

The classic approach to controlling buildings, especially ESS, is rule based control (RBC) due to its simplicity. However, RBC does not allow advanced management of e.g. active storage. Advanced control approaches of the recent years propose one single MPC controlling the entire building comprising the buildings' zone control as well as the energy supply optimisation, (Oldewurtel et al., 2012; Privara et al., 2013). While the operation with one global MPC would guarantee optimality, it is too rigid for application in industrial building automation.

This work introduces a modular predictive control concept (MPCC) for the energy supply level using dedicated predictive controllers for the respective circuits' physical characteristics. Basic circuits with heat

exchangers and continuous pumps can be approximated by linear state space systems, whereas the hybrid models are represented by piecewise affine (PWA) systems. All models are analytically derived based on thermodynamic principles and energy balance equations, (Berkenkamp and Gwerder, 2014; Mayer et al., 2015). The overall structure is capable of optimising heating and cooling supply at minimum cost and maximal usage of renewable energy sources. Furthermore, an efficient management of the active storage connected with the switching aggregate is guaranteed due to the application of a dedicated mixed-integer MPC (MI-MPC). The MPCC is designed to be embedded into a hierarchical building control structure, decoupling the energy consuming office level (OL) from the energy supply system level. In the OL a predictive controller is assumed to maximise user comfort while minimising the supply energy respecting disturbances, e.g. (Killian et al., 2015). It thus provides the reference trajectory for heating and cooling power for the MPCC. The modularity of the MPCC enables a flexible application in industrial building automation using dedicated models and MPCs allowing separate implementation and tuning. The main contributions of the paper therefore are:

- A modular predictive control concept (MPCC) for building energy supply systems (ESS) maximising the usage of renewable energy sources at minimum cost.
- Supply circuits with switching aggregates and stratified storage are modelled as hybrid systems and controlled by MI-MPCs aiming at an efficient management of aggregates and storage.
- Flexible application in industrial building automation leading to an application specific control architecture.
- A simulation study showing the performance of the proposed MPCC compared to a rule-based controller applied to a demonstration building in Austria.

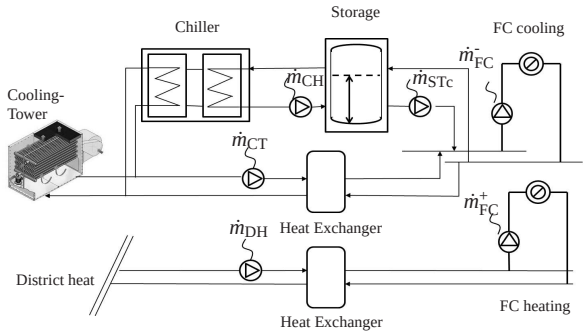
The remainder of this paper is structured as follows: In Section 2 the demonstration building setup as well as the overall control structure is given. The building models for the ESS dedicated for the different MPCs are explained in Section 3, whereas the predictive controllers are introduced in Section 4. The simulation results for the demonstration building are shown in Section 5 and finally, a conclusion is drawn in Section 6.

2 Modular Model Predictive Control Concept

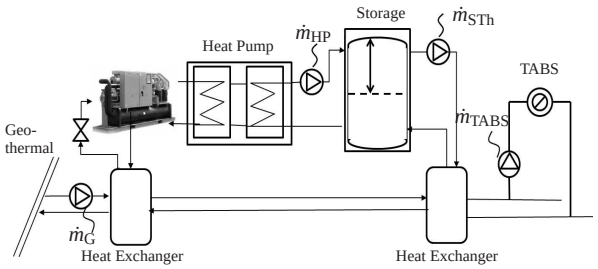
Within this Section the building setup and the overall MPCC for the demonstration building is given.

2.1 Building Setup

The building which is presented in this work is a $27.000m^2$ University building in the center of Salzburg, Austria. It has five floors above ground containing several large and numerous smaller meeting rooms, offices and lecture rooms. For this work focus is put on the second and third floor, which comprise of about 500 rooms of some $13.000m^2$, almost all used as offices. Both floors are supplied by Fan Coils (FC) and a Thermal Activated Buildings System (TABS). The ESS of this building consists of heating and cooling supply circuits for FC and TABS, see Figure 1. The FC supply is split into cooling supply based



(a) FC circuits including free cooling, the chiller, and district heat.



(b) TABS circuits including geothermal source and the heat pump.

Figure 1. Energy supply circuits for cooling and heating of the University building in Salzburg, Austria.

on free cooling and chiller circuit and heating supply from the district heat. TABS has only one piping system supplied by the geothermal source and is routed via the heat pump circuit in case of heating.

2.2 Modular Predictive Control Concept

The modular predictive control concept (MPCC) generally consists of independently acting MPCs with the same target - one MPC for each supply circuit comprising the corresponding energy source as well as the supply system of the building. Basic circuits consisting of heat exchangers and continuous pumps can be approximated by linear models. Consequently, linear MPCs (LMPC) are applicable in this case. However, if switching aggregates have to be considered, the predicitve controller not only has to optimise the continuous manipulated variables but also the discrete aggregate's switching state. Moreover, the coupled active storage changes its operating mode in

a discontinuous fashion depending on the switching instance. Therefore, a dedicated mixed-integer MPC (MI-MPC) is applied optimising latter circuits considered as hybrid systems. The control structure for the proposed ESS, see Figure 2, is designed according to the available energy sources and aggregates shown in Figure 1(a) and Figure 1(b) which distinguishes between FC and TABS heating and cooling supply. For the FC cooling system an LMPC controls the free cooling circuit, whereas an MI-MPC manages the cooling supply from the chiller including a stratified storage tank. The FC heating supply is sourced by the district heat and controlled by the second LMPC. The TABS is supplied by the geothermal source either used directly in the case of cooling or routed via the heat pump and subsequent stratified storage tank if heating is required. Hence, an LMPC is active for cooling and an MI-MPC for heating. Furthermore, the ESS control structure is embedded into an overall hierarchic building control structure with a predicitve controller for the OL, e.g. (Killian et al., 2015), which is responsible for providing a prediction of the required heating and cooling power, $\dot{Q}_{\mathrm{FC}}^{\mathrm{ref,+}}$ respectively $\dot{Q}_{\mathrm{FC}}^{\mathrm{ref,-}}$, for each energy supply system. All variables and parameters used are listed in Table 1 and the two types of MPCs are formally described in Section 4.

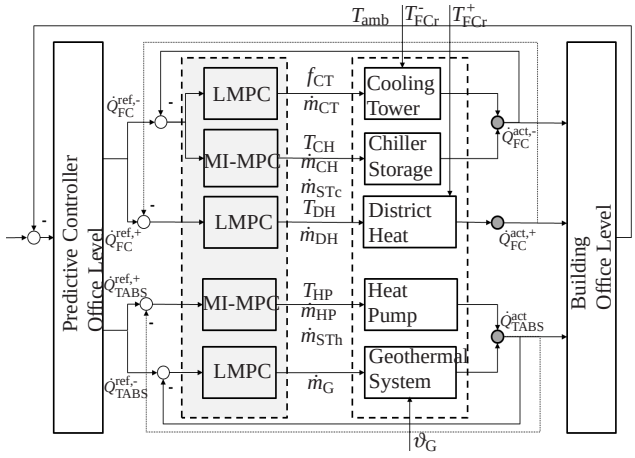


Figure 2. Control structure for cooling and heating circuits for FC and TABS embedded into a hierarchical building control structure.

Table 1. Nomenclature.

Variable	Description	Unit
$\dot{m}_{\mathrm{CT}}$	mass flow from cooling tower	[kg/s]
f_{CT}	fan speed of cooling tower	[m/s]
T_{amb}	ambient temperature	[°C]
T_{FCr}^{-}	return temperature for FC cooling	[°C]
T_{CH}	supply temperature of chiller	[°C]
$\dot{m}_{\mathrm{CH}}$	mass flow from chiller to storage	[kg/s]
$\dot{m}_{\mathrm{STc}}$	mass flow from storage of cooling circuit	[kg/s]
T_{DH}	supply temperature of district heat	[°C]
$\dot{m}_{\mathrm{DH}}$	mass flow from district heat	[kg/s]
T_{FCr}^{+}	return temperature for FC heating	[°C]
T_{HP}	supply temperature of heat pump	[°C]
$\dot{m}_{\mathrm{HP}}$	mass flow from heat pump to storage	[kg/s]
$\dot{m}_{\mathrm{STh}}$	mass flow from storage of heating circuit	[kg/s]
$\dot{m}_{\mathrm{G}}$	mass flow from geothermal source	[kg/s]
ϑ_{G}	difference geothermal supply, return temp.	[°C]
$\dot{Q}_j^{\mathrm{ref,+}}$	reference heat flow for supply j heating	[kW]
$\dot{Q}_j^{\mathrm{ref,-}}$	reference heat flow for supply j cooling	[kW]
$\dot{Q}_j^{\mathrm{act,+}}$	actual heat flow for supply j heating	[kW]
$\dot{Q}_j^{\mathrm{act,-}}$	actual heat flow for supply j cooling	[kW]
j	supply: TABS or FC	

3 Energy Supply Level - ESS - Models

In this Section the modelling strategy and structure for the circuits of the ESS shown in Figure 1 is given. Each circuit is modelled individually.

3.1 Linear Models

For building control aspects the achievable heating or cooling power, $\dot{Q}$, of each supply circuit is relevant, which can be approximated by simplified energy balance equations: $\dot{Q} = \dot{m} \cdot \Delta T \cdot cp$, where $\dot{m}$ denotes the mass flow, ΔT the difference of supply and return water temperature, and cp the specific heat capacity of water. Heat exchangers and continuous pumps preferably work around a certain operating point. For the geothermal and the district heat supply two linearised static models based on those thermodynamic principles are analytically derived. The geothermal model contains one manipulated variable, $\dot{m}_{\mathrm{G}}$, one disturbance, ϑ_{G}, and the output $\dot{Q}_{\mathrm{TABS}}^{-}$. The Δ-variables denote the deviation of the variables to the operating point and $\mathrm{COP_G}$ the coefficient of the geothermal performance:

$$\Delta\dot{Q}_{\mathrm{TABS}}^{-} = \underbrace{\mathrm{COP_G} \cdot \mathrm{cp}}_{const.} \cdot [\dot{m}_{\mathrm{G}}|_o \cdot \Delta\vartheta_{\mathrm{G}} + \vartheta_{\mathrm{G}}|_o \cdot \Delta\dot{m}_{\mathrm{G}}]. \quad (1)$$

The district heat model is derived in the same way and contains two manipulated variables, T_{DH} and $\dot{m}_{\mathrm{DH}}$, one disturbance, T_{FCr}^{+}, and the output $\dot{Q}_{\mathrm{FC}}^{+}$:

$$\begin{aligned}\Delta\dot{Q}_{\mathrm{FC}}^{+} \quad &= \underbrace{\mathrm{COP_{DH}} \cdot \mathrm{cp}}_{const.} \cdot [\dot{m}_{\mathrm{DH}}|_o \cdot (\Delta T_{\mathrm{DH}} - \Delta T_{\mathrm{FCr}}^{+}) \\ &\quad + (T_{\mathrm{DH}}|_o - T_{\mathrm{FCr}}^{+}|_o) \cdot \Delta\dot{m}_{\mathrm{DH}}]. \end{aligned} \quad (2)$$

As depicted in Figure 1(a) free cooling is based on the cooling tower. Free cooling is exclusively used if the chiller is inactive. The ambient temperature, T_{amb}, constrains the cooling tower's operation for free cooling which is also a main disturbance next to the return water temperature T_{FCr}^{-}. Modelling cooling towers analytically aims at detailed complex models with non-linear dynamics of high order which are not suitable for the usage within MPCs. Hence, black-box identification is expedient if

historic data of the cooling tower in operation is available. Since the cooling tower can be operated at two fan speeds $i \in \{1,2\}$, the system can be approximated by two linear static models:

$$\dot{Q}_{\mathrm{FC}}(i) = c_{i,1} \cdot T_{\mathrm{amb}} + c_{i,2} \cdot T_{\mathrm{FCr}} + c_{i,3} \cdot \dot{m}_{\mathrm{CT}} + c_{i,4}, \quad (3)$$

where the corresponding coefficients $c_{i,k}$ have to be estimated within the black-box identification routine using historic data of the free cooling system. Note that the model in Eq. (3) is linear in the parameters $c_{i,j}$, thus least squares methods can be employed for optimal parameter estimation, (Ljung, 1999).

3.2 Hybrid Models

The chiller and the heat pump are switching aggregates with latency times, such that minimum up and down times have to be respected, e.g. after switching on the aggregate it must operate for a minimum up time until it can be shut off again and vice versa. Furthermore, the stratified storage tanks can operate in two basic modes: charging and discharging. Each mode is represented by a dedicated model with continuous variables. The discrete switching state of the aggregate (on/off), l_{on}, specifies which mode is exclusively active at each time. These operation modes further depend on the difference of the mass flows to, $\dot{m}_l$, and from, $\dot{m}_{\mathrm{STk}}$, the storage tank where $l = \{\mathrm{CH},\mathrm{HP}\}$ denotes the aggregate and $k = \{\mathrm{c},\mathrm{h}\}$ the cooling or heating circuit, (Mayer et al., 2015). The hybrid dynamic models contain three continuous states, $x(t)$, namely the thermocline of the storage $z_k(t)$, the temperature of the cold respective hot water $T_k(t)$, and the cooling respective heating power $\dot{Q}_j(t)$. The three continuous manipulated variables, $u(t)$, are the supply temperature of the aggregate $T_l(t)$, the mass flow from the aggregate to the storage $\dot{m}_l(t)$, and the mass flow from the storage to the TABS or FC supply $\dot{m}_{\mathrm{STk}}(t)$. $l_{\mathrm{on}}(t)$ is the discrete manipulated variable representing the switching state of the corresponding aggregate l for each time t. The continuous output $y(t) = \dot{Q}_j(t)$ denotes the cooling respective heating power for the supply j to the building. For each operating mode a model is firstly analytically derived through first order differential equations and secondly linearised at a fixed operating point. The non-linear dynamics can then be approximated by a hybrid system state-space formulation with discrete as well as continuous inputs represented by a piecewise affine (PWA) system:

$$x(t+1) = A_h x(t) + B_h u(t), \qquad \text{if } \delta_h(t) = 1, \quad (4a)$$
$$y(t+1) = Cx(t), \quad (4b)$$

where the binary variables $\delta_h(t) \in \{0,1\}, \forall h = 1,..,3$, are introduced to denote the status of the operation mode h and the system matrices are $A_h \in \mathbb{R}^{3\times3}$ and $B_h \in \mathbb{R}^{3\times4}$. $C = \begin{bmatrix}0 & 0 & 1\end{bmatrix}$ for all three modes since the third state is equal to the output. The explicit matrices for the chiller circuit model are given in (Mayer et al., 2016), whereas for the modelling of the heat pump circuit the reader is referred to (Mayer et al., 2015).

4 Model Predictive Controllers

The formal description of the two MPC types used within the MPCC and their common objective are given in this Section.

4.1 Objective Function

The predictive controller for the OL, e.g. (Killian et al., 2015), is responsible to guarantee user comfort by keeping the indoor temperature within a certain tolerance at minimum energy demand. The objective for the ESS on the other hand is to minimise the deviation to the required power and the energy costs.

For all MPC implementations a quadratic optimisation target is used, where the deviation to the reference trajectory of the cooling respective heating power is penalised with factor Q_y. Furthermore, the energy costs represented by Q_u caused by the manipulated variables are taken into account. Both additive terms are considered for each time step t over the whole prediction horizon Np. The Δ-variables again denote the deviation from the corresponding operating point. The formal description of the objective is given by:

$$J^\star = \min_{\Delta u \in U} \sum_{t=0}^{Np-1} \left\| \Delta\dot{Q}_j^{\mathrm{ref}} - \Delta\dot{Q}_j^{\mathrm{act}} \right\|_{Q_y}^2 + \left\| \Delta u(t) \right\|_{Q_u}^2, \quad (5)$$

4.2 LMPC

The three LMPCs for this work have a quadratic optimisation target as presented in Eq. (5). They only differ in the model they rely on. The FC model for free cooling uses a linear model with absolute inputs, whereas the TABS geothermal model and the FC district heat model are a linearised model with Δ- variables which denote the deviation from the corresponding operating point. All three LMPCs are implemented according to the receding horizon strategy, (Camacho and Alba, 2013).

4.3 MI-MPC

In Section 3 the hybrid models for the chiller and the heat pump circuits are motivated. The objective is given in Section 4.1. The corresponding constraints are:

PWA model as given in Eq. (4),
$$\delta_h(t) \in \{0,1\}, \quad (6a)$$
$$\sum_h \delta_h(t) = 1, \quad (6b)$$
$$u_{\min} \le u(t) \le u_{\max}, \quad (6c)$$
$$x_{\min} \le x(t) \le x_{\max}, \quad (6d)$$
$$l_{\mathrm{on}}(t) - l_{\mathrm{on}}(t-1) \le l_{\mathrm{on}}(\omega_{\mathrm{up}}), \text{(Off/On switch)} \quad (6e)$$
$$l_{\mathrm{on}}(t-1) - l_{\mathrm{on}}(t) \le 1 - l_{\mathrm{on}}(\omega_{\mathrm{down}}), \text{(On/Off switch)} \quad (6f)$$

$\forall j \in \{\mathrm{TABS},\mathrm{FC}\}$ and $l \in \{\mathrm{CH},\mathrm{HP}\}$, where $u_{\min}$ and $u_{\max}$, respectively $x_{\min}$ and $x_{\max}$, denote the the capacity limits of the manipulated variables and the physical bounds of the stratified storage. The constraints on latency times

with minimum up and down times are given in Eq. (6e) and Eq. (6f) with $\omega_{\text{up}} = t, t+1, ..., \min(t+Np, t+T_l^{\text{up}}-1)$ if we consider the minimum up time and $\omega_{\text{down}} = t, t+1, ..., \min(t+Np, t+T_l^{\text{down}}-1)$ in the other case. Eq. (6b) denotes that at each time only one hybrid mode can be active. Since the objective given in Eq. (5) is quadratic the resulting optimisation problem is a mixed-integer quadratic problem (MIQP) to be solved each time step $t = 0, \cdots, Np-1$. For this work a branch and bound algorithm is applied, (Mayer et al., 2016), which relaxes the original problem by replacing integrality constraints, (6a), i.e. integer and particularly binary variables are allowed to span over the whole continuous interval, aiming at solving many QPs and searching for the best solution.

5 Simulation Results

In this Section the simulation setup is given. Furthermore, simulation results showing the performance of the MPC-C are discussed and the comparison results to a simuated rule-based controller (RBC) are given.

5.1 Simulation Setup

The simulation for the demonstration building described in Section 2.1 is based on a snapshot of historic data of the implemented automation system for the disturbances ambient temperature and ϑ_{G}. The simulation is shown from the beginning of September until the end of November 2014. The comparison between MPCC and RBC is given for all seasons 2014. The prediction horizon Np for all predictive controllers is 12 hours and the sampling time is one hour. The return water temperature for the cooling FC circuit, T_{FCr}^{-}, is $20°C$, whereas for the heating circuit the return water temperature, T_{FCr}^{+}, is $24°C$. The two stratified storage tanks have a volume of almost $16m^3$ each.

5.2 Demonstration of MPCC Performance

The simulation study shows the performance of the proposed modular MPC concept for the demonstration building. For this work, the power demand trajectories are given by the OL predictive controller introduced in (Killian et al., 2015) for both TABS and FC supply. Since there is only one piping system for TABS, the predicted power is split into a negative cooling, $\dot{Q}_{\text{TABS}}^{\text{ref,-}} = \min(\dot{Q}_{\text{TABS}}^{\text{ref}}, 0)$, and a positive heating trajectory, $\dot{Q}_{\text{TABS}}^{\text{ref,+}} = \max(\dot{Q}_{\text{TABS}}^{\text{ref}}, 0)$. For the FC system the reference trajectories are already split by the OL controller. The simulation for all MPCs, the LMPCs as well as the MI-MPCs, is run simultaneously. However, for the FC cooling supply two circuits are implemented but only one can be active at a time (either chiller or free cooling). Therefore, an additional rule is applied which prefers the usage of the renewable energy source respectively of the corresponding LMPC if the ambient temperature does not exceed $18°C$.

Figure 3 shows the ambient temperature profile for the simulation period from September to November 2014. One can see a drop of the mean temperature after hour 1200 by about $7°C$. The green line depicts the technical limit for the usage of the free cooling circuit.

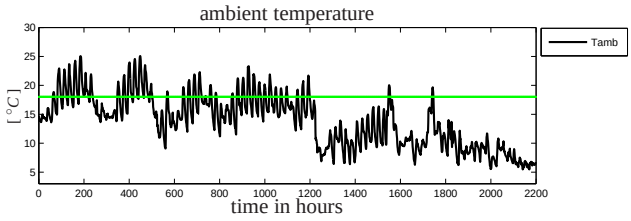

Figure 3. Ambient temperature profile starting with 1st Sept. 2014.

Figure 4 shows the simulation results for the TABS circuits, where according to the ambient temperature profile in the first half of the simulation period cooling is requested by the OL, represented by $\dot{Q}_{\text{TABS}}^{\text{ref,-}}$. The temperature spread of ϑ_{G} is sufficient to provide the required cooling energy only from the geothermal source, the manipulated variable $\dot{m}_{\text{G}}$ for the supply of $\dot{Q}_{\text{TABS}}$ is given in the second subplot. The heat pump is inactive over large parts of this first simulation period which can be seen at the red line in the last subplot. From hour 1200 onwards heating is requested by the OL, $\dot{Q}_{\text{TABS}}^{\text{ref,+}}$, and supplied by the heat pump circuit with perfect fit. The temperature of the water supply from the heat pump as well as the pumps of the heat pump circuit are presented in the second subplot.

Figure 5 shows the simulation results for the FC circuits. The references for cooling, $\dot{Q}_{\text{FC}}^{\text{ref,-}}$, and heating, $\dot{Q}_{\text{FC}}^{\text{ref,+}}$, are computed by the OL controller. The first subplot shows the performance of the MI-MPC and LMPCs for the FC circuits. In the second and third subplot the manipulated variables are presented. The red lines denote the contributions to FC heating supply of the district heat circuit, whereas the blue and grey lines show the temperature and mass flows for the chiller circuit. The green line in subplot three depicts the mass flow of the pump from the cooling tower of the free cooling circuit. The last subplot indicates which cooling circuit is active. Note, that free cooling is always active if the technical condition $T_{\text{amb}} \leq 18°C$ is fulfilled. Since the energy demand for the cooling FC circuit is low, the chiller is not regularly active, even if free cooling cannot be activated. Due to the specific hydraulic architecture of the demonstration building the pump supplying the cold water from the stratified storage tank has to be activated if free cooling is not active. Thus, a minimal deviation to $\dot{Q}_{\text{FC}}^{\text{ref,-}}$ has systematically be taken into account in these periods (see blue line in first subplot in Figure 5).

5.3 Comparison between MPCC and RBC

ESS are conventionally controlled by rule-based controllers (RBC). The RBC of the demonstration building is also simulated for comparison: Free cooling is also preferred but it may only be active if ambient temperature has been below $18°C$ for the past three hours. The chiller has to be switched on if the low storage temperature is higher than $12°C$ and switched off if it is lower than $7°C$.

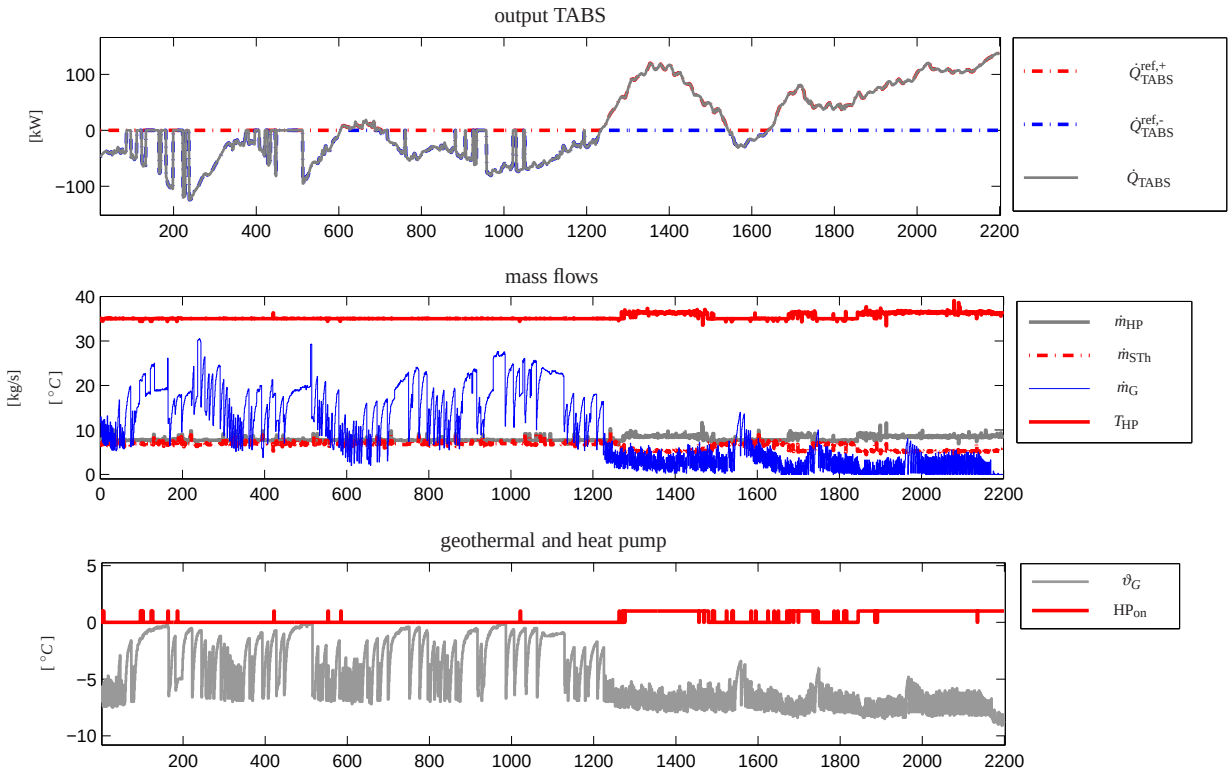

Figure 4. Simulation results for the TABS circuits starting with 1st Sept. 2014.

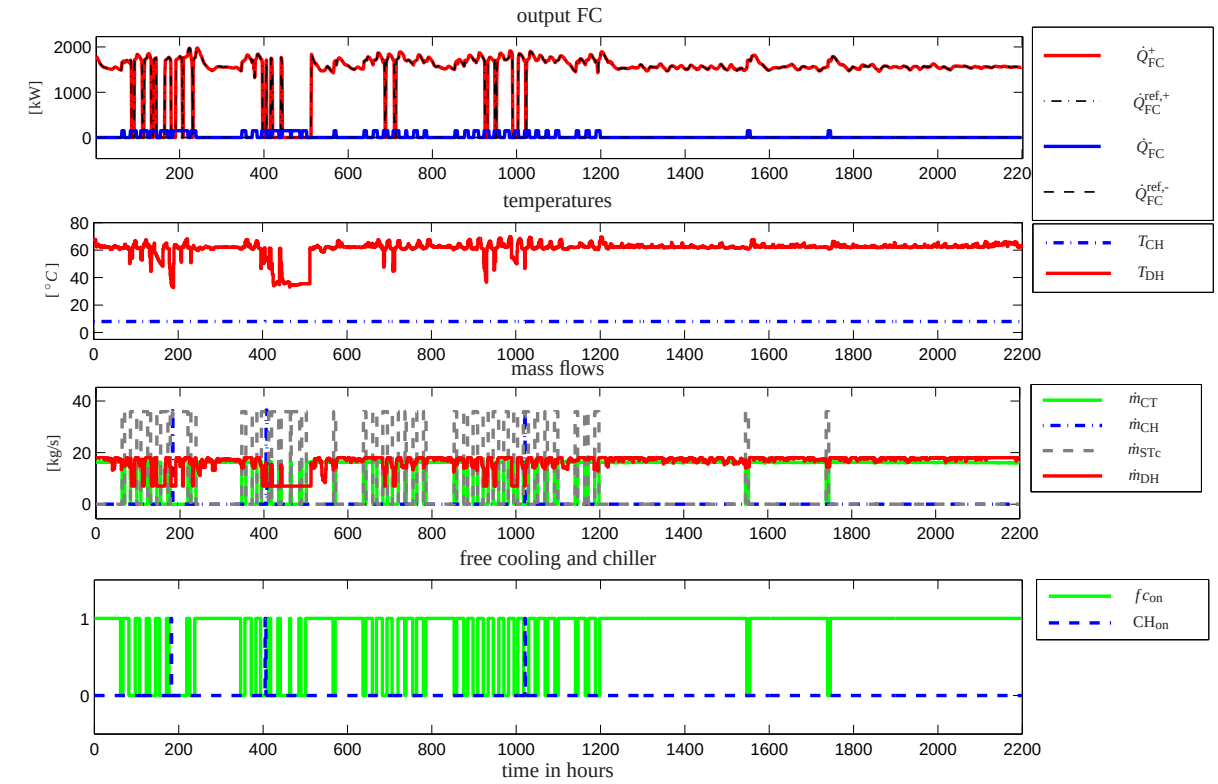

Figure 5. Simulation results for the FC circuits starting with 1st Sept. 2014.

Compared to this RBC the proposed MPCC achieves an increase of free cooling hours of almost 5% in winter (January-March and December 2014) up to over 30% in summer (June-August 2014). About 30% to 40% more cooling power $\dot{Q}^{-}$ is supplied via free cooling using the MPCC. The number of transitions of the chiller from state off to on can be reduced by around 15% in summer up to 60% in transition period (April-May and September-November 2014), which is equivalent to a significant reduction for maintenance cost for the aggregate. Table 2 shows the precise figures of the MPCC in percentage of the RBC. Simulation results show the best results for the

Table 2. Performance of the MPCC compared to the RBC in percentage according to the seasons.

season	fc hours	$\dot{Q}^{-}$ via fc	chiller state trans.
winter	104.7	130.5	0.0
transition	108.4	134.9	39.1
summer	132.6	141.2	84.8

MPCC cooling supply during summer, where the predictive character of the control concept is most effective compared to the conventional controller.

Relaxing the upper limit of $T_{\text{amb}} \leq 18^{\circ}C$ for the extended usage of free cooling leads to an average increase of mass flow of the cooling tower $\dot{m}_{\text{CT}}$ at lower variance. Table 3 lists the simulation results for the upper limit varying from $18^{\circ}C$ to $22^{\circ}C$ for autumn 2014. The number of free cooling hours is given in percentage of the simulation hours.

Table 3. Effect of a relaxation of the upper limit T_{amb} on $\dot{m}_{\text{CT}}$.

upper limit	fc hours [%]	mean $\dot{m}_{\text{CT}}$	std. dev. $\dot{m}_{\text{CT}}$
$18^{\circ}C$	89.1	21.8	8.2
$20^{\circ}C$	96.2	23.4	5.6
$22^{\circ}C$	99.5	24.0	3.6

The proposed MPCC allows to pursue different strategies for heating and cooling control, depending on the parametrisation of the weighting factors of the optimisation targets. For this work emphasis was put on the maximal usage of renewable energy sources with minimum cost while assuring minimal deviation of the delivered cooling and heating power for the supply systems in order to maximise the user comfort in the OL. The simulation results show, that the proposed MPCC is able to meet the requirements of the OL predictive controller almost perfectly and to maximise the usage of renewable energy sources such as free cooling. Furthermore, maintenance cost can be reduced due to a reduction of state transitions of the switching aggregates.

6 Conclusions

This paper introduces a modular predictive control concept (MPCC) for modern energy supply systems (ESS) of large buildings with several energy sources and supply circuits. Due to its modularity the concept is flexibly applicable for industrial building's ESS control, which is shown on a demonstration building in Austria. The resulting MPCC includes linear MPCs as well as mixed-integer MPCs (MI-MPC) dedicated for the efficient control of basic circuits respectively those with switching aggregates such as chillers with active storage. The simulation study shows that the proposed MPCC is able to accurately deliver a prescribed cooling respective heating power trajectory at minimum cost and a maximal usage of renewable energy sources. The MPCC is capable to maximise the usage of free cooling and - due to the MI-MPC - to efficiently manage the switching aggregates: compared to a RBC simulation results show an increase of free cooling hours of up to 30% and a reduction of the chiller's transitions from state off to on by up to 60% aiming at a consequent decrease of maintenance cost depending on the respective season of the year. Simulation results of the MPCC are therefore very promising for the future implementation in the demonstration building.

Abstract

The present paper deals with a study of different climate effects and defining boundary conditions on mould growth risk inside building envelope. The case structure represents a common envelope of timber-framed single-family house. Weather conditions from Utsjoki, Oulu and Joensuu are considered in the analysis representing climate gradients wet and dry, coastal and inland conditions during a period of 6 years.

Mould growth initiation and progression require a sufficiently high humidity at suitable temperature range. Coastal regions characteristically have humid and warm climate that causes higher risk for mould growth than the more dry inland locations. The most unfavorable conditions for mould growth were seen in the coldest and the northernmost location. Hygro-thermal simulation also presented significant differences in key interior boundary conditions that, considering standard approach, may be interpreted as potential structural health issues.

Keywords: hygro-thermal simulation, mould growth risk assessment, climate effect, structural health

1 Introduction

The recent studies in sustainability, energy use and health of buildings show a trend towards low-energy housing solutions and material development that supports energy conservation. The industry tries to create a space for the creativity of designers in designs while ensuring low total energy use, energy harvesting options and low level of heating energy losses. Although indoor designs and visible surfaces are often highlighted in house designs, characteristics of climate conditions inside the structural elements should not be forgotten, even if they are hidden from the residents.

Current structures tend to be highly insulated causing a significant gradient in the hygro-thermal conditions inside the multi-layer building components (Fedorik *et al*, 2015). A certain combination of temperature and humidity exposure leads to favorable conditions for mould growth (Hukka et al, 1999; Viitanen *et al*, 2007; Viitanen *et al*, 2010) and the existence of mould spores may cause allergic reactions (Mundarri and Fisk, 2007). The presence of mould and fungi significantly influence material properties and in long run may cause structural deterioration and costly rebuilds. This is a problem especially in cases when moisture is enclosed to envelope in building stages and the insulated wall is unable to balance it with outdoor or indoor conditions.

The presence and impact of e.g. moulds in workplaces, schools and houses has become a widely discussed issue during the recent decades. The mould issue in this context was initially found in historic buildings, where indoor ventilation was not provided or it was very inefficient (Pirinen 2011). While improved ventilation and air-exchange may indeed significantly affect the indoor conditions and protect interior wall-surfaces from the mould growth, the multi-layered envelope and/or foundation and roofs may still be under a risk of mould growth. Insufficient knowledge of designers and house owners further increase the risk of unsuitable design and maintenance issues.

There are three ways to analyses house designs for their hygro-thermal properties prior to the build-up stage: lab-tests, on-site measurements and numerical simulation. Although numerical simulation is not as accurate as the other methods, its advantage consists especially of timesaving and low expenses. If suitable verification is done, simulation is helpful in predicting the risk factors against moulds (Woloszyn and Rode, 2008).

2 Objectives

The aim of the this study consists of finding the differences in hygro-thermal conditions inside an envelope element and defining key differences in mould index (mould growth probability indicator) depending on the defined outdoor and indoor climate conditions. Data defining outdoor boundary conditions were obtained from official weather stations located in Joensuu, Utsjoki and Oulu for a 6-year period (2009-2015, see Figure 1). The indoor boundary conditions were taken as multiplication of 1-year data measured in a corresponding family house and, for comparison, data

according EN ISO 13788:2012 dependent on actual exterior conditions.

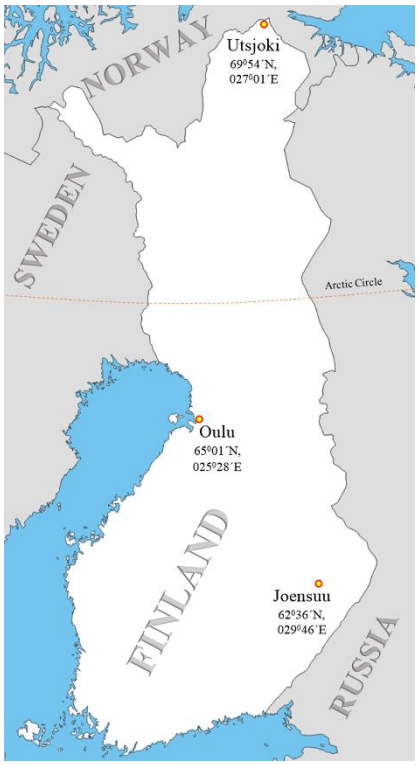

Figure 1. Localization of analyzed weather stations.

3 Applied Methodology

Temperature and humidity during the exposure time are the major factors driving the mould growth. Mould growth risk simulation is based on the model developed by the Tampere University of Technology and Technical Research Centre of Finland (VTT). RH_{crit} determines the limits between favorable and unfavorable conditions, in temperature range from 0 to 50 °C. The minimum humidity for a mould spore to start growing depends on material sensitivity, being here 80 or 85% (Ojanen *et al*, 2011). In the case the hygro-thermal conditions are favorable, the mould growth risk increases. Otherwise, if the conditions are unfavorable for mould growth initiation, the risk decreases depending on the exposed time for unfavorable conditions.

The risk of mould growth is analyzed using a mould index value (MI, M_{index}), which is expressed by an empirical model that is based on the variables of temperature, relative humidity and exposure time, as shown in our recent study (Fedorik *et al*, 2015). A border between favorable and unfavorable conditions for mould-growth initiation is defined by critical relative humidity (RH_{crit}).

The RH_{crit} varies with regard to the sensitivity of material (Ojanen *et al*, 2011), where examples and classification of materials applied in the research is specified in Table 1. The equation is valid for material sensitivity classes 1 and 2. In the case of classes 3 and 4, the minimal RHcrit must be at least 85%, which is the degree of humidity required for initiation of mould growth on a surface of this type of material.

The numerical hygro-thermal simulation was performed by Wufi®2D (Sedlbauer *et al*, 2001; Künzel, 1995), where two-dimensional model of the presented wall-envelope was created. Wufi applies two-dimensional heat and moisture transfer by the governing transport equations, while drivers for the heat and moisture transfer are vapor pressure and moisture content.

4 Analyzed Structure

The studied structure represents a common Finnish single-family timber-framed wall element. The geometry consists in gypsum board layer installed on the interior surface, 50 mm continuous mineral wool, 200 mm mineral wool filling the timber-frame, wind-proof board, 32 mm air-gap and 23 mm exterior cladding made of painted wood panels (Figure 2).

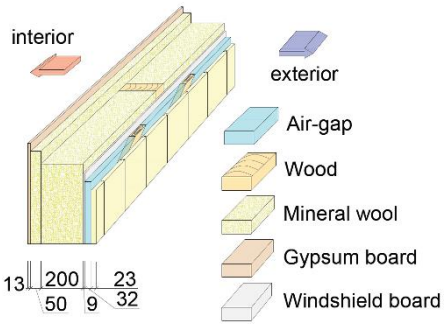

Figure 2. Schematic of the studied wall element structure.

The numerical model represents a horizontal cut-off plane of the structure (Figure 3). The hygro-thermal data was collected from 9 points (in red) considered as the most important, where humidity can creep into the structure. The geometry of the numerical model and localization of the analyzed points are given in the Figure 3. Material properties of each element are considered as they are defined in Wufi®2D material library.

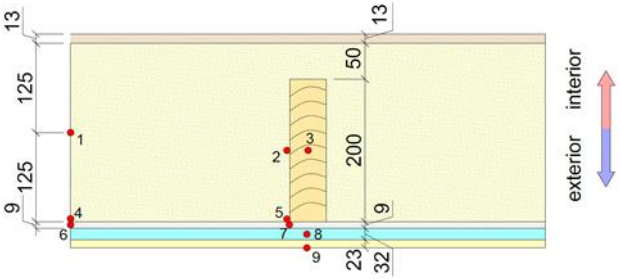

Figure 3. Analyzed points 1-9 within the wall structure.

5 Boundary Conditions

The presented study applies exterior weather conditions from three different cities across Finland. The conditions from a typical coastal, inland and northern city were applied (Figure 1). The northernmost city Utsjoki in Finland is characteristic by dry and cold weather, Oulu for its humid conditions and Joensuu represents conditions for common Finnish inland city where the climate is more warm and dry. The climate data was recorded in these cities by Finnish Meteorological Institute's weather stations for 6 years from 1.4.2009 to 31.3.2015. The weather conditions in 2010 for the cities are shown in the Figure 4 (Temperature) and Figure 5 (relative humidity. RH). The time step applied in the presented study is 1 hour.

The house interior data was considered from two perspectives. At first, as defined according to EN ISO 13788:2012 considering humidity class 3 and constant indoor temperature (at 20 °C). Secondly, actual indoor boundary conditions were measured during one year (2010) in a family house located in Oulu/Finland. These were considered to remain the same every year for the whole 6 years period.

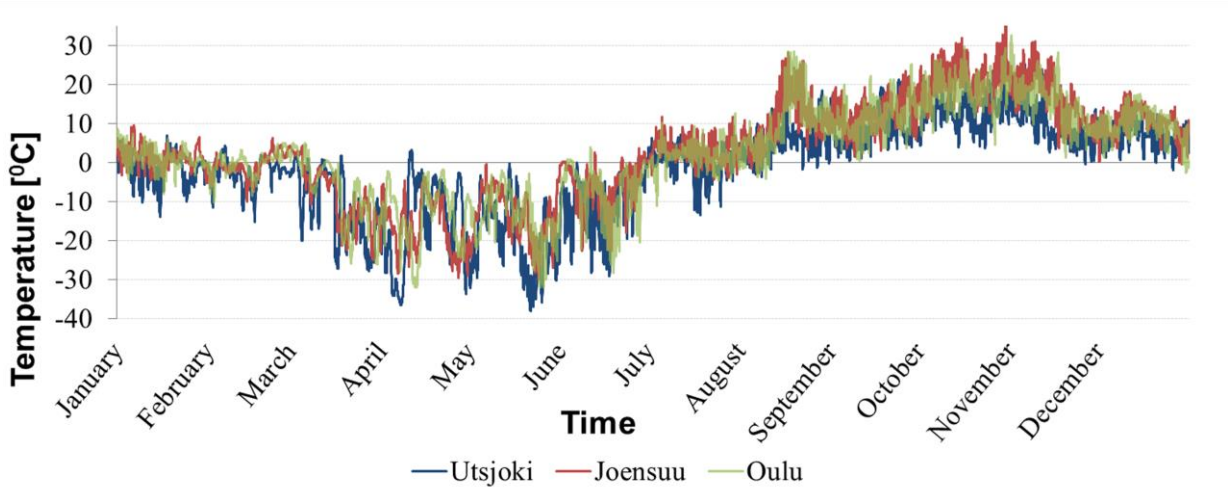

Figure 4. Development of annual temperature in 2010.

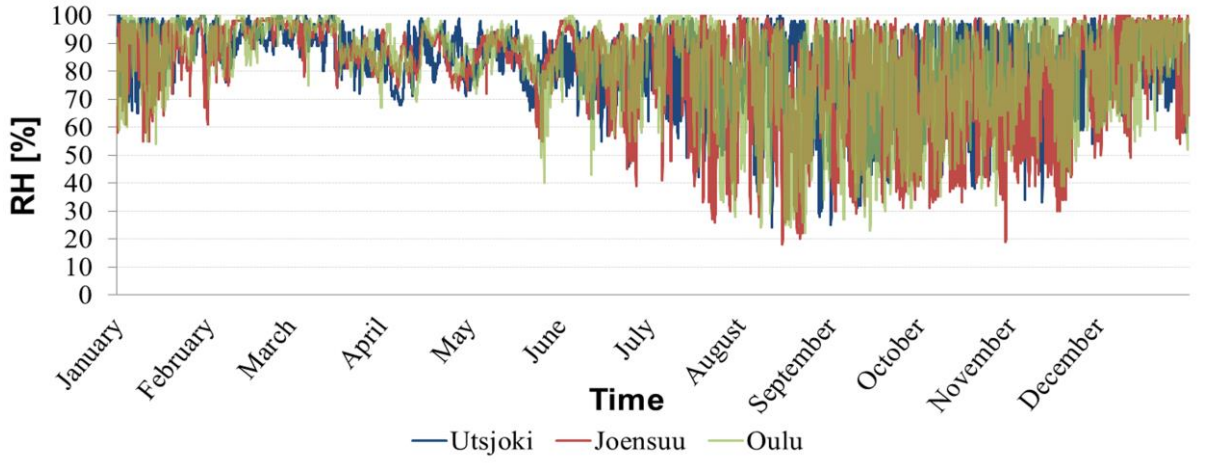

Figure 5. Development of annual humidity in 2010.

6 Results and Discussion

The presented study analyses the effect of different boundary conditions on mould growth risk inside an envelope of a common Finnish family house. The achieved results do not represent any major risk for the structure from the mould index point of view, although the differences between different cities vary significantly.

The evaluated mould index achieves quite low values, representing no or very subtle mould existence according to (Ojanen *et al*, 2011). On the other hand, significant differences were achieved in number of favorable conditions between the analyzed cities. The favorable conditions behind a possibility of mould growth initiation should be considered in house design.

Graphical illustration of favorable and unfavorable conditions for mould growth obtained at point 5, located between insulation and wind-proof board near the exterior wall-surface, are shown in Figures 6 to 8. The dots in the figures represent conditions of temperature and humidity achieved at each time-step of the solution, where the red dots represent conditions favorable for mould growth and blue unfavorable. It must be noted that the red dots do not mean initiation of mould, but they indicate the favorable conditions where growth can take place. Important part for mould starting to grow is the exposure time.

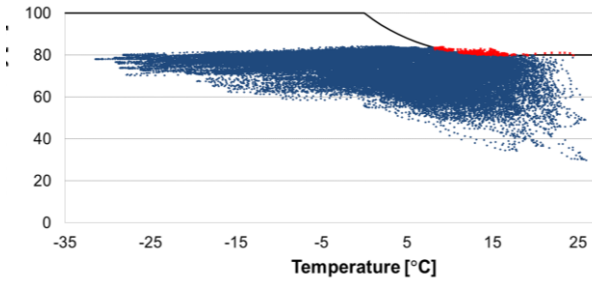

Figure 6. Favorable conditions for mould growth at exterior corner of timber-stud (point 5 in Figure 3) in Utsjoki.

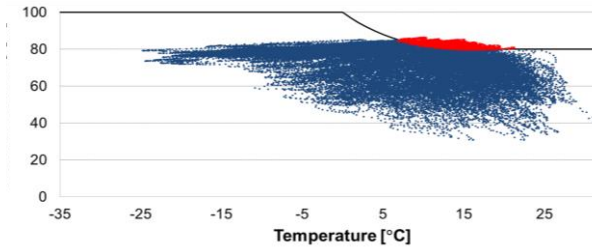

Figure 7. Favorable conditions for mould growth at exterior corner of timber-stud (point 5 in Figure 3) in Joensuu.

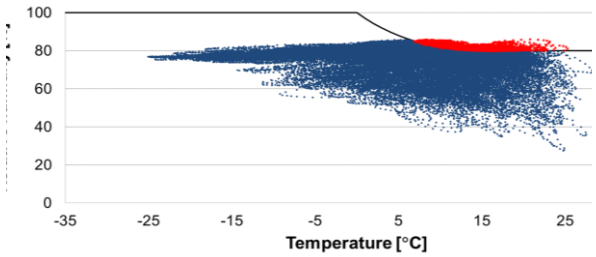

Figure 8. Favorable conditions for mould growth at exterior corner of timber-stud (point 5 in Figure 3) in Oulu.

It can be seen that the weather conditions in Utsjoki cause only briefly the conditions for favorable environment for mould growth compared to conditions in Joensuu and especially in Oulu. The evaluated maximum mould index achieved and percentage period when the structure is exposed to favorable conditions for mould growth at each of the analyzed points considering measured interior boundary conditions are summarized in the Table 1, where points 1 to 3 are not included as far as the mould index was always 0.

Table 1. M_{index} and Favourable Conditions Considering the Measured Interior Conditions.

Analysis point	Joensuu		Oulu		Utsjoki	
	$max\ M_{index}$	F_{cond} [%]	$max\ M_{index}$	F_{cond} [%]	$max\ M_{index}$	F_{cond} [%]
4	0.01	6.16	0.01	6.70	0.01	1.93
5	0.14	4.35	0.18	5.49	0.02	0.58
6	0.01	6.76	0.02	7.44	0.01	2.23
7	0.16	4.77	0.17	6.06	0.02	0.91
8	0.40	15.34	0.67	18.24	0.14	7.14
9	5.96	26.42	5.99	29.99	5.59	16.67

In the case of applying interior boundary conditions according to EN ISO 13788:2012, the favorable environment for mould growth and evaluated mould growth risk values are slightly bigger. It means that according to presented study, the applied measured interior conditions ensure healthier conditions for the structure although in both cases the mould index represents no mould growth during the analyzed period at all inner points. The summary of the favorable conditions and maximal value of mould growth risk achieved during the analyzed period is given in the Table 2.

Table 2. M_{index} and Favourable Conditions Considering Standardized Interior Conditions.

Analysis point	Joensuu		Oulu		Utsjoki	
	$max\ M_{index}$	F_{cond} [%]	$max\ M_{index}$	F_{cond} [%]	$max\ M_{index}$	F_{cond} [%]
4	0.02	11.07	0.03	13.43	0.01	3.56
5	0.27	7.01	0.39	9.79	0.03	1.58
6	0.02	10.92	0.03	13.17	0.01	3.59
7	0.22	6.12	0.29	8.26	0.03	1.40
8	0.45	15.75	0.75	18.76	0.14	7.38
9	5.96	26.42	5.99	29.99	5.59	16.67

The highest mould index value was found on the exterior surface of the envelope. A development of mould index at point 8, located in the exterior air-gap between wind-proof board and exterior cladding are illustrated in the Figure 9.

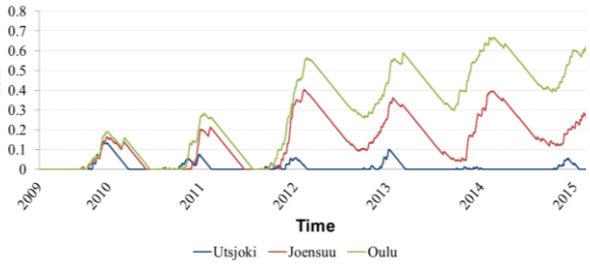

Figure 9. M_{index} in air-gap between the gypsum-board and exterior cladding (point 8 in Figure 3).

The highest mould index value was achieved on the exterior surface of the envelope. Differences in mould index development on the exterior surface of the envelope for the analyzed cities are figured in the Figure 10. At this point, notable differences in climatic variation can be seen. The humid climate in Oulu causes steeper developing of the mould index than Joensuu and Utsjoki climate. The lowest mould index is achieved in Utsjoki. It seems that for this 6-year period of analysis the houses built in all three locations are able to dry once wetted and the periods of high humidity are insufficient to cause significant issues. The ability of wall structure to dry once wetted is therefore critical to prevent significant problems and mould growth, as shown in our previous study (Fedorik *et al*, 2015).

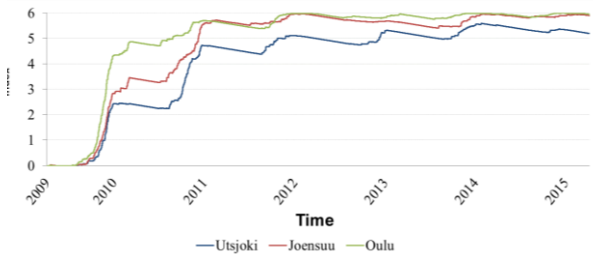

Figure 10. M_{index} on the exterior surface of envelope (point 9 in Figure 3).

7 Conclusions

The presented study presents analysis of climate effect on mould growth risk inside an envelope of timber-framed family house. As expected, the worst conditions for house health are achieved in coastal city of Oulu that has characteristically humid climate. The best results were found on climate located in the northernmost city of Finland Utsjoki, where low humidity and temperature cause unfavorable conditions for mould growth initiation.

Significant difference in numerical simulation of hygro-thermal conditions of buildings is made by defining the relevant boundary conditions. In addition, applying measured or standardized interior boundary conditions lead to different results, although none of them represents a danger of serious mould growth in the analyzed case. On the other hand, if more sensitive materials would be used, mould growth in a structure in humid environment may occur. Using one set of conditions to analyze a standard structure is likely to lead into misjudgment of the structural health if the actual location of the house is significantly different in its climate conditions.

Abstract

Modeling is a useful tool for decision making in the project phases. In the case of reinforced concrete structures, we must be able to locate representative parameters in order to optimize costs. This paper assesses the impact of the column arrangement and building height. The variation of the costs for the foundation and two floor interaxis are discussed. The results are assessed by the ratio of cost per square meter executed. The optimization of the geometry of the building is determined by the interaxis distances and the selected structural thickness. In the case studied the arrangement of the pillars in a 6x6 meters grid using 4 heights offers the best economic results.

Keywords: reinforced concrete, costs, columns arrangement, structures, modeling

1 Introduction

The decisions made in the early stages of a project have a significant impact on its future development. The economic costs can and should be dimensioned so that the investor has the smallest possible uncertainties. Despite this construction projects have a long deployment time that introduces those unwanted uncertainties. This work focuses on structural solutions through the use of reinforced concrete (Amir, 2013; CTE, 2006; CYPECAD, 2015).

The intensive application of reinforced concrete has been produced largely by the advancement and study of the behavior of new materials and the development of new technologies. This is the origin of structural engineering that deals with the conception, design and construction of structures emerged. We want to emphasize that in the same way that society evolves, technology, materials and available tools do (De Albuquerque *et al*, 2012; Delijani *et al*, 2015; EHE-08 2008).

The structural solution costs represent a significant percentage within any project. With an eye to the future by implementing algorithms it is necessary to know the impact of different variables that affect the final cost of a given solution (Fernández-Ceniceros *et al*, 2010; Kaveh *et al*, 2011; Koksal *et al*, 2013).

As representative geometric variables in the definition of one building they have been considered the number of pillars or columns and the height of the building. For the structural solution of the floors a bidirectional forged or slab structure recoverable coffer with a constant structural depth has implemented, but modifying the interaxis (Moretti, 2014; Poluraju *et al*, 2012; Porwal and Hewage, 2012).

This range of solutions is made by using three elements mainly: Concrete, steel and formwork elements.

2 Proposed Methodology

The proposed methodology focuses on assessing the economic impact incurred in the process of building a reinforced concrete structure assuming that the reticular forged recoverable coffer is selected for the horizontal structure. This choice is not accidental because, it presents some remarkable features:

- Materials incorporated to the structure are permanently only two, in this case steel and concrete. In all cases it is used concrete HA-25/P/20/IIa and steel B-500S.
- In this case the difference in the performance of each alternative is faithfully reflected in the variation of the quantities consumed of steel and concrete.
- The use of recoverable coffer.

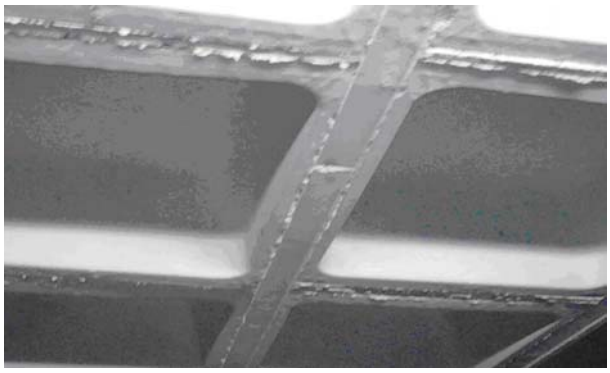

Figure 1. Final result after removal of the provisional formwork.

To execute these structures, once consolidated the pillars, a framework is used (Figure 1). Once the structure consolidates these elements are retrieved and used in subsequent structures. For the assessment of costs it is important to establish the number of uses. In this paper this variable is 50.

Obviously the cost of a structure will be lower when the material consumption are optimized (reducing the amounts of concrete and steel) and the use of formwork materials and labor.

The proposal is to make the modeling of a square building of dimensions 24x24 meters using different arrangements of columns and number of plants (Figure 2). For the arrangement of pillars three values of the grid have been selected: a situation of short lights of 4x4 meters, another common situation in building alternative of 6x6 meters, and 8x8 meters with overhead lights. The modeled cases include 4 floors, 6 floors, 8 floors and 10 floors. The buildings have a height on the ground floor of 4 meters and the rest of floor slabs with heights of 3 meters, devoting the last forged to a flat roof.

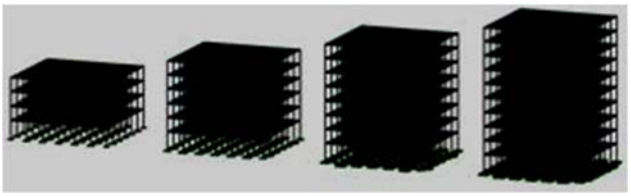

Figure 2. Modelling buildings.

All the floors have been solved using a structural depth of 30 centimeters (25 of box more 5 cm of compression layer). The distances of the models are varied using two discrete solutions of 60 and 80 centimeters (Figure 3), the width of nerve and the coating remained constant. Thus the own weights of the two alternatives of the implemented floor slab are 4.70 kN/m^2 and 4.03 kN/m^2 respectively.

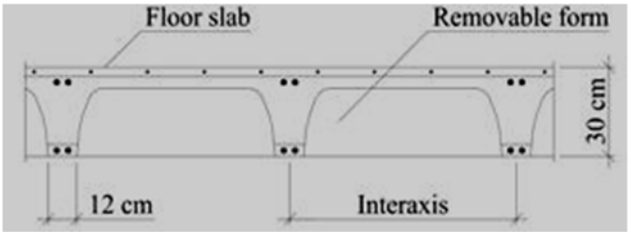

Figure 3. Alternative sections of implemented floors.

Regarding the considered loads, facade loads have been introduced as uniform loads on the perimeters of the floors with a value of 7 kN/m, and on deck this value is reduced to 3 kN/m. For surface loads on the floors 2kN/m^2 has been considered for permanent loads and 2kN/m^2 for overhead use. In the cover these values have changed, 3 kN/m^2 for permanent loads and 1kN/m^2 for overload use. Wind loads were implemented considering the Spanish legislation and snow loads are included in overload considered indoor use. For dimensioning the foundation, it has been considered an average benefit in the soil bearing capacity, on the maximum permissible stress, 0.2 N/mm^2.

Table 1. Unit Cost Items Considered.

Description	**Cost (€)**
m² System formwork foundation plinth.	19.94
m² lean concrete layer (thickness 0.1 m).	10.22
m^3 foundation of reinforced concrete, concrete made with HA-25/P/20/IIa manufactured in plant, and discharge from truck.	104.70
Reinforcing steel kg UNE-EN 10080 B 500 S, developed in industrial workshop. Including transportation and placement work.	1.00
m^3 of concrete for pillars made of concrete HA-25/P/20/IIa manufactured in central and poured with cupolas, assembly and disassembly of reusable formwork system metal sheets.	349.65
Reticular m², total depth 30=25+5 cm, made with concrete HA-25/P/20/IIa manufactured in central; discharge with pump on continuous formwork system; nerves "in situ" 12 cm, welded wire in compression layer. No impact of pillars.	37.60
Unites of recoverable formwork PVC, 76x80x25 cm for 50 uses, including special pieces.	2.29
Unites of recoverable formwork PVC, 56x60x25 cm for 50 uses, including special pieces.	1.75
m^3 of concrete for slabs manufactured in Central HA-25/P/20/IIa.	76.88

The definition of the structure will be made following the Spanish legislation and using a structural calculation software tool named CYPECAD. Performing calculations provides data on the consumption of materials, which in the selected type represent significant values used in the comparison. By using a database of construction, the prices of each of the studied alternatives are obtained.

Table 2. Items Considered for Each Block Of The Structure.

	items	**units**
foundation	Cleaning concrete HL-15 / P / 20	m^3
	Reinforcing steel B 500 S	kg
	Concrete HA-25 / P / 20 / IIa	m^3
	Shuttering fundation	m^2
columns	Column formwork	m^2
	Reinforcing steel B 500 S	kg
	Concrete HA-25 / P / 20 / IIa	m^3
floor	Formwork wrought	m^2
	Reinforcing steel B 500 S	kg
	Concrete HA-25 / P / 20 / IIa	m^3
	boxes	units

The cost of the structure is divided into three sections: foundation, pillars or columns and floor. This scheme follows the construction process, and the prices for the various items are presented in Table 1.

These prices combined with the results of consumption of each alternative allow us to obtain the costs of the proposed solutions. Table 2 lists the items that are incorporated in each block with the units used.

		10	71.244	52.629	448.337	572.209	96,9

3 Objective

The main objective is to have a vision of the cost of the entire structure. The inclusion of three variables will allow to compare different alternatives and select the one that is most viable from the economic point of view.

The novelty lies on the inclusion of variations in the geometry of the building (arrangement of the pillars and building height) combined with the definition of the structural solution used (forged 60x60 and 80x80 centimeters interaxis).

To facilitate the monitoring of the cost of the structure it has been divided into three blocks with a different treatment. The foundation with four blocks for the lean concrete, steel foundation, structural concrete and formwork needed. The pillars are elements with a production process in which the cleaning concrete disappears, repeating the previous three blocks and presenting totally different yields.

4 Case study

Performing calculations by regulations currently in use in Spain determines the technically viable alternatives. From those viable solutions, material consumption are found: steel, concrete and auxiliary elements (formwork and caissons) at different values for each block of the structure; the data are reflected in Table 3. The modeling analysis allows controlling deformations and adapting the optimal arrangement of the structure, all rigorously complying with current regulations.

Known data set consumption and prices of each item can determine the cost of each alternative as reflected in Table 4.

The production cost is done add the amount of each item. In this case we have taken into account the variations in consumption of both materials and auxiliary means necessary.

The total cost of the structure has been obtained and the graphical representation of the results is divided into two blocks. Figure 4 represents the impact of each block in each studied alternative.

For this configuration of the floor inside buildings of four floors, solution employing fewer supports (8x8) has a total cost that is 13.43% higher than the alternative with the highest number of supports (4x4). In the case of solutions for buildings of 10 floors this difference becomes greater resulting in a 16.26%. If we analize the results in regard to the foundations these values are completely different in low buildings since the cost of the foundation is increased by 97.83% whereas in tall buildings the decreased number of pillars an increase of 38.21%. Reducing the number of supports makes the starting pillars decrease.

With 60x60 interaxis configuration total costs increase as the number of carriers it is reduced for all modeled buildings.

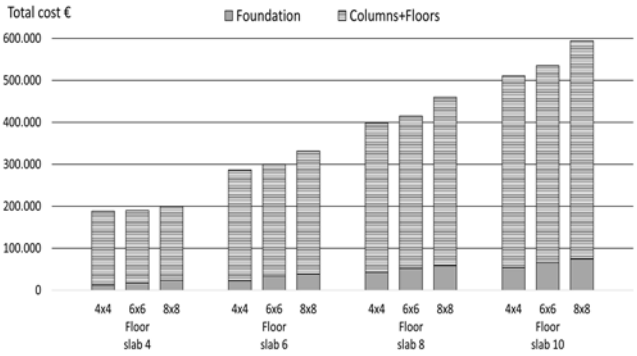

Figure 4. Total cost alternatives interaxis 60x60.

The results for structural solutions that employ larger interaxis (80x80) are shown in Figure 5.

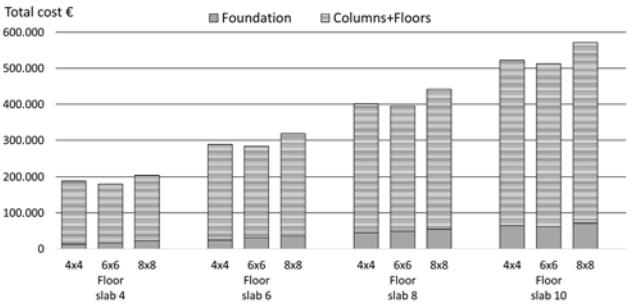

Figure 5. Total cost alternative interaxis 80x80.

For this configuration of the floor inside buildings of four floor employing fewer supports (8x8) has a total cost which is 8.59% higher than the alternative with the highest number of supports (4x4). In the case of buildings of 10 floors this difference becomes greater resulting in a 9.47%. If we analyze the results in regard to the foundations these values are completely different in low buildings since the cost of the foundation is increased by 71.90% whereas in tall buildings the decreased number of pillars drives to an increase of 10.44%. Reducing the number of supports makes the starting pillars decrease and the cost of the slabs being greater increases in recent increases.

This configuration of the floor, increasing the interaxis, allows better solutions in total cost when the 6x6 grid for the same height of the building is implemented. In the four heights minimum cost values are obtained.

Solutions with more supports (4x4) have similar costs for both interaxis being lower in 60. The differences are below 2.40%. Solutions with fewer brackets (8x8) costs are similar, being lower in 80. The resulting differences are extended below 4.01%.

While these results are interesting, we consider much more relevant to compare the ratios of the structural solution. In this case the cost per executed square meter is analyzed, and the numerical results are reflected in the

last column of Table 4, while graphical results are presented jointly for both interaxis in Figure 6.

The extreme values have a variation of 31.72% and are:

- The minimum cost 76.3 € / m2 for a building of 4 heights with me interaxis 6x6 grid 80 cm.
- The maximum cost 100.5 € / m2 for a building of 10 heights with me interaxis 8x8 grid 60 cm.

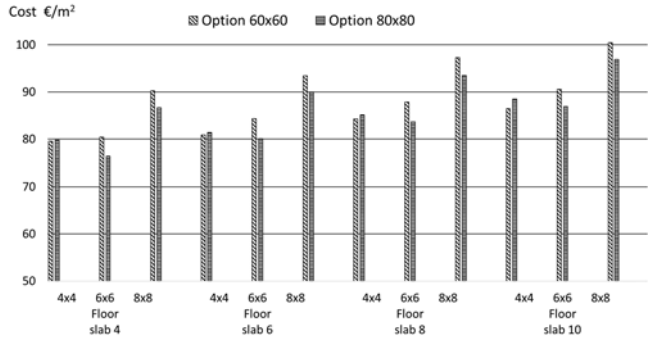

Figure 6. Ratio of cost € / m2 different alternatives.

Interaxis solutions by 60 cm range from 79.6 € / m2 for buildings of 4 heights and 4x4 grid to 100.5 € / m2 in the case of 10 heights and 8x8 grid. This is a variation of 26.26%. For proposals by interaxis 80 cm range from 76.3 € / m2 for buildings of 4 heights and 6x6 grid to 96.9 € / m2 in the case of 10 heights and 8x8 grid. This is a variation of 27.00%.

5 Conclusions

As a preliminary conclusion, it is noteworthy that variations make that the results present significant oscillations. The own reinforced concrete structural definition incorporates decisions affecting the cost produced in the design phase and implementation.

The tool implemented here is very useful when combined and incorporated the cost or impact of the land on which it is intended to build. The combination of both values allows the designer to locate a lower cost alternative.

Disregarding the impact of the land, and for a structural thickness of 30 centimeters, the most economical solutions are located in low buildings of 6x6 meters grid and interaxis distances of 80 centimeters. The worst alternative is located when employed 60 centimeters interaxis and reticles of 8x8 meters.

Structurally, the 30 centimeter thickness is oversized for reticles of 4x4 meters and it presents very high amounts of steel for reinforcement grids of 8x8 meters. This is the reason why the best solutions appear in the grid of 6x6 meters. This phenomenon is more pronounced when increasing the interaxis distances. This is one of the reasons why this is the most used structural thickness in structures in buildings in Spain.

This novelty presents a clear practical application to real cases, since the casestudy has been selected only as a way to present the proposed methodology based on the ratio of cost per square meter executed, but the methodology is widely applied to real cases. In fact, this piece of research is based on the information obtained from thousands of real cases, from a building interprise, which have also been used to validate the proposal.

Furthermore, the use of the results of this work by the designer permits the optimization of the decisions based on the conclusions obtained in the general case.

Efficiency of QEs in USA Through Estimation of Precautionary Money Demand

Yoji Morita Shigeyoshi Miyagawa

Department of Economics, Kyoto Gakuen University, Japan, {morita-y,miyagawa}@kyotogakuen.ac.jp

Abstract

FRB adopted "quantitative monetary easing" three times as QE1 (2008m11,2010m06), QE2 (2010m11,2011m06) and QE3 (2012m09,2014m12). In this paper, we showed that "Reserve at the FRB" is effective to the economy through a transmission path of a stock market in QE1, effective through housing price channel in QE2 and QE3, and effective through an exchange rate channel in QE3, where impulse responses in VAR model are calculated with "reserve, stock prices, exchange rate, industrial production, and cpi_core (or housing price)" in monthly data of USA.

Furthermore, we investigated behaviors of M2 money in QEs periods. Decomposing M2 into transaction money demand and precautionary one, we estimated precautionary money demand as a function of industrial production, business condition denoted by napm and reserve at the FRB. We showed that increasing "Reserve at the FRB" is comparatively effective in QE1 rather than in QE2 and QE3 through the behavior of napm.

Keywords; QE1, QE2, QE3, nontraditional monetary policies

1 Introduction

The subprime problem in 2007 and Lehman crisis in 2008 caused serious depressions in the world economy. Many central banks set interest rates around zero, and carried out "nontraditional monetary policies" in large scales. Generally speaking, operation of short term interest rates based on for example Taylor rule is called "traditional monetary policy", while in financial crisis of these days a traditional monetary policy has no room to operate around zero interest rates, and hence, many central banks were forced to adopt nontraditional monetary policies. There are three kinds of nontraditional monetary easing in USA.

Federal Reserve Board (FRB) decreased FF rate from 2 % at Lehman crisis (2008m09) to 0-0.25 % (2008m12). Furthermore, additional easing policies were done by operations of buying long term government bond, Residential Mortgage-Backed Securities (RMBS) and agency debt. FRB called these policies as "Credit Easing" in the interval (2008m11,2010m06). We denote these monetary easing in this period as QE1. FRB carried out QE2 during (2010m11,2011m06), where long term government bonds of 600 billion dollars were purchased. QE3 was operated during (2012m09,2014m10), where FOMC decided on 2012m12 to buy MBS of 40 billion dollars and long term government bonds of 45 billion dollars per month. However, from 2014m01, FRB gradually decreased buying operations every month and stopped QE3 on 2014m10.

(Bernanke, 2009) said that the essence of QE1 is "credit easing", that is, reducing the cost of private brrowing by direct purchases of privately issued debt instead of government debt. (Gagnon et al., 2011) reported that large-scale asset purchases in QE1 have been successful in doing lower longer term private borrowing rates, which should stimulate economic activity. (Fratzscher et al., 2013) showed highly effectiveness of QE1 compared with QE2 and analysed the global spillovers of the FRB's QE. International spillover effects of US QE were investigated by (Bhattarai et al., 2015). (Wen, 2014) studied the likely impact of QE and its exit strategy with three aspects; (i)the timing of the exit, (ii)the pace of the exit and (iii)the private sector's expectations of when and how the FRB will exit. (Engen and Reifschneider, 2015) showed that by the unconventional monetary policies in USA the peak unemployment effect does not occur until early 2015, while the peak inflation effect is not anticipated until early 2016.

(Hall et al., 2012) analyzed European economy including financial crises 2007 and 2008, focusing on the stability of M3 money demand function through a generalized cointegration concept "TVC". (Fawley and Neely, 2013) described the circumstances of and motivations for the quantitative easing programs of the FRB, Bank of England, European Central Bank, and Bank of Japan during the recent financial crisis and recovery.

Efficiency of QE in Japan during (2001,2006) was shown by (Honda et al., 2007) through transmission paths of both stock market and exchange rate. They used SVAR model. (Sawada, 2014) applied Honda's method to USA case and showed that base money operated at QEs are efficient to the economic activity.

First, in this paper, following (Honda et al., 2007) and (Sawada, 2014), we construct VAR models with 5 variables (reserves, stock prices, exchange rate, industrial production, cpi) in QE1, QE2 and QE3, and investigate the efficiency from "reserves" to "industrial productions" through transmission paths of stock market, exchange rate and/or housing price in each of QEs.

Secondly, focusing our attention on money demand function of "M2", we decompose "M2" into precautionary

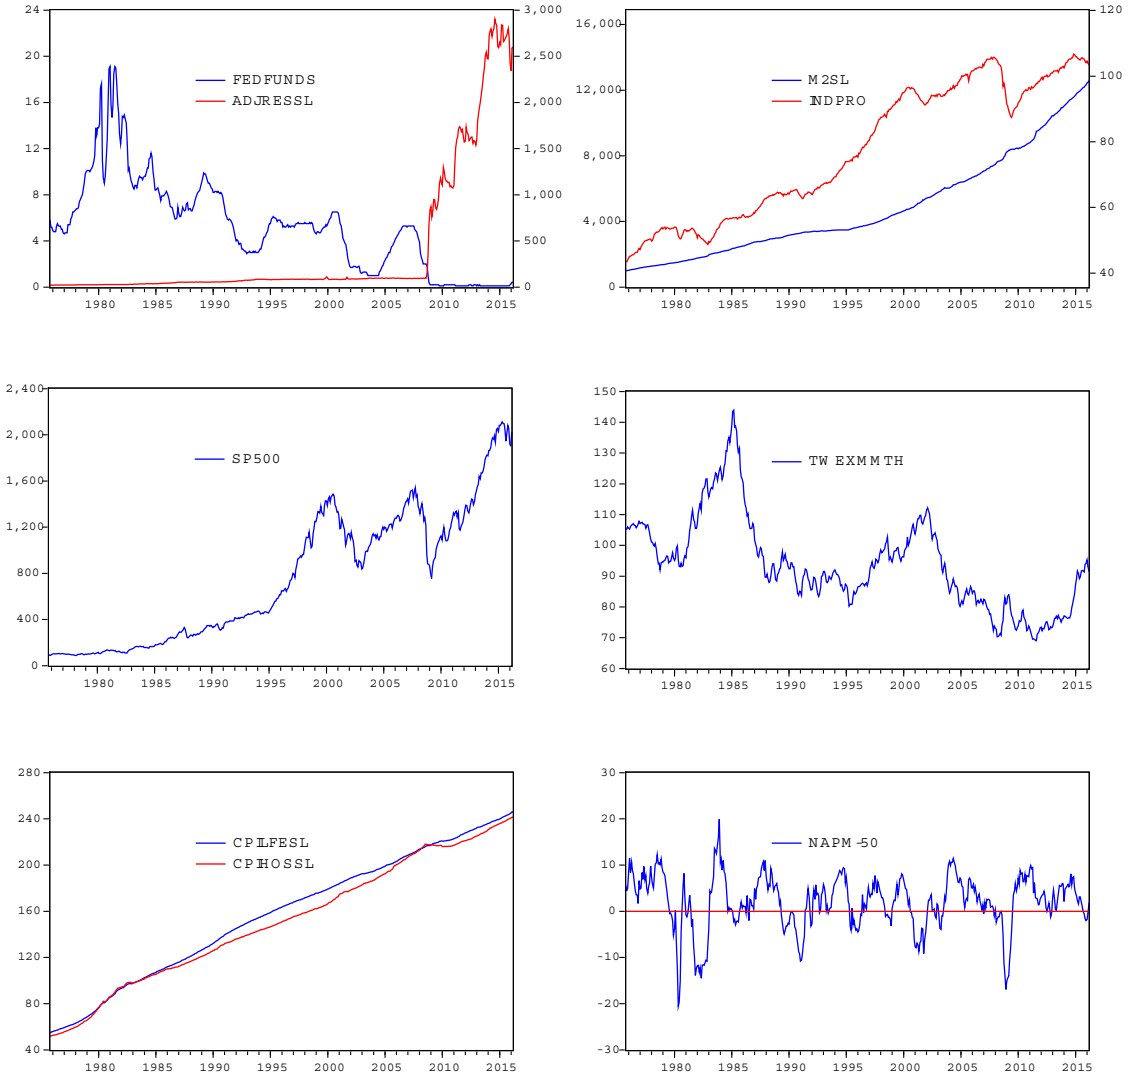

Figure 1. $fedfunds(t)$ and $adjressl(t)$, $indpro(t)$ and $m2sl(t)$, $sp500(t)$, $twexmmth(t)$, $cpilfesl(t)$ and $cpihossl(t)$, and $u(t)$ in (1975m10, 2016m03)

and transaction money demands and estimate precautionary one as a function of economic activity, reserves and business condition during (1975m10,2016m03). Thus, we can investigate behavior of M2 money in QEs. Since (Morita and Miyagawa, 2016) estimated precautionary money demand and analyzed QE monetary policy in Japan with quarterly data, we apply this method to the analysis of US data.

2 Data Properties

Monthly data through (1975m10, 2016m03) are obtained from FRED. Variables and symbolic notations are given in Table 1. See Figure1 for behavior of each variable.

Two kinds of unit root tests are carried out; DF-GLS (ERS) test with unit root as the null hypothesis and KPSS test with stationarity as the null hypothesis. The results are shown in Table 2. Every variable except $u(t)$ is shown to be nonstationary. Hereafter, we treat these variables in

Table 1. List of variables

$adjressl(t)$ = St.Louis adjusted reserves
$fedfunds(t)$ = federal funds rate
$m2sl(t)$ = M2 money stock
$indpro(t)$ = industrial production index
$cpilfesl(t)$ = consumer price index, less food & energy
$cpihossl(t)$ = consumer price index, housing
$sp500(t)$ = S&P500 index
$twexmmth(t)$ = trade weighted exchange index
$napm(t)$ = ISM manufacturing, PMI composite index
$u(t) = napm(t) - 50$
$u_-(t) = \min\{u(t), 0\}$ $\quad$ $u_+(t) = \max\{u(t), 0\}$

Table 2. Unit Root Test in $(1975m10, 2016m03)$

var.	ERS	*lag*	KPSS	*trend*
$\ln(m2sl/p)$	4.98	2	2.51∗	*const.*
$\ln(indpro)$	1.52	3	2.72∗	*const.*
$\ln(sp500/p)$	-2.02	1	0.29∗	*trend.*
$\ln(twexmmth)$	-1.32	1	1.47∗	*const.*
u	$-4.33*$	2	0.01	*const.*
$\ln(adjressl/p)$	0.92	2	1.66∗	*const.*
$\ln(p)$	0.24	9	2.61∗	*const.*
$\ln(cpihossl)$	0.61	9	2.62∗	*const.*

∗ denotes 1% significance level and $p = cpilfesl$.

levels in order to avoid cointegration analysis.

3 Macro Money Systems in QEs

Letting $x = (\ln(adjressl) - \ln(p),\ \ln(sp500) - \ln(p),\ \ln(twexmmth),\ \ln(indpro),\ \ln(p))'$, we consider VAR model of the form with the lag order i given by AIC,

$$x(t) = A_0 + A_1 x(t-1) + \cdots + A_i x(t-i) + \varepsilon(t), . \qquad (1)$$

3.1 Behavior in QE1=(2008m11,2010m06)

Setting sampling interval as QE1, impulse responses of (1) are depicted in Figure 2, where a solid line implies a calculated impulse response and two dotted lines show 95 % confidence intervals. For economy of space, we only show responses of 5 variables corresponding to three kinds of impulse shocks; ”reserves“, ”sp500“ and ”exchange rate (twexmmth)“.

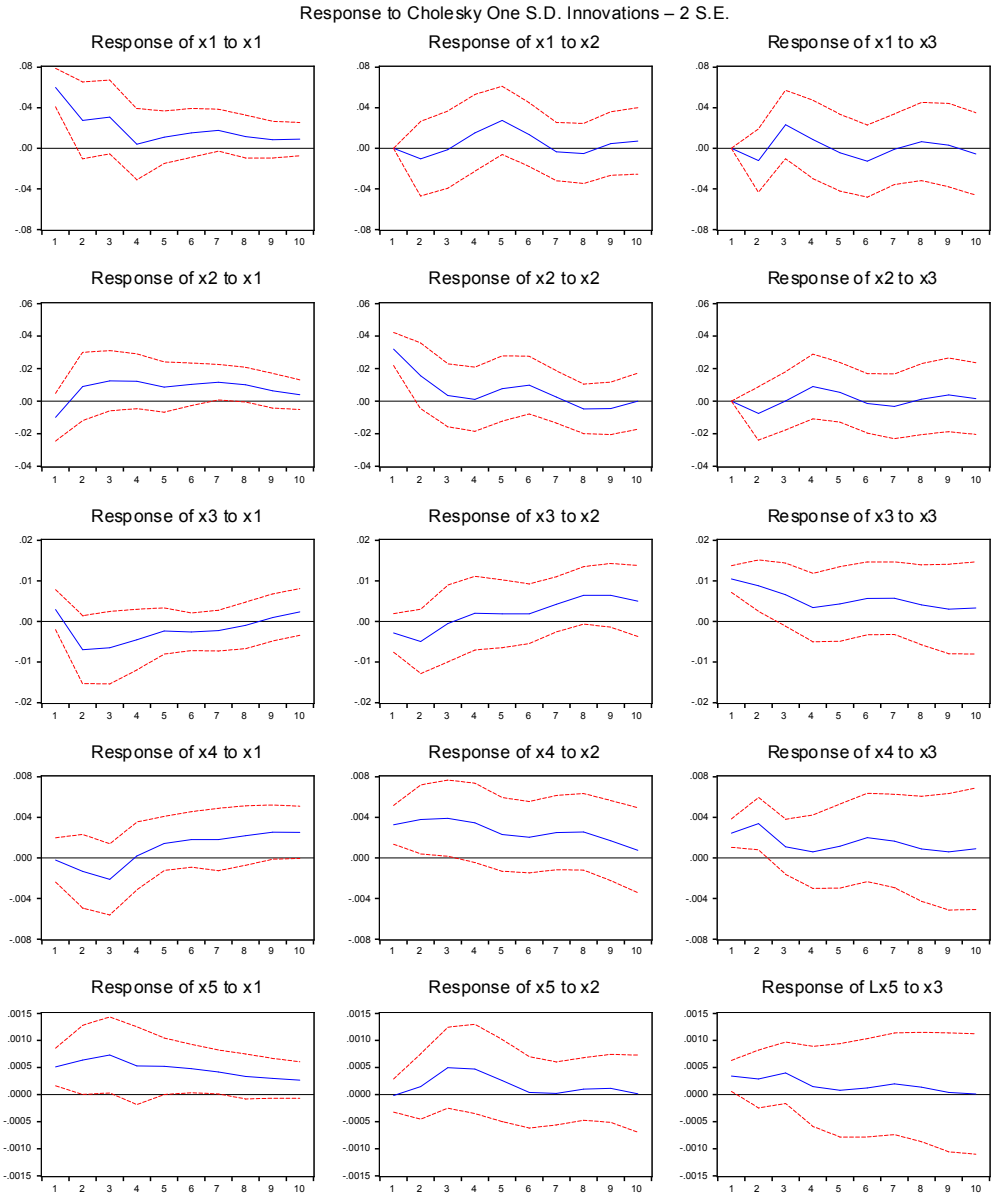

Figure 2. Impulse responses of the system with $x = (x_1, x_2, x_3, x_4, x_5)'$, where in the figure we denote $x_1 = \ln(adjressl/p)$, $x_2 = \ln(sp500/p), x_3 = \ln(twexmmth), x_4 = \ln(indpro), x_5 = \ln(p)$ in QE1=(2008m11,2011m06).

Hereafter, if necessary, we abbreviate *reserves* and *twexmmth* by *rsrvs* and *rex* respectively.

1st:	$rsrvs(\uparrow) \Longrightarrow$	$rsrvs(\uparrow)$	$stock(\cdots\uparrow)$
	$rex(\downarrow)$	$indpro(\cdots\uparrow)$	$p(\uparrow)$
2nd:	$stock(\uparrow) \Longrightarrow$	$rsrvs(\cdots)$	$stock(\uparrow)$
	$rex(\cdots)$	$indpro(\uparrow)$	$p(\cdots)$
3rd:	$rex(\uparrow) \Longrightarrow$	$rsrvs(\cdots)$	$stock(\cdots)$
	$rex(\uparrow)$	$indpro(\uparrow)$	$p(\uparrow)$

where $rex = twexmmth(\uparrow)$ implies "high appreciation of dollar", and where $(\cdots)$ and $(\cdots\uparrow)$ mean "statistically not significcant" and "at first not significant but after several months significantly $\uparrow$" respectively.

We can see that $reserves(\uparrow) \rightarrow indpro(\uparrow)$ on the 1st column, and that $reserves(\uparrow) \rightarrow stock(\uparrow) \rightarrow indpro(\uparrow)$ on the 1st and 2nd columns. It should be noticed, however, that $reserves(\uparrow) \rightarrow rex(\downarrow) \not\rightarrow indpro(\uparrow)$ on the 1st and 3rd columns. Therefore, we can conclde that there is a transmission path in QE1 through a stock market, but not through exchange rate.

3.2 Behavior in QE2+α=(2010m11,2012m08)

Since QE2 is too small to construct VAR model, we extend the sampling interval QE2 to $QE2+\alpha = (2010m11, 2011m06) + (2011m07, 2012m08)$ just before starting QE3.

Impulse responses of (1) are depicted in Figure 3, where a solid line implies a calculated impulse response and two dotted lines show 95 % confidence intervals.

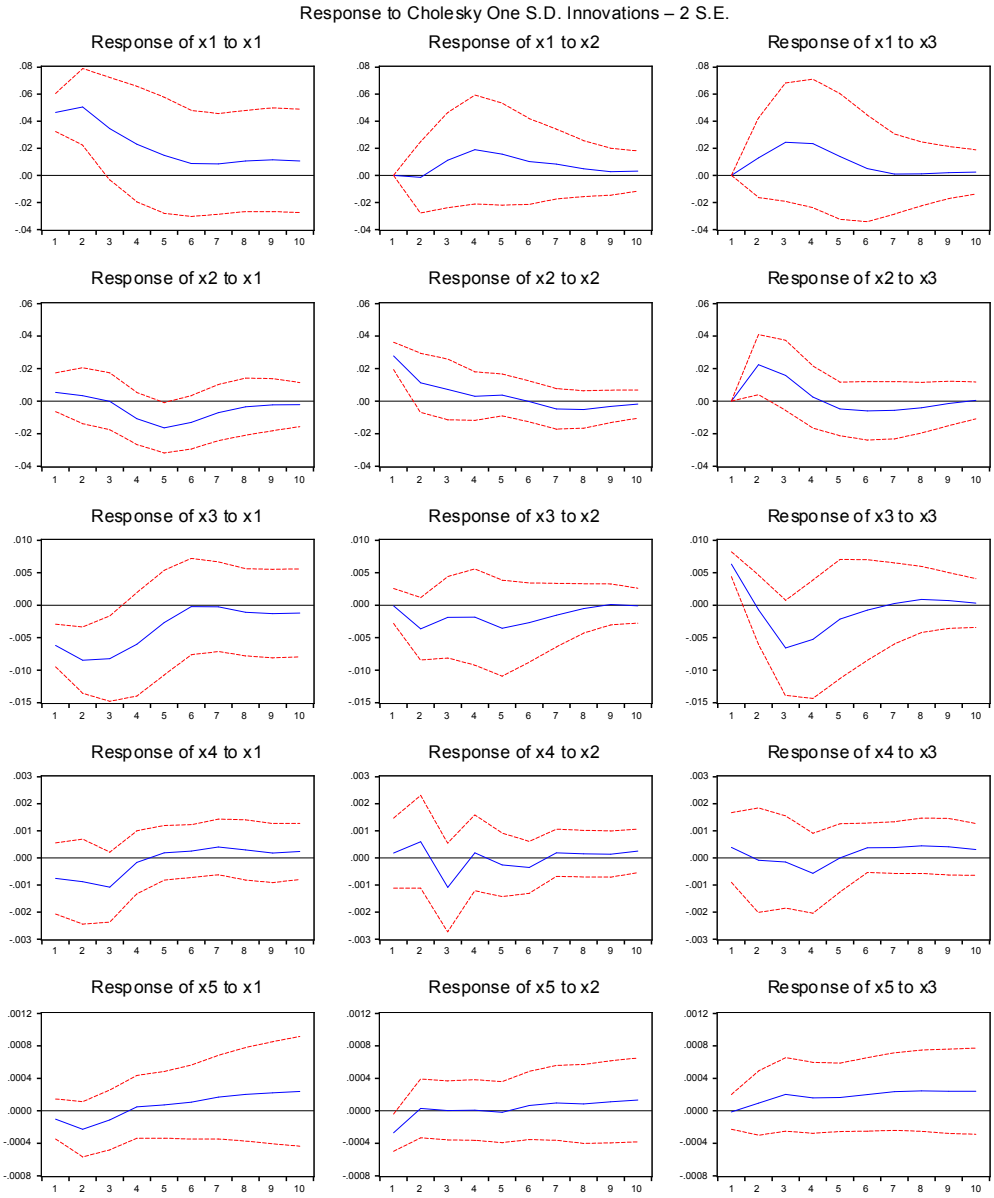

Figure 3. Impulse responses of the system with $x = (x_1, x_2, x_3, x_4, x_5)^{'}$, where in the figure we denote $x_1 = \ln(adjressl/p)$, $x_2 = \ln(sp500/p), x_3 = \ln(twexmmth), x_4 = \ln(indpro), x_5 = \ln(p)$ in $QE2+\alpha = (2010m10, 2012m08)$.

Responses of 5 variables are shown, corresponding to three kinds of impulse shocks; ”reserves“, ”sp500“ and ”exchange rate (twexmmth)“.

1st:	$rsrvs(\uparrow) \Longrightarrow$	$rsrvs(\uparrow)$	$stock(\cdots\downarrow)$
	$rex(\downarrow)$	$indpro(\cdots\downarrow)$	$p(\cdots)$
2nd:	$stock(\uparrow) \Longrightarrow$	$rsrvs(\cdots)$	$stock(\uparrow)$
	$rex(\cdots)$	$indpro(\cdots)$	$p(\downarrow)$
3rd:	$rex(\uparrow) \Longrightarrow$	$rsrvs(\cdots)$	$stock(\uparrow)$
	$rex(\uparrow)$	$indpro(\cdots)$	$p(\cdots)$

In this period of QE2, we cannot say any transmission path from $reserves(\uparrow)$ to $indpro(\uparrow)$.

3.3 Behavior in QE3=(2012m09,2014m10)

Setting sampling interval as QE3, impulse responses of (1) are depicted in Figure.4, where a solid line implies a calculated impulse response and two dotted lines show 95 % confidence intervals. For economy of space, we only show 5 variables responses corresponding to three kinds of impulse shocks; ”reserves“, ”sp500“ and ”exchange rate (twexmmth)“.

1st:	$rsrvs(\uparrow) \Longrightarrow$	$rsrvs(\uparrow)$	$stock(\uparrow)$
	$rex(\downarrow)$	$indpro(\cdots)$	$p(\cdots)$
2nd:	$stock(\uparrow) \Longrightarrow$	$rsrvs(\cdots)$	$stock(\uparrow)$
	$rex(\cdots)$	$indpro(\downarrow)$	$p(\cdots)$
3rd:	$rex(\uparrow) \Longrightarrow$	$rsrvs(\cdots)$	$stock(\cdots)$
	$rex(\uparrow)$	$indpro(\downarrow)$	$p(\downarrow)$

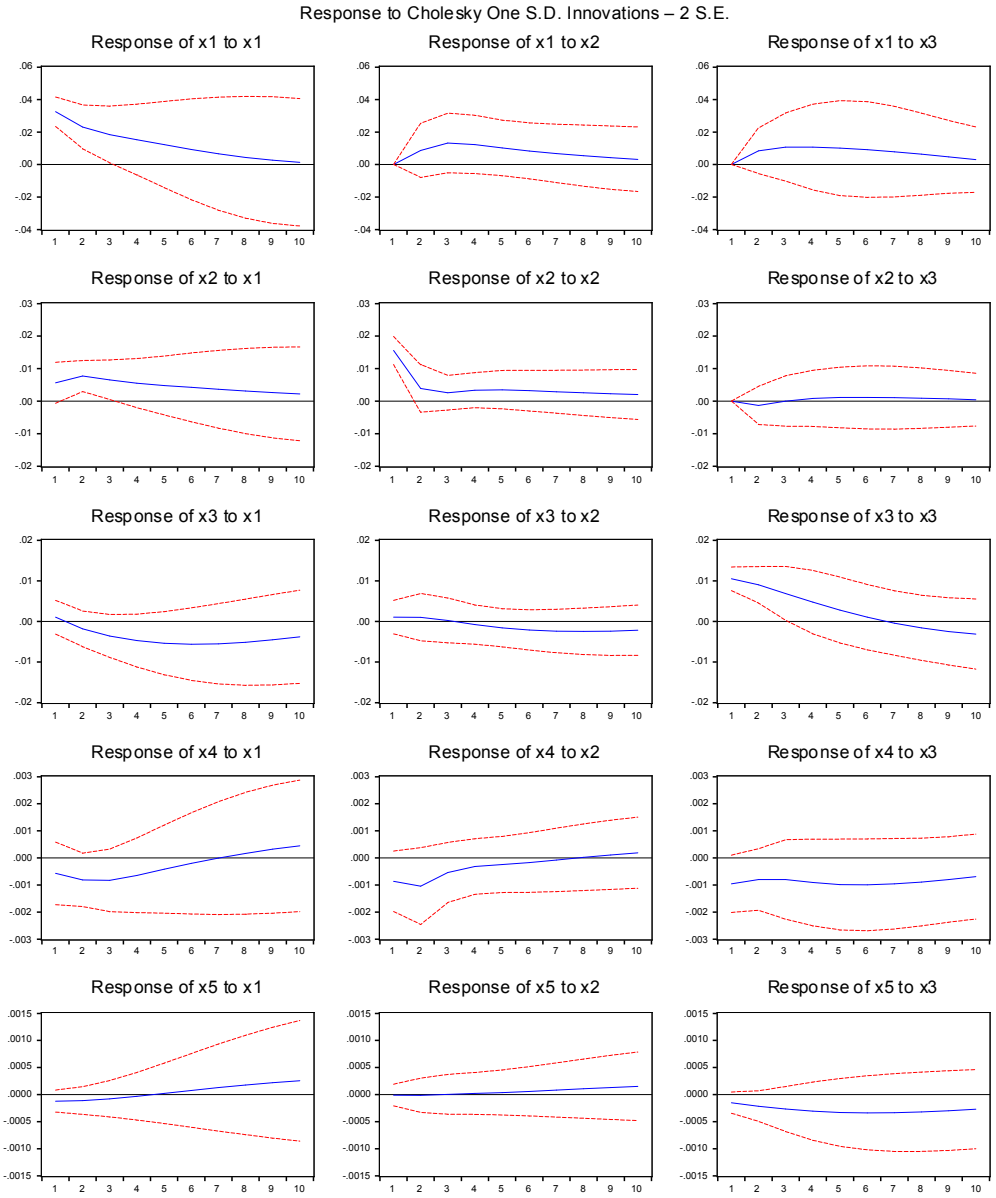

Figure 4. Impulse responses of the system with $x = (x_1, x_2, x_3, x_4, x_5)^{'}$, where in the figure we denote $x_1 = \ln(adjressl/p)$, $x_2 = \ln(sp500/p), x_3 = \ln(twexmmth), x_4 = \ln(indpro), x_5 = \ln(p)$ in QE3=(2012m09,2014m10).

We can see that $reserves(\uparrow) \to rex(\downarrow) \to indpro(\uparrow)$ on the 1st and 3rd columns, while we can see that $reserves(\uparrow) \to stock(\uparrow) \not\to indpro(\uparrow)$ on the 1st and 2nd columns.

Therefore, we can conclude that there is a transmission path in QE3 through exchange rate, but not through a stock market.

4 Transmission Path of Housing Price from Reserve to Economic Activity

In this section, we consider the influence of housing price to the economy. Defining, in (1), $x = (\ln(adjressl/p), \ln(indpro), \ln(cpihossl))'$ and estimating VAR model, we can obtain impulse responses corresponding to the sampling intervals $QE1$, $QE2+\alpha$ and $QE3$. Remark that 5 variables VAR model with $\ln cpilfesl$ replaced by $\ln cpihossl$ in the preceding section gives us a similar result as in this section with 3 variables. For economy of space, we only show the results without figures of impulse responses.

We can see that
(QE1) $reserve(\uparrow) \not\to cpihossl(\uparrow)$,
($QE2+\alpha$) $reserve(\uparrow) \to cpihossl(\uparrow) \to indpro(\uparrow)$,
(QE3) $reserve(\uparrow) \to cpihossl(\uparrow) \to indpro(\uparrow)$.

So, we can conclude that there is a transmission path through housing price in QE2 and QE3, not in QE1.

5 Decomposition of $M2$ into Transaction and Precautionary Money Demands in (1975m10, 2016m03)

In this section, we statistically quantify how much money contributed to the recovery of the economy when the FRB increased reserves. We would decompose the money stock denoted by $m2sl(t)$ into the transaction money and the precautionary money demands.

5.1 Estimation of Precautionary Money Demand

Precautionary money demand will increase when the liquidity concern among the private sector intensify in the depression, while its demand will decrease when the concern dispels in the boom. We use here the $u(t) = napm(t) - 50$, where $napm(t)$ implies "ISM manufacturing: PMI composite index" in order to qualify the unobservable variable, which would affect the precautionary money demand.

Properties of precautionary money demand can be listed as follows:

[Properties of prec. money demand]

- $indpro(\uparrow) \Longrightarrow prec.\ money\ demand(\uparrow)$ as Keynes said.
- $prec.\ money\ demand(\uparrow)$ for future anxiety when economy is in depression.
- prec. money demand is affected by reserves in QEMP.

[Assumption of prec. money demand]

$$\begin{aligned} & prec.\ money\ demand(t) \\ = \ & c_1 * indpro(t) * cpilfesl(t)/1000 \\ + \ & (c_2 * u_n(t) + c_3 * u_p(t)) * \frac{m2sl(t)}{1000} \\ + \ & c_4 * adjressl(t) * dummy_{adjressl}(t) \end{aligned} \tag{2}$$

In the above assumption, the 2nd term on the RHS means that the precautionary money demand is a function of napm, because people try to hold more money when financial anxiety rises, and that the demand may depend on the level of M2. The 3rd term represents effect of the FRB's monetary policies. We take into consideration the policy change by adding the dummy variable. The reserves began to be increased by FRB from September 2008. We have set both of $ff\ rate$ and $adjressl$ as monetary policies, but $ff\ rate$ was not significant, and was deleted in (2). Dummy variable denoted by $dummy_{adjressl}(t)$ in (2) takes value 1 for $t = (2008m09, 2016m03)$ and takes value 0 otherwise.

[Log-likelihood function] The growth rate model of $indpro(t)$ is taken into consideration, and the log-likelihood function of $\Delta\ln(indpro)$ should be maximized with respect to every parameter containing prec. money demand, where in the following equation "$prec.\ money\ demand(t)$" is abbreviated by "$prc.\ mny(t)$".

$$\begin{aligned} & \Delta\ln(indpro(t)) = d_1 * \Delta\ln(indpro(t-1)) \\ + \ & d_2 * \Delta\ln(indpro(t-2)) + d_3 * \Delta\ln(indpro(t-3)) \\ + \ & d_4 * \Delta\ln((m2sl(t-1) - prc.mny(t-1))/p(t-1)) \\ + \ & d_5 * \Delta\ln((m2sl(t-2) - prc.mny(t-2))/p(t-2)) \end{aligned} \tag{3}$$

Table 3 shows estimation results in (2) and (3) .

Table 3. Estimation results of (2) and (3) in $(1975m10, 2016m03)$

	coefficients	*std.error*	*z-statistics*	*prob.*
c_1	143.46	140.57	1.021	0.3074
c_2	-11.82	4.905	-2.410	0.0160
c_3	-4.847	3.256	-1.489	0.1365
c_4	1.003	0.345	2.907	0.0036
d_1	0.118	0.048	2.450	0.0143
d_2	0.176	0.0518	3.399	0.0007
d_3	0.247	0.0389	6.355	0.0000
d_4	0.0425	0.0290	1.468	0.1422
d_5	0.0340	0.0255	1.335	0.1819

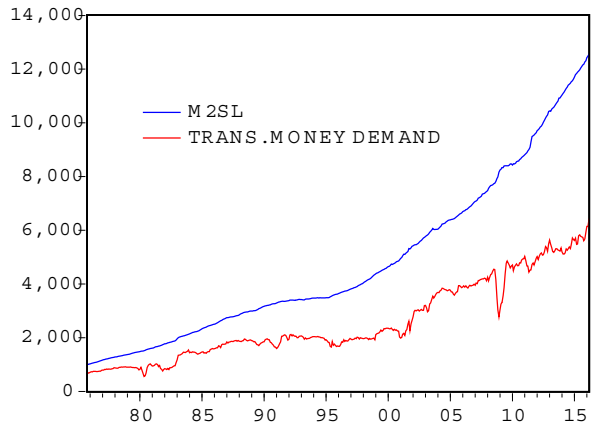

Figure 5. *m2sl* and *trans.money demand* estimated in (1975m10, 2016m03)

Figure 5 shows the nominal money stock *m2sl* and the trans. money demand. The difference "*m2sl* − *trans. money demand*" measures the prec. money demand. We find that the difference begins to expand rapidly around 1995, 2000 and 2008.

Figure 6 depicts the comparison of trans. money demand with prec. one in (2008m09, 2016m03) including QE1,QE2 and QE3. In this figure during the QEMP period, prec. money demand as well as trans. money demand gradually increases except for the beginning of QE1. In the zero interest rates period, there may exist the phenomena of "Liquidity trap" such that easing money by the central bank is only saved without consumption. However, in our estimation, prec. money demand increases while trans. money demand is also increasing. We may insist that the "Liquidity trap" does not exist in QEMP period.

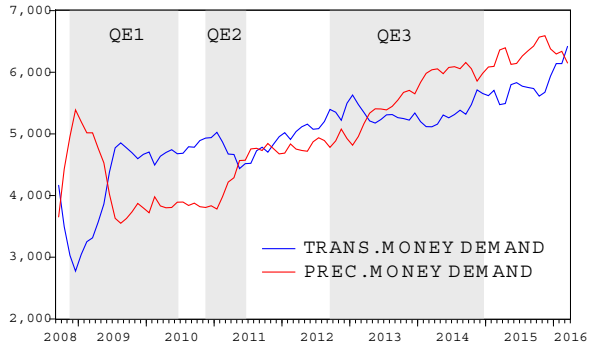

Figure 6. Estimation results of *trans. money demand* and *prec. money demand* in (2008m09, 2016m03)

5.2 The Role of Business Condition $u(t) = napm - 50$ in Transmission Mechanism of QEMP during $QE1, QE2+\alpha$ and $QE3$

We estimate VAR model of $y = (\ln(adjlfesl(t)),\ u(t),\ \ln(trns.\ mny\ dmnd(t)),\ \ln(prc.\ mny\ dmnd(t))^{'}$ with x replaced by y in Eq.(1) . We focus on the role of $u(t)$ in the transmission mechanism of easing monetary policy. Figures 7, 8 and 9 show impulse responses to a one standard deviation shock to four variables in periods of QE1, $QE2+\alpha$ and EQ3 respectively.

In QE1, we can see the following behavior:

1st:	$\ln(adjressl)(\uparrow) \Longrightarrow$	$adjressl(\uparrow)$
	$u(\cdots\uparrow)$	$trns.mny(\downarrow\uparrow)$
	$prc.mny(\uparrow)$	
2nd:	$u(\uparrow) \Longrightarrow$	$\ln(adjressl)(\cdots)$
	$u(\uparrow)$	$\ln(trns.mny)(\uparrow)$
	$ln(prc.mny)(\downarrow)$	
3rd:	$\ln(trns.mny)(\uparrow) \Longrightarrow$	$\ln(adjressl)(\downarrow)$
	$u(\uparrow)$	$\ln(trns.mny)(\uparrow)$
	$ln(prc.mny)(\downarrow)$	
4th:	$\ln(prc.mny)(\uparrow) \Longrightarrow$	$adjressl(\uparrow)$
	$u(\cdots\uparrow)$	$trns.mny(\cdots\uparrow)$
	$prc.mny(\uparrow)$	

Summarizing the behavior in QE1, we can say that a quantitative monetary easing has a positive effect on USA's economy. On the 1st column of Figure 7, we can see first $reserve(\uparrow) \rightarrow prec.demand(\uparrow)$. At the same time, *trans.demand* changes from downward to upward during several months: $trans.demand(\downarrow \cdots \uparrow)$. u rises along with *trans.demand* on the 1st column, while on the 2nd column, $u(\uparrow) \rightarrow trans.demand(\uparrow)$.

In $QE2+\alpha$, we can't see the path from reserve to trans. demand in Figure 8.

In QE3, on the 1st and 2nd columns of Figure 9, we can see
$reserve(\uparrow) \not\rightarrow trans.demand(\uparrow)$,
$reserve(\uparrow) \rightarrow u(\uparrow)$,
$u(\uparrow) \rightarrow trans.demand(\uparrow)$.
Thus, we can say that efficency of QEs is, in order, given by $QE1 > QE3 > QE2$.

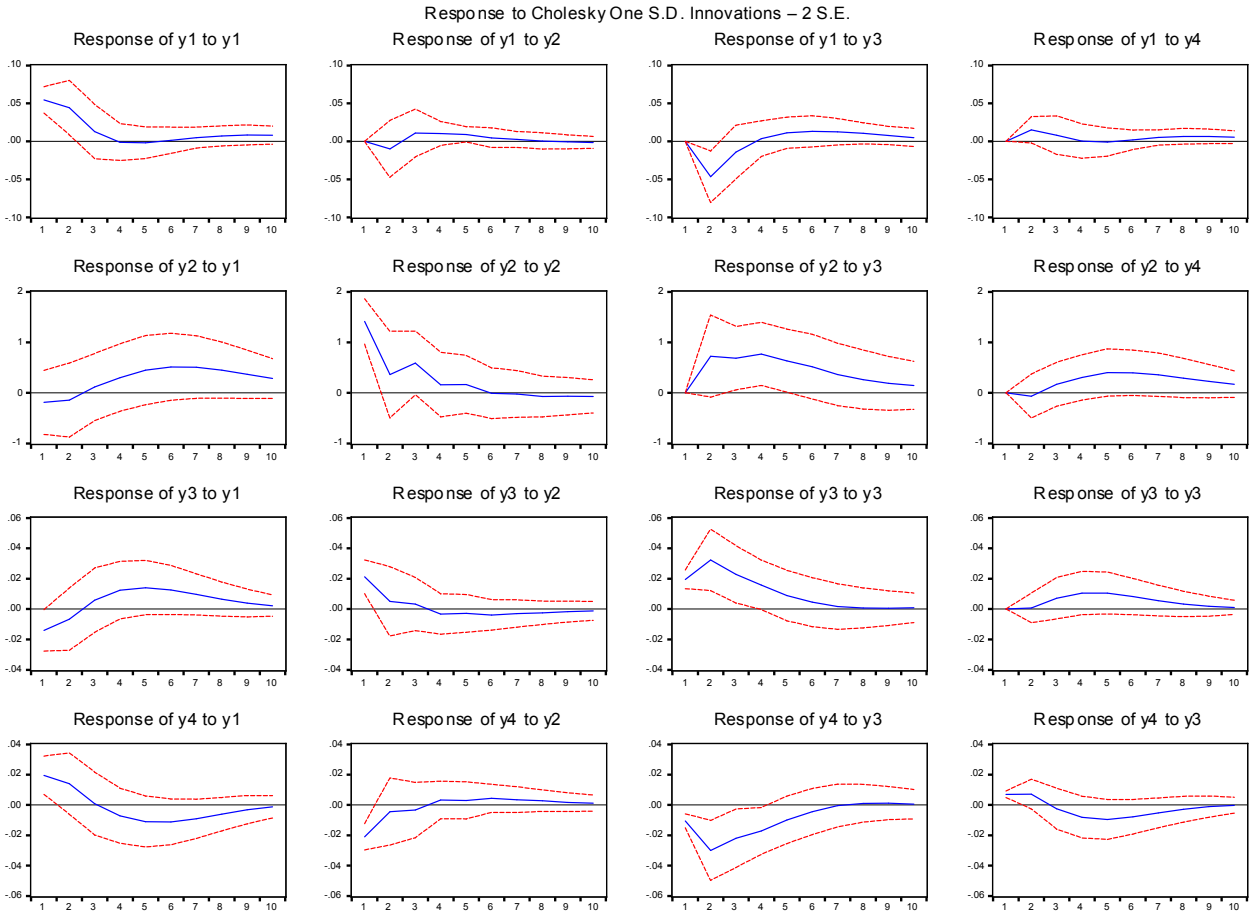

Figure 7. Impulse responses of the system with $y = (y_1, y_2, y_3, y_4,)'$, where in the figure we denote $y_1 = \ln(adjressl/p), y_2 = u(t)$, $y_3 = \ln(trans.\ money\ demand(t)), y_4 = \ln(prec.\ money\ demand(t))$ in QE1.

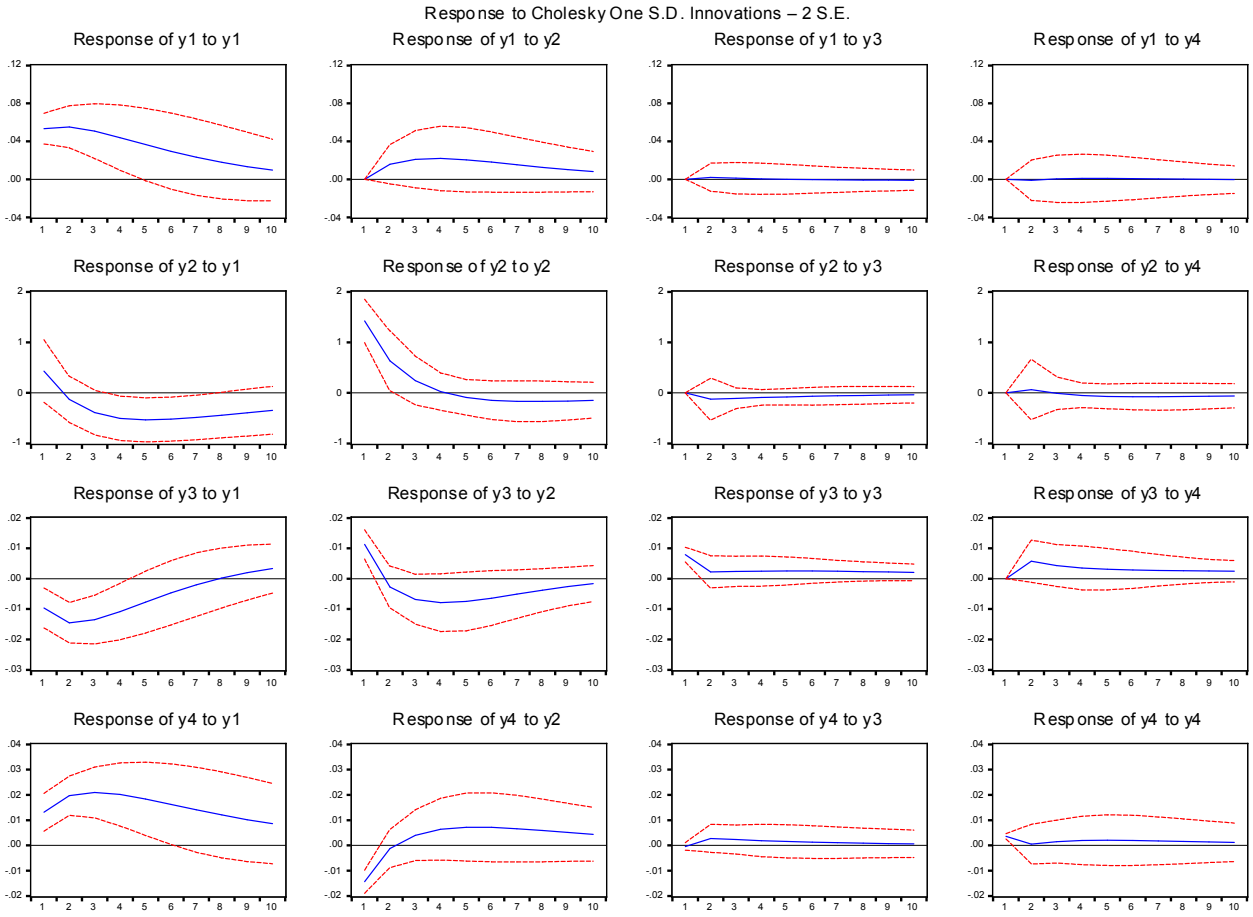

Figure 8. Impulse responses of the system with $y = (y_1, y_2, y_3, y_4,)^{'}$, where in the figure we denote $y_1 = \ln(adjressl/p), y_2 = u(t)$, $y_3 = \ln(trans.\ money\ demand(t)), y_4 = \ln(prec.\ money\ demand(t))$ in $QE2 + \alpha$.

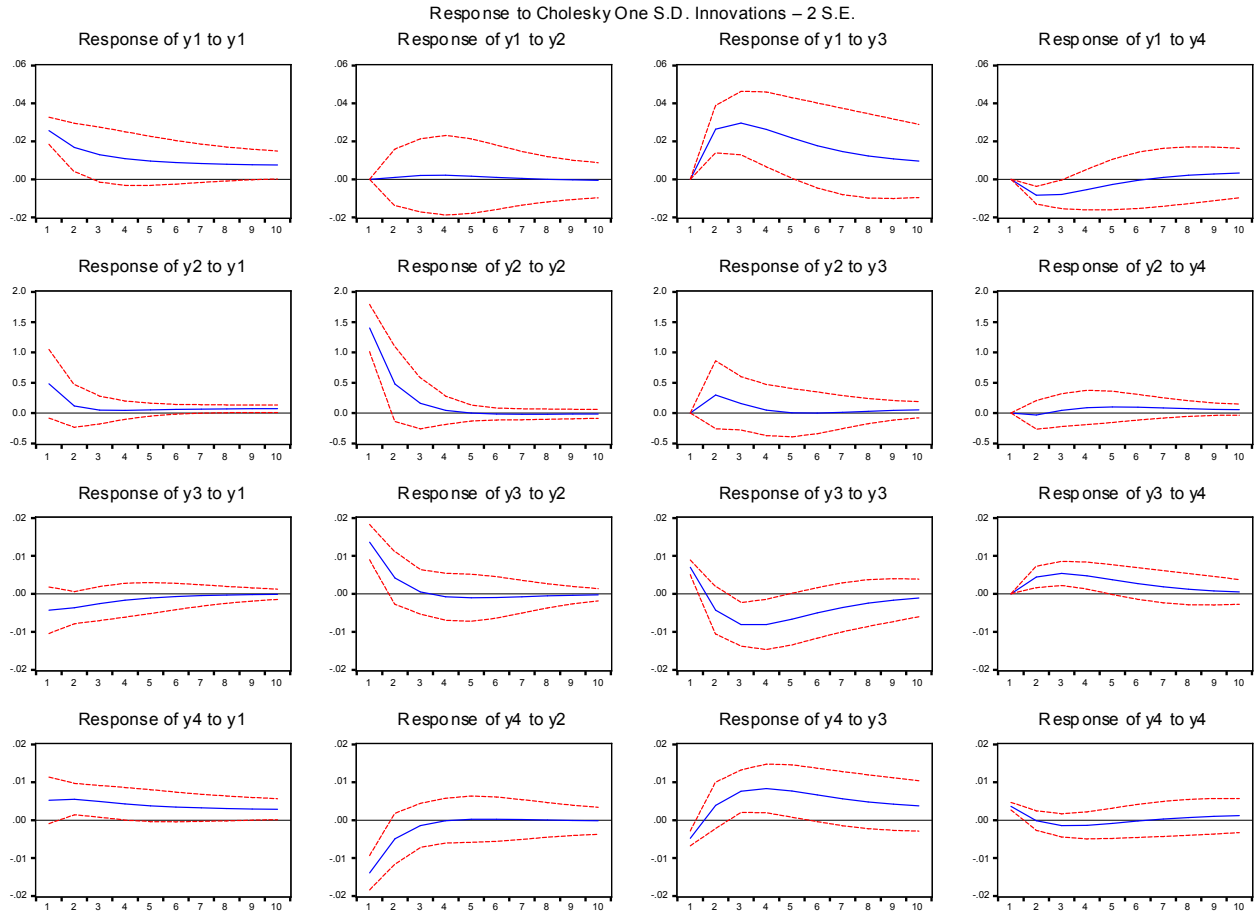

Figure 9. Impulse responses of the system with $y = (y_1, y_2, y_3, y_4,)$', where in the figure we denote $y_1 = \ln(adjressl/p), y_2 = u(t)$, $y_3 = \ln(trans.\ money\ demand(t)), y_4 = \ln(prec.\ money\ demand(t))$ in QE3.

6 Conclusions

We investigated efficiency of QE1, QE2 and QE3 in USA in two ways. First, usual VAR models were constructed and we can see that QE1 is effective through a transmission path of a stock market, QE2 and QE3 are effective through housing price path, and that QE3 is effective through an exchange rate path. Secondly, decomposing M2 into precautionary and transaction money demands, we can estimate precautionary money demand as a function on "industrial production", business condition and reserves. By investigating relationship among reserves, business condition, transaction and money demands, we see that QE1 is most effective and that QE3 is effective and that QE2 is not so effective. .

Abstract

The riser of a dual fluidized bed gasification reactor heats bed materials by burning residual char particles coming from gasification part of the reactor. A validated Computational Particle Fluid Dynamic (CPFD) model is applied to simulate combustion of char particles in a riser of dual fluidized bed gasification reactor in a demonstration plant with 8 MW fuel capacity. The plant is located in Güssing, Austria. The three-dimensional model is used investigate combustion reaction as a function of the bottom, primary and secondary air feed rates. The results show there is a still possibility to improve combustion reaction by optimizing air feed rates, which can maximize the bed material temperature without increasing additional char particles feed.

Keywords: dual fluidized bed, gasification, biomass, combustion, riser

1 Introduction

Biomass gasification is one of the promising technologies for combined heat and power production and synthesis processes leading to the production of liquid biofuels. Biomass has two major advantages: it is carbon dioxide neutral and homogeneously and locally available all over the world (Asadullah, 2014). There are various types of gasification technologies such as fix bed, moving the bed and fluidized bed (Basu, 2013). Dual fluidized bed steam gasification is one of the latest technologies among them (Göransson et al., 2011; Hofbauer et al., 2001).

Steam gasification in a dual fluidized bed reactor is a complex thermochemical process by which biomass is converted to a mixture of combustible and non-combustible gasses and other minor components. The combustible gasses are called producer gas. The major components of the producer gas are carbon monoxide, hydrogen, and methane. The non-combustible gasses are carbon dioxide and water vapor (Hofbauer et al., 1997, 2002a,b). The principle of the dual fluidized bed gasification reactor is shown in Figure 1. The reactor consists of two parts where one is a bubbling fluidized bed gasification reactor, and the other is a circulating fluidized bed combustion reactor. The gasification reactions are endothermic, and heat required for the reactions is supplied by circulating hot bed materials from the combustion reactor (Kern et al., 2013). The bed material can be sand or olivine particles. The primary purpose of the bed material is to transfer heat from the combustion reactor to the gasification reactor. The bed material is heated in the combustion reactor by burning char particles. The char particles, are residual char after the gasification process, which is transported from the gasification reactor to the combustion reactor along with the bed materials.

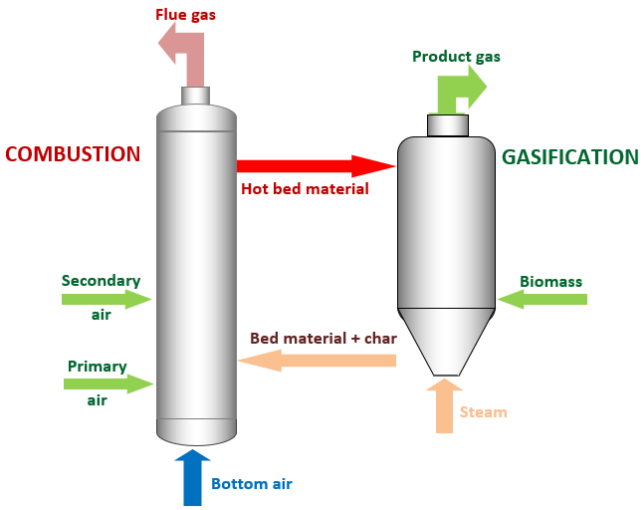

Figure 1. Principle of dual fluidized bed gasification system.

To optimize the performance of the reactor, gas-particle flow and combustion reaction should be optimized. It means that the reactor should have a minimum fluctuation of bed material temperature, steady transport of hot bed material to the gasification reactor and optimum gas flow rates (Snider and Banerjee, 2010). The temperature of bed material depends on the combustion reaction. The combustion reactions are dependent on the amount of oxygen supply. In the combustion reactor, the oxygen for the combustion reaction is provided from the air which is fed to the reactor from three position as the bottom, primary and secondary air.

The temperature of the bed material is self-controlled by the reactor as a whole. If the temperature of circulated bed material is low, the gasification reaction rates

become slower leaving more unreacted residual char particles to circulate to the combustion reactor. The more char particles circulated to the combustion reactor, the more the temperature of the bed materials is increased and vice versa (Pfeifer et al., 2011; Wang and Chen, 2013). The self-stabilization process requires two essential conditions to be fulfilled. Firstly, the initial temperature of the bed materials should be maintained near to the reaction temperature (about 850°C) which is achieved by burning a part of the producer gas to start up the reactor. Secondly, it is important to maintain constant bed material circulation rate which depends on the air feed rates and air feed positions in the reactor. Previous studies performed by the authors showed that the optimum ratio of bed materials to biomass feed rate was 25-30 for Güssing plant (Thapa and Halvorsen, 2014).

Preheated air is fed to the combustion reactor from the bottom and two positions along the height of the reactor as primary and secondary air. The air supplies necessary oxygen for combustion reaction and simultaneously serves as fluidizing gas to transport heated bed materials to the gasification reactor. The feed air is preheated to achieve better combustion of char in the reactor.

It is not well understood, whether all residual char particles coming from the gasification reactors are totally combusted during the flow along the riser of the combustion reactor. It is because the gas velocity in the combustion reactor is high and the residence time may not be long enough for all char particles to undergo complete combustion. Moreover, the air feed should ensure sufficient oxygen to burn all char particles.

The fluid dynamics of the combustion reactor requires the lower part of the reactor to be in bubbling fluidization regime, which means that the bottom air feed velocity should be lower. If the velocity is very high, a part of flue gas can pass to the gasification reactor making the product gas diluted by nitrogen and carbon dioxide contained in the flue gas, which is undesirable. The middle and upper parts are in the fast fluidization regime (Kaushal et al., 2008a). Moreover, the flow properties in the reactor vary with height because of the three different feed position of the bottom, primary and secondary air. The flow parameters are different at different temperature due to density and viscosity variation of the fluidizing gas.

A three-dimensional CPFD model is developed to study and optimize fluid dynamic properties and reaction kinetics in the combustion reactor. The gas-particle flow is investigated in high-temperature fluid flow with char combustion. The model is simulated using the commercial Computational Particle Fluid Dynamic (CPFD) software Barracuda VR. 15. The effect of char combustion is studied with varying flow rates of the bottom, primary and secondary airflow rates. The aim of the series of simulation is to investigate char combustion in the reactor and flow rates of the bottom, primary and secondary airflow rates. All parameters used in the simulations are based on the combustion riser in the biomass gasification plant in Güssing, Austria.

2 Mathematical Model

In this work, a Computational Particle Fluid Dynamic (CPFD) model is applied to simulate the gas-solid flow with heat transfer and chemical reactions. The CPFD numerical methodology incorporates multi-phase-particle-in-cell (MP-PIC) method (Andrews and O'Rourke, 1996; Snider, 2001). The gas phase is solved using Eulerian grid and the particles are modeled as Lagrangian computational particles. Gas and particle momentum equations are solved in three dimensions. The fluid is described by the Navier-Stokes equation with strong coupling to the discrete particles. The particle momentum follows the MP-PIC description which is a Lagrangian description of particle motions described by ordinary differential equations coupling with the fluid (Snider and Banerjee, 2010).

In the CPFD numerical method, actual particles are grouped into computational particles, each containing a number of particles with identical densities, volume and velocities located at a specific position. The computational particle is a numerical approximation similar to the numerical control volume where a spatial region has a single property for the fluid. With these computational particles, large commercial systems containing billions of particles can be simulated using millions of computational particles. This possibility of the CPFD numerical method is used in this work to simulate the riser part of the large scale dual fluidized bed steam gasification plant.

Governing equations

The volume averaged fluid mass and momentum equations are:

$$\frac{\partial(\varepsilon_g \rho_g \mathbf{u}_g)}{\partial t} + \nabla(\varepsilon_g \rho_g \mathbf{u}_g \mathbf{u}_g) = \varepsilon_g \nabla p - \mathbf{F} + \varepsilon_g \rho_g \mathbf{g} + \varepsilon_g \tau_g \quad (1)$$

where ε_g, ρ_g, and $\mathbf{u}_g$ are gas volume fraction, density and velocity respectively, p is gas pressure, $\mathbf{g}$ is the acceleration due to gravity, $\mathbf{F}$ is the rate of momentum exchange per unit volume between the gas and solid phase and τ_g is stress tensor which can be expressed in index notation as:

$$\tau_{g,ij} = \mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) - \frac{2}{3} \mu \delta_{ij} \frac{\partial u_k}{\partial x_k} \quad (2)$$

where μ is shear viscosity. The shear viscosity is the sum of laminar shear viscosity and turbulence viscosity based on the Smagorinsky turbulence model. In the model, large eddies are directly calculated. The unresolved sub-grid turbulence is modeled by using eddy viscosity. The turbulence viscosity is given as:

$$\mu_t = C \rho_g \Delta^2 \sqrt{\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right)^2} \quad (3)$$

where C is sub-grid eddy coefficient and known as Smagorinsky coefficient.

MP-PIC method calculates the particle phase dynamics using the particle distribution function (PDF), f_p. A transport equation is solved for the PDF. The transport equation for f_p is given by [14] and is expressed as:

$$\frac{d_{f_p}}{dt}+\frac{\partial(f_p u_p)}{dx}+\frac{\partial(f_p A_p)}{du}=\frac{f_D-f_p}{\tau_D} \tag{4}$$

where u_p is particle velocity, f_D is the particle distribution function for the local mass averaged particle velocity and τ_D is the collision damping time. A_p is the particle acceleration which is given by:

$$A_p=\frac{\partial u_p}{dt}=D_p\,(u_g-u_p)-\frac{1}{\rho_p}\nabla p_g+g-\frac{1}{\varepsilon_p\rho_p}\nabla\tau_g+g+F_p \tag{5}$$

In the equation above, ε_p is particle volume fraction, ρ_p is particle density, p_g is gas pressure, τ_p is contact normal stress. More details about the τ_p can be found in (O'Rourke and Snider, 2010). F_p is the particle friction per unit mass, related to the relative particle motion and becomes important at very low particle flow at near closed packed bed (Snider, 2007) and D_p is the drag function. The Wen-Yu drag model is implemented in this work (Wen, 1966).

$$D_p=C_D\frac{3}{8}\frac{\rho_g}{\rho_p}\frac{|u_g-u_p|\varepsilon_g^{-2.65}}{r_p} \tag{6}$$

where

$$D_p=C_D\begin{cases}\frac{24}{Re}\left(1+0.15\,Re^{0.678}\right), & Re<1000\\ 0.44, & Re\geq 1000\end{cases} \tag{7}$$

$$Re=\rho_g\frac{|u_g-u_p|r_p}{\mu_g}\quad\text{and}\quad r_p=\left(\frac{m}{\frac{4}{3}\pi\rho_p}\right)^{\left(\frac{1}{3}\right)} \tag{8}$$

3 Model Parameters and Geometry

The dimensions of the reactor are the same as the combustion reactor in the biomass gasification plant in Güssing, Austria. The basic dimensions of the combustion part of the reactor are shown in Table 1.

Table 1. Reactor Dimensions.

Dimensions	*Units*	*Value*
Diameter	m	0.66
Height	m	12
Primary air inlet	m	1.5
Secondary air inlet	m	3.5

In the plant, the gasification and combustion occur simultaneously in the bubbling fluidized bed gasification reactor and in circulating fluidized bed combustion reactor. The whole reactor is a combination of these two. However, the aim of current study is only the combustion part of the reactor. Therefore, the combustion part of the reactor is separated in the model replacing circulation of the bed materials by the inlet and outlet boundaries. Dotted lines in Figure 2 show the control volume of model geometry.

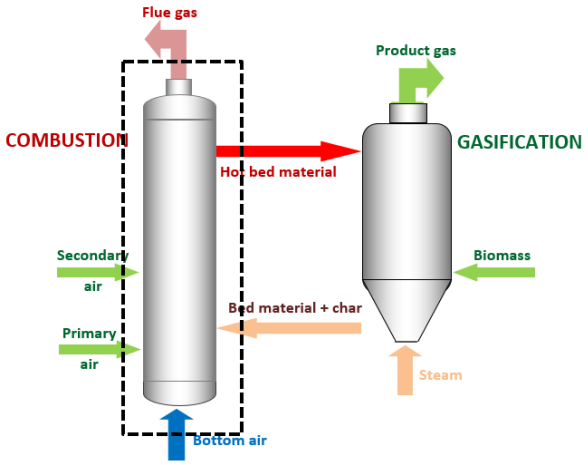

Figure 2. Control volume of model geometry.

In the CPFD computational model, grid generating and solving flow and reactions in a rectangular geometry is better than in a circular geometry. For this reason, the circular diameter of the geometry is converted into rectangular with the equivalent cross-sectional area. The geometry used in the CPFD model with all boundary conditions and grids are shown in Figure 3.

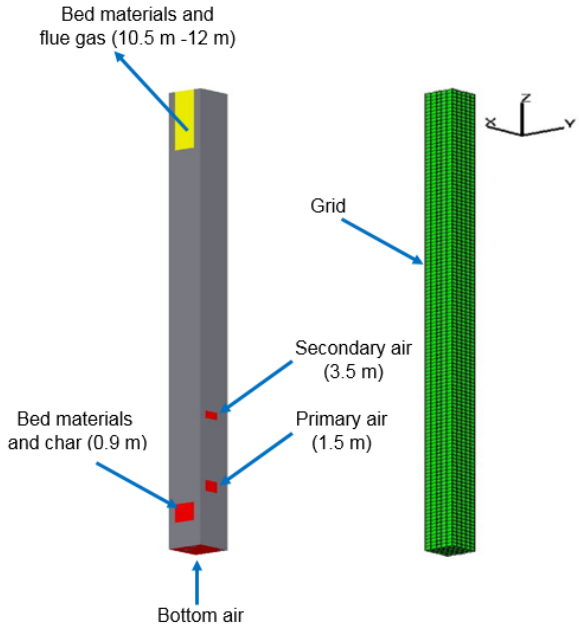

Figure 3. Grid and boundary conditions of the riser.

The combustion reactor uses air as a fluidizing agent as well as an oxidizing agent. The gas-particle flow involves a complex mixture of air, flue gas, olivine particles

and char. The properties of gas and particles used in the simulation are given in Table 2.

Table 2. Properties of Solids and Gases.

Properties	*Units*	*Value*
Olivine particle size	μm	200-800
Olivine density	kg/m^3	2960
Char particles size	mm	1-5
Char density	kg/m^3	200
Air density	kg/m^3	0.27-1.06
Air temperature inlet	K	333-1300
Air viscosity	$Pa \cdot s$	$[1.98\text{-}4.9]\cdot 10^{-5}$

In the combustion reactor, olivine particles and char have a wide range of size distribution. The size distribution of char and bed materials are presented in Figure 4(a) and 4(b) respectively.

The particle sizes expressed in the figure are the radius of particles. It is because Barracuda uses radius to represent particle size. The combustion reactions and their reaction kinetics involved in the CPFD model is given in Table 3 (Kaushal et al., 2008a).

Chemical reactions can affect gas flow rates, gas compositions, particle sizes and particle densities. The reactions, on the other hand, can be affected by temperature, gas-particle mixing and gas feed positions and feed rates in the reactor. There is strong interdependence between reaction chemistry and particle-fluid dynamics. Therefore, it is important to take into account the change in flow behavior due to the combustion reaction in the riser.

The volume average chemistry is used in the current model. The gas volume of each cell in the grid acts as control volume for the reaction calculations. In volume average chemistry, each control volume is the gas volume in a cell. The reactions are written in stoichiometric form. Temperature, pressure and solid dependence are entered as rate coefficients.

The particle dependency term is the radius of the particle. The temperature is the average temperature of the particle and the bulk fluid.

It is assumed that the particle temperature is constant within the particle.

4 Results and Discussions

To simulate the riser of the Güssing plant and to investigate the combustion reaction, the first series of simulations were run with the gas and fuel feed parameters as reported from the biomass gasification plant in Güssing (Kaushal et al., 2008a). The parameters are presented in Table 4.

The table shows the flow rate of the bottom, primary and secondary air with different temperatures. The reason for feeding the air at various position and temperatures is to control the combustion process and bed material circulation rate. The mixture of bed materials and residual char is fed to the combustion reactor at a temperature of 1073 K. The char is combusted in the reactor and it gradually heats the bed materials while moving up along the height of the riser. Therefore, the particle temperature is gradually increased as they move towards the top of the reactor. The temperature of the gas and particles are measured from the bottom and every one-meter height of the reactor. The simulated fluid and particle temperature along the height of the reactor is shown in Figure 5.

The figure indicates that the fluid and particle temperature are changing with height in the riser. At every position in the reactor, the fluid temperature is higher than particle temperature. It indicates that the heat transfer between particles and fluid is not sufficient due to high velocity and low residence time. The fluid temperature deviates sharply from particle temperature above the height of 2 m. This point is just above the primary air feed point. Preheated primary air significantly improves the char combustion process in the reactor and increases the temperature. However, after about 8 m height, the fluid and particle temperature do not increase indicating that char combustion does not occur above this height of the bed.

The char particle volume fraction and the mole fraction of the major components of the flue gas is presented in Figure 6. The figure shows that the residual char particles fed to the combustion reactor are not completely burned. The existence of the small amount of char particles at the top of the reactor suggests that the char particles are recirculated back to the gasification reactor. As expected, the mole fraction of CO_2 increasing from the bottom to the top while the oxygen mole fraction is decreasing. The oxygen mole fraction is almost zero at a height about 7 m implying that there is an insufficient amount of oxygen to obtain total combustion of char particles. The small amount of H2 at the top of reactor makes that fact clearer.

The *CO* concentration is a strong function of the available oxygen. Hence, the primary air flow which is the biggest among the all air flow rates influences the *CO* concentration most (Kaushal et al., 2008b).

A series of simulation were run by gradually increasing the bottom airflow rate. The results are presented in Figure 7.

An increasing amount of bottom air increases the gas and particle temperature. The maximum particle temperature is increased from about 1150K to about 1220K in the first series of simulations (Figure 5). The increase in temperature without increasing the mass flow rate of the char particles indicates that not all the char particles are burned. In other words, there is still some uncombusted char particles passing through the combustion reactor to the gasification reactor. However, increasing the bottom air increases the fluid temperature much more than the particle temperature. It may be due to decreased residence time for the particles in the combustion reactor. Increased bottom air flow rate increases the fluidization velocity making particles be transported faster. In addition, the high feed rate of bottom air is not desirable due to the risk of flue gas leakage to the gasification reactor.

creased in this case.

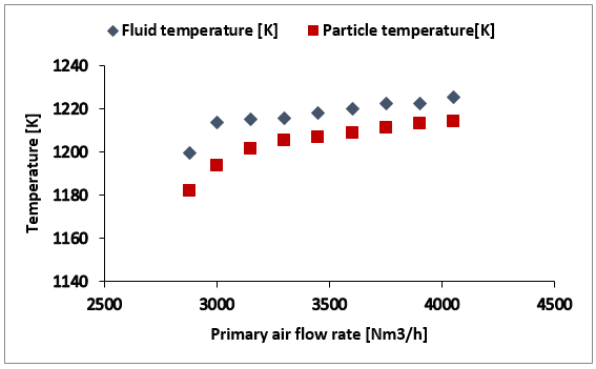

Figure 8. Fluid-particle temperature with increasing primary air flow rate.

The results of the simulation series with increasing secondary air flow rate also show that there is a significant change in fluid-particle temperature as shown in Figure 9.

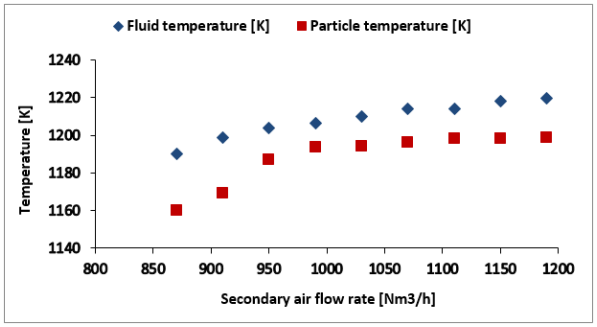

Figure 9. Fluid particle temperature with increasing secondary air flow rate.

The overall particle temperature distribution along the combustion reactor is presented in Figure 10.

The particle temperature distribution at increasing air flow rates of the bottom, primary and secondary air are compared with the particle temperature at the air flow rate used at the Güssing plant. The results show that increasing primary and secondary air flow rates result in higher and more uniform particle temperature distribution in the

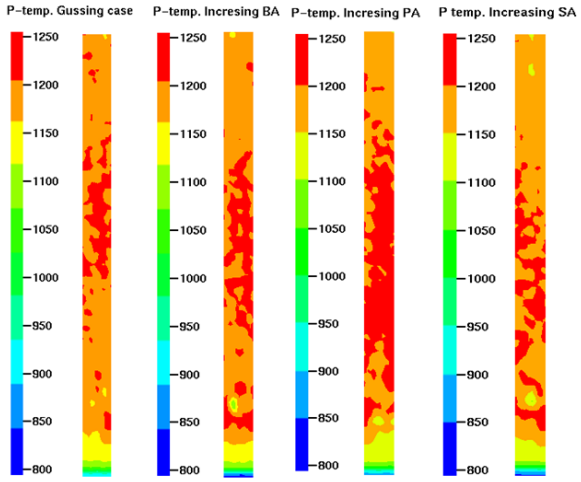

Figure 10. Snapshot of particle temperature distribution along the combustion reactor at 400s of simulation time.

reactor.

5 Conclusions

A 3D CPFD model is developed to investigate the effect of bottom, primary and secondary air flow rates in the combustion process and bed material temperature in the riser of a dual fluidized bed biomass gasification reactor. The simulated reactor is located at 8 MW fuel, biomass gasification plant in Güssing, Austria. Series of simulations were run using commercial CPFD software Barracuda V15. The first series of simulation were performed with all parameters as in the Güssing plant. The results show that some un-combusted char particles are passing through the reactor. Three series of simulations carried out with increasing bottom, primary and secondary air feed rate. All the cases show increasing temperature with increasing air feed rates at a constant feed rate of char particles. The results of the simulations also indicate that increase in primary air flow rate results in the highest particle temperature with more uniform temperature distribution along the reactor than the cases with increasing bottom and secondary air feed rate. The results show that there is still a possibility for optimization of air flow rates for combustion reaction in the riser.

Peak Load Cutting in District Heating Network

Petri Hietaharju Mika Ruusunen
Control Engineering, University of Oulu, Finland, {petri.hietaharju,mika.ruusunen}@oulu.fi

Abstract

Simulations of different peak load cutting scenarios in district heating of buildings were performed. Decrease in percentages of 30%, 50%, and 70% in peak loads was analyzed for the two modelled apartment buildings. Simulation results show that even 70% peak load cuts are possible in individual buildings. However, results also reveal that for some buildings 30% peak load cuts would require compromising with the indoor temperature. Therefore, it is important to take into account the different heat storing capacities available in each of the buildings. In future, systems with multiple buildings will be studied to effectively utilize individual heat storing capacities to cut city level peak loads. Simulations presented in this article show that better energy efficiency in district heating can be achieved by predicting the energy consumption and utilizing the thermal mass of a building.

Keywords: district heating, peak load cutting, optimization, indoor temperature prediction, modelling

1 Introduction

Heat represents more than half of the world's total energy consumption and three-quarters of the fuels used to meet this heat demand consist of fossil fuels (Eisentraut and Brown, 2014). Despite these facts, heat is largely ignored in the climate change debate. Nevertheless, it is important to implement new energy efficiency measures in the heat sector. Cutting peak loads in district heating network is one of such measures and in this work peak load cutting is studied with simulations.

Peak loads in district heating network occur when the heat demand exceeds the production capacity of available heating power. This means that reserve power plants need to be started to satisfy the heating demand. This raises production costs (and also environmental impact) for the energy producer as more expensive oil is used for fuel instead of wood, peat or coal. Therefore, it is in the interest of energy companies to cut peak loads and reduce the use of oil. Additionally, CO_2 emissions are also reduced. At the same time, more accurate and stable indoor temperature control could be achieved by implementing the optimization routines for energy consumption.

A concept for peak load cutting has been presented in (Hietaharju and Ruusunen, 2015). The concept aims to cut peak loads by utilizing building thermal mass as a short term heat storage. Building thermal mass and its use in peak load cutting has also been discussed in (Braun, 2013; Henze et al., 2007; Sun et al., 2013; Kensby et al., 2015; Hagentoft and Kalagasidis, 2015; Ståhl, 2009). Braun (2013) presented a review on load control utilizing building thermal mass including simulation, laboratory and field studies. It showed that there is significant saving potential for using building thermal mass, but it is affected by many factors, including utility rates, type of equipment, occupancy schedule, building construction, climate conditions, and control strategy. These factors were further studied by Henze et al. (2007) using a sensitivity analysis. Sun et al. (2013) presented a more recent look into peak load cutting. They found that in existing studies more than 30% daily peak load reduction and also significant overall cost savings from 8.5% to 29% had been achieved utilizing building thermal mass. They also found that there exists model based as well as model free solutions. The amount of energy stored in the building thermal mass is difficult to identify and model based solutions are needed, but they mention the difficulties related to complex physical models and their identification.

Kensby et al. (2015) demonstrated that heavy buildings can tolerate relatively large variations in district heating energy while still maintaining desired indoor temperature. The effect of heating power reduction on indoor temperature was also studied by Hagentoft and Kalagasidis (2015). In case of 1 °C change in the control signal, the indoor temperature drop was below 0.2 °C after 24 hours, which shows that the building thermal mass can be potentially utilized for peak load cutting. However, they mention that the results are highly dependent on the thermal characteristics of the building. In that regard, Ståhl (2009) found that thermal effusivity, which is a function of thermal conductivity and heat capacity and represents the materials ability to exchange thermal energy with its surroundings, is the most important parameter when considering the heat storage capacity of a building. Heavy buildings have higher thermal effusivity and therefore offer higher energy storage capacity compared with light buildings with lower thermal effusivity. Also,

the indoor temperature is typically more stable in heavy buildings.

To utilize thermal mass effectively to cut peak loads and optimize heat consumption, one has to be able to predict the future heat demand. This can be achieved by modelling the thermal behavior of a building, namely the indoor temperature. This way also the quality of living for the residents can be ensured by maintaining the indoor temperature at acceptable level despite the cuts in heating power. In this work, an indoor temperature model (Hietaharju et al., unpublished) was applied to simulate peak load cutting in two apartment buildings. Finally, simulation results for different peak load cutting scenarios are presented and discussed.

2 Data

Two apartment buildings located in the city of Jyväskylä in Finland were studied. Building 1 was constructed in 2011 whereas Building 2 was constructed in 1972 and renovated in 1993. Basic information about the buildings is presented in Table 1. Ground plans and elevation drawings were also available for the studied buildings.

Measurement data for both of the buildings was acquired in early January 2015. Data included hourly values for heating power. In addition, outdoor temperature measurements were recorded for the same time period. Hourly indoor temperature measurements for both buildings were also available. Both buildings contained several indoor temperature measurements which were located in living rooms and hallways.

Table 1. Building Information.

	Building 1	**Building 2**
Year of construction	2011	1972
Year of renovation	-	1993
Floors	4	7
Apartments	75	53
Living space (m^2)	3563	3024
Floor space (m^2)	4200	3703
Volume (m^3)	15617	12400

3 Methods

Previously identified and validated (Hietaharju et al., unpublished) indoor temperature model was used for predicting the indoor temperature evolution over time in the buildings. The model structure (Equation 1) is based on Newton's cooling law and includes heat capacity (C) and heat loss coefficient (U) as physical parameters. Inputs for the model are indoor temperature (T_i), outdoor temperature (T_o), and heating power (P) which can include a lag of k hours. Time step (Δt) for the model is one hour. Model output is the hourly indoor temperature along the defined prediction horizon.

$$T_{i,t} = a\left(T_{i,t-1} + \frac{\Delta t}{C}\left(P_{t-1} - U\left(T_{i,t-1} - T_{o,t-1}\right)\right)\right) + b \quad (1)$$

Initial data described in Section 2, including ground plans and elevation drawings, was used to calculate physical model parameters. Some assumptions were made about the construction materials due to insufficient information. After the calculation of the physical model parameters, input data mentioned before was used to estimate additional model parameters a and b. The indoor temperature model was then utilized to optimize heating power in pilot buildings considering different peak load cutting scenarios.

The scenarios for cutting the peak loads considered simulations for 30%, 50%, and 70% reduction in the heating power. These cuts were made at the morning hours between 7 and 10 am. Load cuts were calculated from the actual measured district heating power. During the simulations, maximum allowed power was restricted accordingly during the peak load hours. Cost function for peak load cutting minimized the power consumption while keeping the indoor temperature between the control limits. This was achieved with a constraint by increasing the cost function value if the indoor temperature would have exceeded the limits according to the model prediction. Also the increase and decrease in the amount of heating power was restricted to prevent too large hourly power changes.

All modelling and optimization work was programmed and evaluated in MATLAB® software with simulations. MATLAB®'s *simulated annealing* algorithm was utilized in peak load cutting simulations to optimize the usage of heat energy per building with respect to the constraint. In all the succeeding simulations, the prediction horizon of 100 hours was applied with acquired data from the buildings.

4 Results and Discussion

Firstly, both apartment buildings were modelled applying the indoor temperature model (Hietaharju et al., unpublished). Modelling results are presented in Table 2. The model performance was evaluated by calculating mean absolute error (MAE), mean absolute percentage error (MAPE), and root mean squared error (RMSE).

Table 2. Performance of the Indoor Temperature Model.

	Building 1	**Building 2**
MAE (°C)	0.24	0.38
MAPE (%)	1.07	1.69
RMSE (°C)	0.33	0.44

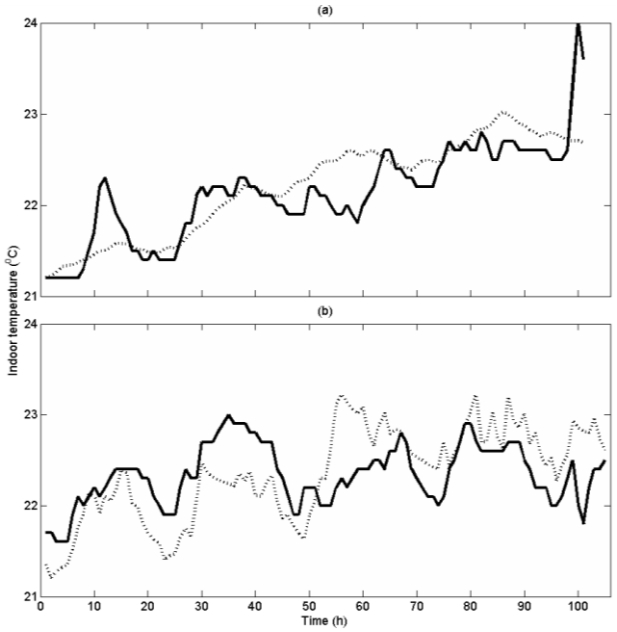

Figure 1. Measured (solid line) and predicted (dotted line) indoor temperature: (a) Building 1 and (b) Building 2.

Figure 1 shows the measured and the modelled indoor temperatures with data from Building 1 and Building 2. The time period for simulations was from January 3rd 2015 to January 7th 2015. For the Building 1, indoor temperature measured from the living room was used as a reference. Respectively, for the Building 2 the temperature measured at the hallway was the model reference. It is important to notice the dynamic behavior that the model manages to capture. Although the modelled indoor temperature somewhat deviates from the measured temperature, the changes and trends are still captured by the model. This model property is further emphasized if the model is to be used for control purposes. Also, MAE, MAPE, and RMSE seem to be reasonably low in case of the two building data sets.

Next, different peak load cutting scenarios were simulated utilizing the identified indoor temperature models. For both of the buildings 30%, 50%, and 70% peak load cuts during morning hours between 7 and 10 am were applied in the simulation. Value of 22 °C was assumed to be the minimum desired indoor temperature for both of the buildings during the simulation. The upper limit for the indoor temperature was set to 23 °C for the Building 2 and to 24 °C for the Building 1. These upper limits were determined from the historical indoor temperature data. Figure 2 and Figure 3 show the simulation results for the peak load cutting. For the indoor temperature, measured and optimized indoor temperatures are presented. The grey bar in the district heating graph represents the peak load period during which the maximum allowed heating power was restricted. Restricted power values were calculated from the measured district heating power by taking the average of the measured district heating power during the peak load period and multiplying this by the desired cut percentage.

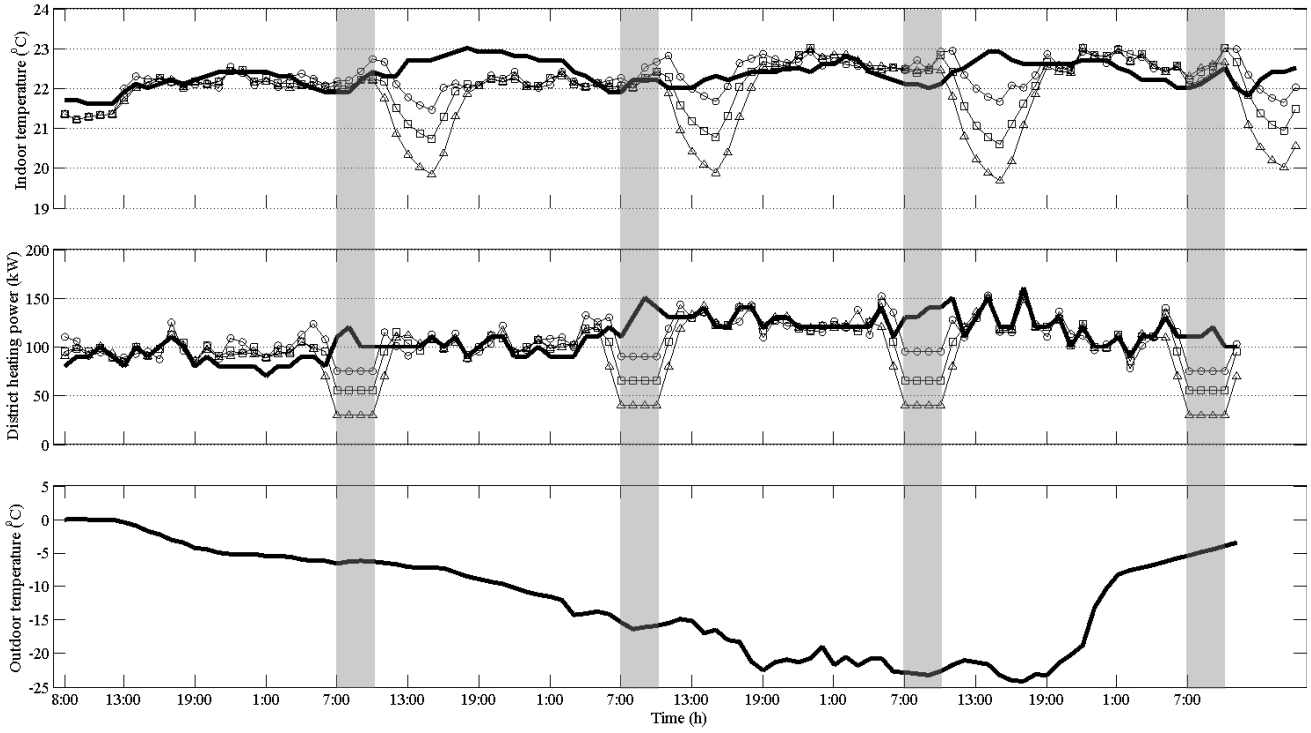

Figure 2. Simulation results for Building 2 in the case of 30%, 50%, and 70% peak load cut during 7-10 am (grey bars). Upper: measured (solid line) and simulated (30%: circle; 50%: square; 70%: triangle) indoor temperature. Middle: measured (solid line) and simulated (30%: circle; 50%: square; 70%: triangle) district heating power. Lower: measured outdoor temperature.

In Figure 2 for the Building 2, a clear change in indoor temperature can be seen as a result of peak load cutting. Delay in the indoor temperature response is due to the lag in the applied model. For the 30% peak load cut it can be seen that at first, the temperature rises to the set upper limit as heat is stored into the building before the peak load period. Then, the temperature drops as the heating power is limited to lower level during the peak loads. In the case of Building 2, the indoor temperature drops below the minimum of 22 °C in all of the simulated peak load cutting scenarios. For 50% and 70% peak load cuts the storage capacity of the building is not enough and the indoor temperature decreases significantly due to the peak load cutting. For the simulation period, the total energy savings are 2.2%, 7.5%, and 15.8% for the 30%, 50%, and 70% peak load cuts respectively.

As can be seen in Figure 3, the simulated change in indoor temperature in the Building 1 is small when compared with simulation results in case of the Building 2 staying between 22 and 23 °C. Nevertheless, the increase in temperature can be observed before the peak load period. Also, it can be clearly seen that the indoor temperature is higher in general on larger peak cuts to be able to perform the peak cut without compromising with the indoor temperature. Unlike in Building 2, the indoor temperature remains above 22 °C in Building 1. Total energy savings for the 50% and 30% peak load cuts for the simulation period were 1.0% and 2.9% respectively. With 70% peak cut energy is not saved during the simulation period but 2.3% more is needed. These results are much lower in comparison with the savings achieved for Building 2. This is partly caused by the high peak in the first four hours in the heating power, which can be seen in Figure 3. This is due to the fact that the initial measured indoor temperature in Building 1 is below the desired level and it has to be raised. If the heating power for these first four hours is excluded from the total energy saving calculations, total energy savings are 6.2%, 4.1%, and 0.7% for the 30%, 50%, and 70% peak load cuts respectively. This shows that energy is saved with every peak load cut percentage, but the savings are still lower, except for 30% cut, when compared with Building 2. This results from the fact that in Building 2 heat is not significantly stored with 50% and 70% peak load cuts as the storage capacity is not enough to compensate for such large cuts and therefore the total energy savings are significantly higher in comparison with Building 1 but the indoor temperature has to be compromised. Higher savings for the 30% peak load cut in Building 1 compared with Building 2 can be explained with larger heat storage capacity in Building 1. In Building 2, 30% peak load cut requires all heat storage capacity to be utilized as can be seen in Figure 2 where the indoor temperature rises to the maximum limit of 23 °C before the peak load cut periods. In Building 1, heating power can be kept on a

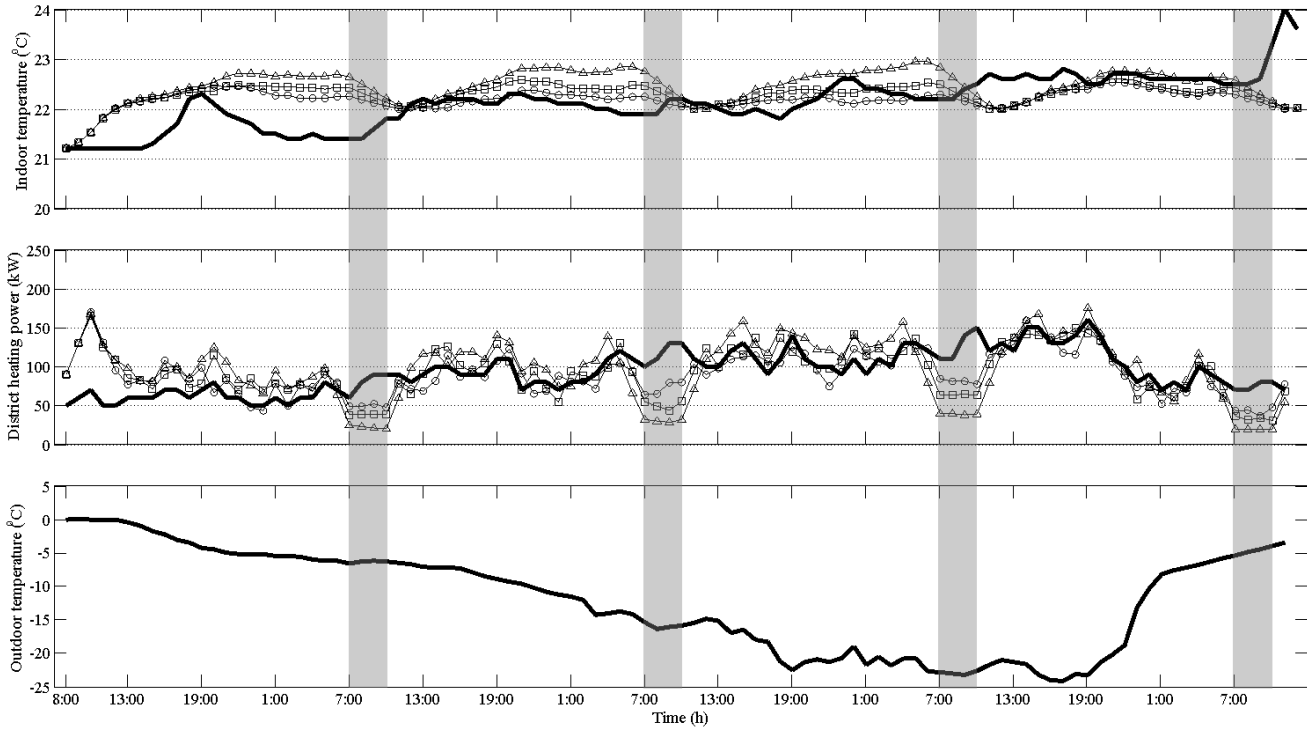

Figure 3. Simulation results for Building 1 in the case of 30%, 50%, and 70% peak load cut during 7-10 am (grey bars). Upper: measured (solid line) and simulated (30%: circle; 50%: square; 70%: triangle) indoor temperature. Middle: measured (solid line) and simulated (30%: circle; 50%: square; 70%: triangle) district heating power. Lower: measured outdoor temperature.

lower level as the heat storage capacity of the building is more than enough to manage 30% cut in peak loads.

It can be seen from the results that the two buildings have different heat storing capacities. In this view, the Building 2 lacks the heat storing capacity to maintain the desired indoor temperature during the peak load cut of 30% or more, which can be clearly seen in Figure 2. However, the indoor temperature could be allowed to drop below the desired level for the duration of the peak loads. In the case of 30% peak load cut, the indoor temperature in Building 2 decreases at most about 0.5 °C below the desired temperature, which could be very well allowed. With 50% peak load cut the indoor temperature drops 1 °C below the desired temperature, which could still be allowed. If temperature drops of the same kind were also allowed for Building 1, the total energy savings would be more significant. On the other hand, also the maximum indoor temperature could be allowed to rise higher to get more heat storage capacity and ensure that indoor temperature does not drop below the desired level, but this could raise the total energy consumption. This shows how important it is to properly define the constraints for the optimization. Also, it is worth noticing that the studied buildings are apartment buildings where the indoor temperature must be more strictly maintained at acceptable level than for example in a school or an office building where the indoor temperature can be allowed to fluctuate more freely during the off-hours. In these kind of buildings, the use of building thermal mass could be even more effective. This is further supported by the preliminary results from an online test performed by the authors in a school building (Hietaharju and Ruusunen, 2015). There the district heating power was optimized for a 24-hour period and it resulted in 14% energy savings for the period and an average of 25% peak load cut during the morning hours. Nevertheless, buildings exist with different heat storing capacities and therefore it is important to investigate multiple buildings as the city level peak loads are desired to be cut. In that case, the peak cutting would be distributed between the buildings and their storage capacities could be effectively used without extensively variating the indoor temperature of individual buildings. Systems with groups of buildings have already been investigated but will be further studied in the future.

5 Conclusions

An indoor temperature model was applied to simulate different peak load cutting scenarios of district heating. According to the simulations, peak cutting potential in the tested two buildings varied because of different heat storing capacities. Nevertheless, in both of the buildings peak loads could be cut 30%, 50%, and even 70%. In the Building 1, performing the peak cutting did not have a significant effect on the indoor temperature and it stayed between the desired levels. In the Building 2, the heat storing capacity was not enough to cut the peak loads by 30% or more without the indoor temperature fluctuating out of the defined limits. This shows the importance of properly defined constraints for the indoor temperature. Furthermore, these simulations demonstrate that the buildings have different heat storing capacities and therefore it is important to investigate systems with multiple buildings. In that case, the load cutting will be distributed between the buildings and their specific heat storing capacities can be effectively used to take into account variation in the temperature dynamics.

All the results presented in this article are simulations based on actual measured data. The next phase would be to conduct field-tests to evaluate the method's performance in a real building environment. In this article, peak load cutting and optimization is considered in a single building, but the overall goal is to develop optimization and peak load cutting methods for a system of multiple buildings. Having multiple buildings changes the picture completely and one can make conclusions about the energy savings also on city level. Systems with multiple buildings have already been investigated by the authors, but will be further studied in the future. Simulations presented in this article show that better energy efficiency in district heating can be achieved by predicting the energy consumption and utilizing the thermal mass of a building.

Abstract

The energy from biomass can be utilized through the thermochemical conversion process of pyrolysis and gasification. The process involves solid phase and fluid phase interactions. Computational Particle Fluid Dynamics (CPFD) tools are most commonly used for simulations. The chemical processes involved is described by reaction rate expressions and equilibrium constants. These expressions are often not well studied, but rather adapted from previous studies in lack of better knowledge. Methodology and tools are presented to aim in the selection and optimization of rate expressions for a particular process. Simulation tools for reactions in batch or plug-flow conditions are shown applicable to study selected chemical reactions in detail. Results from one such study is compared to CPFD as well as CSTR results of a gasification process. The reaction scheme for the simulation model could be simplified.

Keywords: gasification, reaction kinetics, KINSIM, Barracuda, Aspen Plus, fluidized bed

1 Introduction

Biomass is the oldest source of energy known to men and contributes to 14% of world's energy consumption (Bain *et al.*, 1998; Saxena *et al.*, 2009). Energy recovery from biomass is possible through the thermochemical conversion processes pyrolysis and gasification. In the gasification process, the biomass undergoes endothermic reactions to produce a mixture of combustible gases that is called producer gas, which can be used in gas engines, gas turbines or fuel cells to produce combined heat and electricity or it can be used as raw material in production of liquid bio fuel.

Different types of reactors can be used in the gasification process. The most efficient types are the fluidized bed reactors, and the efficiency of these reactors mainly depends on the thermo-chemical and fluid dynamic behavior in the reactor. (Olofsson *et al.*, 2005; Pfeifer *et al.*, 2011). The fluid dynamics depends on the gas-solid flow inside the reactor while the thermochemical behavior or reactions and their kinetics depend on the heat supply, the residence time and the gas-particle mixing in the reactor. The efficiency of the biomass-based energy technology has to be further increased to make the technology more sustainable in the world energy market, which is still dominated by fossil fuels. Study of chemical reactions and their kinetics in an operating plant or a reactor model, is difficult due to high operating temperature. Computational models are therefore used to optimize the reactors. In order to have a simulation model that predicts chemical composition, it is crucial to implement reaction schemes with reaction rates and the targeting equilibrium composition that correspond to real life conditions.

Different computational models have been used to simulate the biomass gasification process. Thapa et al. (Thapa and Halvorsen, 2014; Thapa *et al.*, 2014) have simulated the gasification process using the Computational Particle Fluid Dynamics (CPFD) tool, by Barracuda VR15 software. Thapa implemented the set of kinetic equations developed by Snider et al (Snider *et al.*, 2011), Kauhsal et al. (Kaushal *et al.*, 2007), Gomez-Barea et al. (Gómez-Barea and Leckner, 2010) and Umeki et al. (Umeki *et al.*, 2010) together with the stoichiometric equations in Barracuda. The results of the simulations were compared to the measured values from an existing biomass gasification plant. The CPFD methodology solves the fluid and particle equations in three dimensions. The fluid dynamics is described by averaged Navier-Stokes equations with strong coupling to the particle phase. To apply CPFD methodology for heat transfer and chemistry, an enthalpy equation is solved to calculate flows with large chemistry-induced temperature variations. The CPFD method is a hybrid numerical method, where the fluid phase is solved using Eulerian computational grid and the solids are modeled using Lagrangian computational particles (Andrews and O'Rourke, 1996; Snider, 2001).

Eikeland et al. (Eikeland *et al.*, 2015) used the process simulation tool Aspen Plus to simulate the biomass gasification process. The reactions are simulated by using Gibbs reactor or continuous stirred tank reactor (CSTR). The Gibbs reactor only includes the stoichiometric equations, whereas the CSTR model includes both the stoichiometric equations and the related reaction rates for analysis of the producer gas composition and its heating value. Eikeland used the the set of kinetic equations developed by Umeki et al. (Umeki *et al.*, 2010). Aspen Plus is a one-dimensional steady state simulation model.

The aim of the current work is to investigate the sets of reaction scheme kinetics published in literature by simulating them using the ReactLab™ KINSIM software from Jplus Consulting (Norman *et al.*, 2016), and compare to the results of the previous works performed with CPFD and Aspen Plus (Eikeland *et al.*, 2015; Thapa and Halvorsen, 2014).

2 Reaction Kinetics

For a reaction of species A and B to C and D, the rate *r* of the forward reaction is in general given by the equation

$$r = k[A]^a[B]^b \quad (1)$$

where *a* and *b* equals the stoichiometric coefficients for an elementary reaction, while this need not be the case for a global reaction consisting of several elemental steps. For a global reaction, the rate-limiting step may include species not present in the global rate formulation. The brackets denotes the concentration (or activities, to be precise) of species *A* and *B* in specified units. The rate constant *k* is a function of temperature as well as specific conditions like the presence of a catalyst. The temperature dependence of *k* can be described by the modified Arrhenius equation

$$k = BT^n exp^{\frac{-E_a}{RT}} \quad (2)$$

where B is a temperature-independent constant (McNaught and Wilkinson, 1997) and n is a number between –1 and +1. The constant n=0 gives the original Arrhenius equation and then usually the letter A denotes the pre-exponential factor. The constant E_a is the activation energy and *R* is the universal gas constant. The reverse reaction rate is given by a similar rate equation. The thermodynamic equilibrium of a chemical reaction corresponds to forward and reverse rates being equal. Thus, denoting the reverse reaction constants with an apostrophe, the equilibrium constant K is given by

$$K = \frac{k(\text{forward})}{k'(\text{reverse})} = \frac{A}{A'} exp^{\frac{-E_a+E'_a}{RT}} = \frac{[C]^c[D]^d}{[A]^a[B]^b} \quad (3)$$

Some reactions, like proton transfer in aqueous solutions, achieve equilibrium close to instantaneous such that product concentrations can be calculated from the equilibrium constants and mass balance. For most reactions, an equilibrium condition is not reached within available time frame, thus product concentrations must be deduced from differential equations. The solution of these may be by algebraic or stochastic methods.

3 Previous Work

Many of the published reaction rate expressions were developed for simulation of coal gasification processes. They have later been applied to biomass sources. In addition, the study of combustion processes involve many relevant species and expressions, and are thus applied for gasification.

3.1 The Gasification Process

The process for gasification of biomass can be divided in three consecutive steps; namely evaporation, pyrolysis, and gasification of resulting char product and volatiles. Both evaporation and pyrolysis proceeds close to instantaneous at the typical process temperatures of above 700 °C. The products after pyrolysis can be characterized as ash, tar, char and gases. The ash fraction is mostly minerals. The tar fraction is higher molecular weight hydrocarbons including small fractions of other elements. Both the ash and tar fractions are of minor importance for the total simulation, and therefore often skipped in the simulation model. The char fraction is mostly solid carbon (C), and is usually treated as pure carbon in following reactions with the pyrolysis gases. The main gases produced from pyrolysis are water (H_2O), carbon monoxide (CO), carbon dioxide (CO_2), hydrogen (H_2) and methane (CH_4). In addition comes the water produced from evaporation. For a fluidized process to work, a fluidization gas is needed. Steam (H_2O) is used in the process studied in this work, while carbon dioxide or air (oxygen, nitrogen) are commonly used in other processes.

3.2 Kinetic Models

The overall chemical reactions to be included in a simulation model then involve reactions between C, CO, CO_2, H_2, CH_4 and H_2O. Some possible chemical reactions are listed in Table 1 and Table 2. Since oxygen is not added to the system, combustion reactions with oxygen has been omitted.

The table field Referring source points to multiple references. It has become common practice to refer to an author who in turn refers to another author and so on, and it is therefore often difficult to evaluate the relevance of the original source, see discussion below.

3.3 Complexity of Sources for Kinetic Rate Equations

For the rates involving solid phase, reference to the Japanese text of Watanabe (Watanabe *et al.*, 2002) is made by Umeki et al. (Umeki *et al.*, 2010). Snider (Snider *et al.*, 2011) is referenced in recent work by Xie (Xie *et al.*, 2012) and Eikeland (Eikeland *et al.*, 2015). Snider in turn refers to Syamlal and Bissett (Syamlal and Bissett, 1992) who refers to a user's manual of a computer program by Wen et al. (Wen *et al.*, 1982).

Wen et al. are listing 4 sets of parameters for 4 types of coal – the parameters are determined from experimental data by Elgin (Elgin, 1974). Any reference to which type of coal that is relevant has been lost in later references.

	$= 2{,}78 \bullet 10^6 exp^{\frac{-1510}{T}}[CO][H_2O]$ $= 1{,}05 \bullet 10^8 exp^{\frac{-5468}{T}}[CO_2][H_2]$	de Souza-Santos – Gibson – Parent (de Souza-Santos, 2004; Gibson and Euker, 1975; Parent and Katz, 1948)
Methane steam reforming reaction: $CH_4 + H_2O \rightleftarrows CO + 3\ H_2$ *+225,5*	$= 3{,}0 \bullet 10^5 exp^{\frac{-15042}{T}}[CH_4][H_2O]$	Gómez – Lindstedt (Gómez-Barea and Leckner, 2010; Jones and Lindstedt, 1988; Yoon *et al.*, 1978)

Reactions *Heat of reaction at 850 °C, ΔH_R (kJ/mol) (Zanzi et al., 2002)*	Reaction rate forward (top) and reverse (bottom) (mol/(m³•s) , J, K)	Referring source
	$= 3{,}1005 exp^{\frac{-15000}{T}} [CH_4][H_2O]$ $= 3{,}556 \bullet 10^{-3} T exp^{\frac{-15000}{T}} [CO][H_2]^2$	Umeki – (Corella) (Corella and Sanz, 2005; Fletcher *et al.*, 2000; Gómez-Barea and Leckner, 2010; Jones and Lindstedt, 1988; Liu and Gibbs, 2003; Thérien *et al.*, 1987; Umeki *et al.*, 2010)
	$= 3{,}10 \bullet 10^{-5} exp^{\frac{-15000}{T}} [CH_4][H_2O]$ $= 1{,}17 \bullet 10^{-3} exp^{\frac{-47900}{T}} [CO][H_2]^3$	revised Umeki – (Lindstedt)
	$= 9{,}1 \bullet 10^{7} exp^{\frac{-15800}{T}} [CH_4][H_2O]$ $= 5{,}52 \bullet 10^{-6} exp^{\frac{211200}{T}} [CO][H_2]^3$	Maki (Maki and Miura, 1997; Modell and Reid, 1974)

For the water-gas shift reaction, the several sources for the reaction rate expression shows a wide variety of reaction rates. Eikeland et al. (Eikeland *et al.*, 2015) refer to Umeki et al. (Umeki *et al.*, 2010). Umeki at al. refers to Corella and Sans (Corella and Sanz, 2005), but are using the GRI expressions referred by Snider et al. (Snider *et al.*, 2011) from Bustamante (Bustamante *et al.*, 2004; Bustamante *et al.*, 2005). Xie et al. (Xie *et al.*, 2012) refers to Gómez-Barea and Leckner (Gómez-Barea and Leckner, 2010), who refers to Biba et al. (Biba *et al.*, 1978) referring to a book by Franks (Franks, 1967).

Biba et al. (Biba *et al.*, 1978) points out that values determined by experiments for the frequency factor cited in the literature are strictly dependent on the form of the carbonaceous material being examined, on the specific surface area, and on the corresponding value of activation energy. They have chosen mean values of literature data, and then made a sensitivity analysis for their mathematical model. Any reference to which type of coal that is relevant has been lost in later references.

The history for kinetic parameters used for the methane steam reforming reaction is similar to preceding text. In addition, it seems that a typing error is introduced by Corella and Sans (Corella and Sanz, 2005) and later referenced by Umeki et al. and Eikeland et al. Corella and Sans refers to work by Thérien et al. (Thérien *et al.*, 1987) and Liu and Gibbs (Liu and Gibbs, 2003) from Fletcher et al. (Fletcher *et al.*, 2000) which includes a reference to Jones and Lindstedt (Jones and Lindstedt, 1988). The typing errors have been corrected in the "revised Umeki-(Lindstedt) source" in Table 2.

3.4 Chemical Equilibria

For reactions that are kinetically restricted and far from equilibrium conditions, only the forward reaction rate is significant. This should, of course, be verified by comparing calculated forward and reverse rates at the simulation conditions.

The water-gas shift reaction is relatively fast (although slower than oxygen combustion) and both forward and reverse rates as well as the equilibrium constant is relevant for most simulation conditions. Bustamante et al. (Bustamante *et al.*, 2005) points out that the wide range of kinetic parameters found in literature is due to varying catalytic effect from surfaces present at experimental conditions. Typically, carbon surfaces or deposits and nickel-containing steel (like Hastelloy®) as well as minerals in ash are shown to have catalytic effect on the reaction, resulting in high reaction rates. The expression for the equilibrium constant of the water-gas shift reaction from several sources are shown in Table 3. The last line source, Callaghan (Callaghan, 2006), is a recent thesis covering the details about the water-gas shift reaction, and presumably represents reliable knowledge about the equilibrium constant for the reaction.

4 Example Screening of Kinetic Rate Equations

In order to have a simulation model that predicts chemical composition, both the reaction rate kinetics and the targeting equilibrium composition should correspond to real life conditions. Taken the vast difference among literature data, the choice of kinetic rate expressions is not straight forward.

Figure 1 compares the equilibrium constant value, K_{eq}, for the water-gas shift reaction based on selected literature data from Table 3. A positive value of $\log K_{eq}$ corresponds to the forward reaction being favored. The reaction is a moderately exothermic reversible reaction, therefore with increasing temperature the reaction rate increases but the conversion of reactants to products becomes less favorable. It is evident from Figure 1 that some sources are using an equilibrium constant not consistent with reliable data. On the other hand, if equilibrium conditions are not reached, the simulation model may still perform sufficiently well. That is, if the reaction rate expressions can reproduce the chemical reactions at present conditions.

Table 3. Expressions for Equilibrium Constant

$\log(K) = -2{,}418 + 0{,}0003855 \times T + \frac{2180{,}6}{T}$	Callaghan (Callaghan, 2006)

The following discussion on reaction rates takes as an example the feed inlet conditions for a fluidized reactor as described by Eikeland (Eikeland *et al.*, 2015) and is comparable by work of Thapa (Thapa *et al.*, 2014). Figure 2 compares the initial reaction rates based on composition at inlet to the reactor and selected reaction scheme. Again, the vast variation in source data is evident. The rate expressions used by Snider from Bustamante is close to the non-catalyzed reaction rates found experimentally by Bustamante (Bustamante *et al.*, 2005). Higher reaction rates presumably are deduced from catalytic conditions. Therefore, a simulation model should include rate expressions from sources that resembles the conditions of the target reactor and biomass feed.

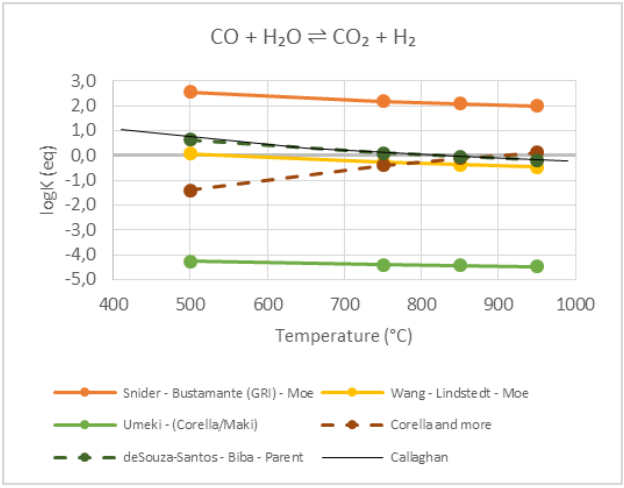

Figure 1. Equilibrium constant for water-gas shift reaction

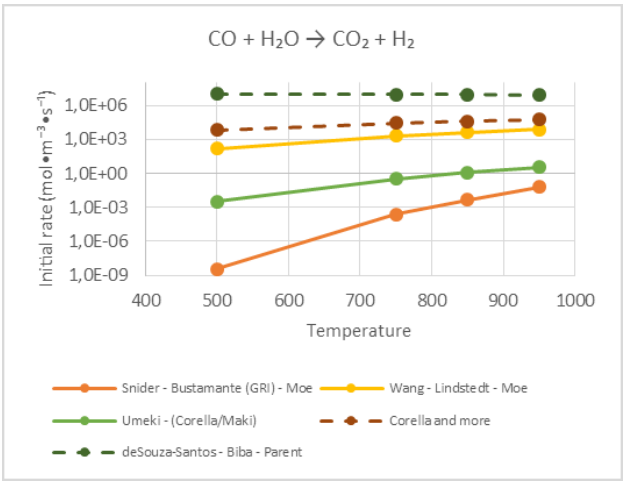

Figure 2. Initial rate of water-gas shift reaction at feed inlet conditions as described by Eikeland (Eikeland *et al.*, 2015).

4.1 KINSIM simulation software

The ReactLab™ KINSIM software from Jplus Consulting (Norman *et al.*, 2016) is one of several software packages available. The software uses MS-Office Excel as frontend to a compiled application of MatLab®. Any defined equilibria is treated as instantaneous, while differential equations for the forward and reverse reaction rates are solved.

4.2 Kinetics

The set of rate expressions used by Thapa (Thapa *et al.*, 2014) together with calculated molar concentrations at inlet feed conditions have been used for time profile simulation of rate expressions. The KINSIM software has been used. The results resemble a batch or plug flow reactor. The residence time 12 s has been chosen to have a conversion comparable to results from Aspen Plus CSTR and Barracuda simulations by Eikeland and Thapa. In addition, simulations with residence time

300 s is shown to get an impression of semi-equilibrium conditions. See Figure 3 to Figure 6.

The Figure 3 to Figure 4 show the water-gas shift reaction to be dominating in consuming CO and water while producing H_2 and CO_2. Still, the semi-equilibrium conditions may not be reached until about 100 s. The total conversion of carbon is strongly limited using this set of rate expressions, and other reactions do not contribute significantly as seen by the very small change in CH_4 concentration. Actually, this imply that a similar simulation result can be obtained by simulating only the water-gas shift reaction. Results including only water-gas shift reaction and water-gas reaction are shown in Figure 5 to Figure 6. At 12 s residence time, the results are identical to the full set of rate expressions. Of course, at 300 s residence time the lacking effect of other reactions are evident, the included carbon conversion reaction is very low.

Figure 7 shows the composition change during the gasification process as simulated at 850 °C by Aspen Plus CSTR, Barracuda CFD and KINSIM plug-flow reactor conditions.

The pyrolysis step corresponds to presumptions for this step made by Thapa and Eikeland (Eikeland *et al.*, 2015; Thapa *et al.*, 2014). In addition, the steam to feed ratio is kept at 1 to 1 weight dry basis. A residence time of 17 s was used for the CSTR conditions, while fluid residence time by Barracuda simulation is estimated to minimum 20 s. The particle residence time is much higher. The last set of results are from using KINSIM with only two rate expressions as shown above. The Barracuda simulation give results that is in between Aspen CSTR and KINSIM plug-flow results while applying the same rate expressions. This is consistent with fluid flow in a fluidized bed reactor be described partly as plug-flow and partly as stirred tank reactor.

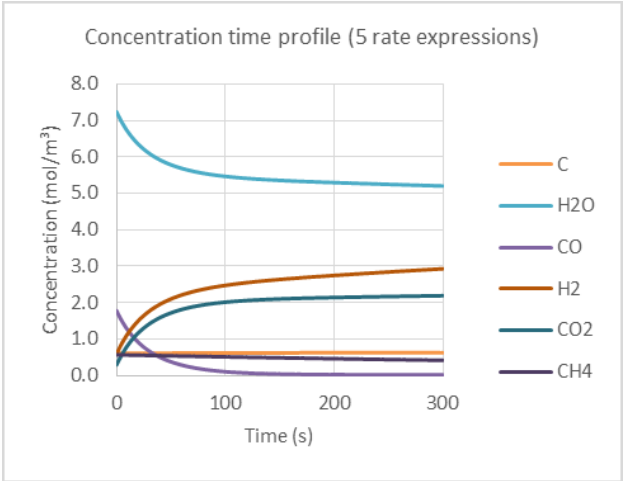

Figure 4. Concentration time profile for the full 5 sets of rate expressions (semi-equilibrium time).

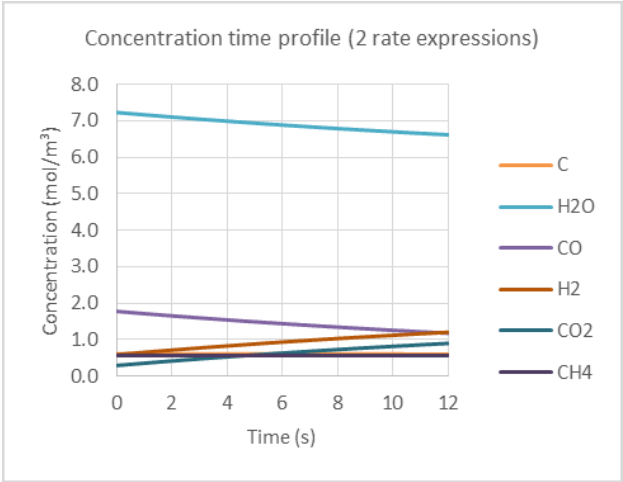

Figure 5. Concentration time profile for only 2 sets of rate expressions (short time).

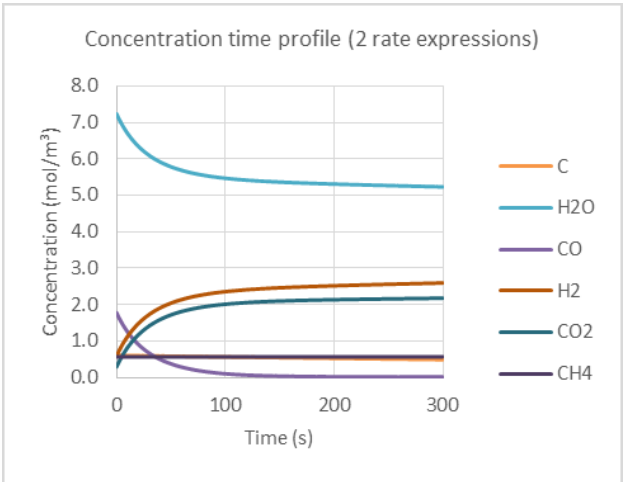

Figure 6. Concentration time profile for only 2 sets of rate expressions (semi-equilibrium time).

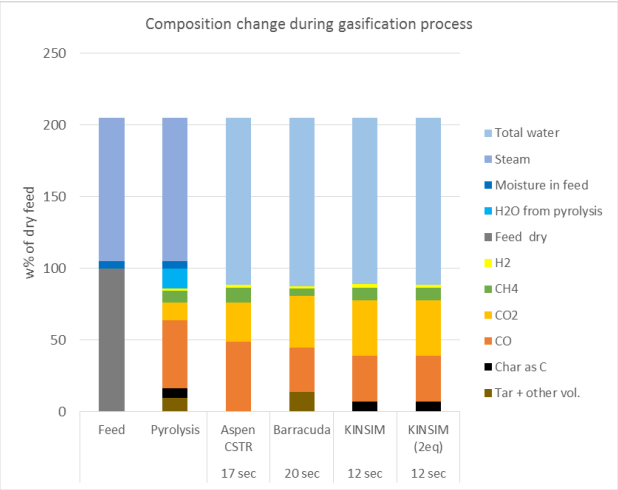

Figure 7. Composition change during a gasification process, feed and steam to outlet stream.

5 Conclusions

The evaluation and screening of candidate rate expressions to be used in a reactor simulation is made difficult by the obscure definition of experimental conditions as background to defined rate expressions. A lightweight tool like KINSIM and others are useful for comparison of several rate expressions and by that evaluate how significant they will contribute to the total simulation. In addition, knowledge about concentrations, residence times and real life results should be used to choose suitable set of rate expressions.

The 5 set reaction scheme studied here could be simplified to 2 sets of reactions by removing those reactions of minimal contribution to overall reaction.

Abstract

This paper describes a Model Predictive Control (MPC) system for voltage control through field excitation of hydroelectric generating units. An attractive feature of MPC is its capability to handle Multiple Input, Multiple Output (MIMO) systems and nonlinear systems taking constraints into account. The system under study is a power system based on detailed models from Matlab's SimPowerSystems™ and parametrized according to the Nordic model from the Norwegian Transmission System Operator (TSO), Statnett. The primary role of the field excitation control system is to quickly respond to voltage disturbances occurring in the power system. The control system is tested for both first-swing transient stability and long term voltage stability.

Power system modeling and control, model predictive control, SimPowerSystems, first-swing rotor enhancement, long term voltage stability, fmincon

1 Introduction

In this paper a Model Predictive Controller (MPC) for field excitation of synchronous generators is tested, and compared to a classical controller typically used for this purpose. MPC is an advanced control methodology that has proved to be successful in real-life applications. An attractive feature of MPC is its capability to handle Multiple Input, Multiple Output (MIMO) systems and nonlinear systems taking constraints into account (Maciejowski, 2002).

There are mainly two requirements for successful operation of a power system (Hegglid, 1983). The first requirement of reliable service is to keep the generators running in parallel (synchronous) and with necessary capacity to meet load demand. If at any time the generator loses synchronism with the rest of the system, significant voltage and current fluctuations may occur and transmission lines may be automatically tripped by their relays at undesired locations (Kundur, 1994).

A second requirement of reliable service is to maintain the integrity of the power network. Interruptions in this network may hinder flow of power to the load, leading to severe blackouts of the power system. This usually requires a study of large geographical areas since almost all power stations and load centres are connected in one system.

A controller should maintain both of these requirements: keeping the generators running in parallel and to maintain the integrity of the power system. This is achieved mainly by reducing the first swing of the rotors of the synchronous generators after large disturbances, and the damping of power oscillations (also small disturbances). Another important requirement for a controller is to provide necessary reactive power supply Q for enhancement of voltage stability. Reactive power can be used to compensate for voltage drops, but must be provided closer to the demands than active power P needs due to transportation limitations of reactive power through the grid.

A flexible power factor control on large synchronous generators located close to points of high demand could enhance the voltage stability of a power system. The Norwegian Network Code FIKS [1] states that synchronous generators ≥ 1 MVA must connect to the grid with a $\cos\phi$ ≥ 0.86 overexcited and ≤ 0.95 underexcited at maximum load (independent of the location from the point of demand). However, necessary enhancement of voltage stability could be secured through use of more advanced control where more reactive power is temporary available from large generators generated locally.

The paper is organized as follows. Section 2 provides a brief overview of field excitation control of synchronous generators. Section 3 describes MPC for the excitation system and the modeling workflow used in this paper. Section 4 describes MPC tuning. Section 5 introduces, describes and discuss the different tests and results from simulations. In Section 6, conclusions and future perspectives are presented.

2 Field Excitation Control

2.1 Capability Curve

Synchronous machines are capable of producing and consuming reactive power. When the machine is overexcited, it generates Q and deliver it to the power system. Negative Q then, flows from the system into the machine to maintain its magnetization when its own field is underexcited. Generally, reactive power support is divided into

[1]Funksjonskrav I Kraft-Systemet 2012 from the Norwegian Transmission System Operator (TSO) (Statnett, 2012)

two categories: static and dynamic (Kundur, 1994). Dynamic reactive power is produced from equipment that can quickly change the Q independent of the voltage level such as a synchronous generator or condenser (generator without active power exchange P with the grid). Thus, the equipment can increase its reactive power production level when the voltage drops, and prevent a voltage collapse.

A generators operating constraints can be visualized through a capability diagram (Farnham and Swarthout, 1953). In Figure 1, the capability curve is shown for the synchronous generator used for simulations in this paper.

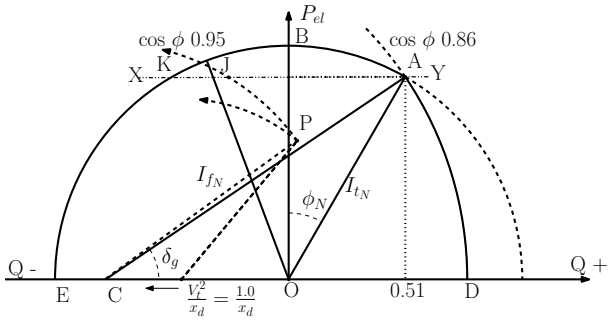

Figure 1. Capability curve for synchronous generator used in simulations. Point A represents the name-plate rated conditions with power factor $\cos\phi = 0.86$ for the generator. Rated (nominal) MVA of the machine $S_N = \sqrt{P_N^2 + Q_N^2}$ is taken as 1.0 per unit on its own rated MVA base. Hence, the rated conditions for machine operation are 0.86 per unit MW and 0.51 per unit MVAr ($\cos\phi = 0.86$, $\sin\phi = 0.51$).

Point A is just one point in a rather extensive area of Figure 1. Few machines are operated at any length of time exactly in the condition of A. The operating conditions in overexcited mode is bounded by the armature current limit AB (circle having its centre at O, and radius equal to rated armature current, I_{t_N} or OA) and the field current limit AD (circle having its centre at C, and radius equal to rated full load field current, I_{f_N} or CA). The controller can control the field current represented by CP in Figure 1. CP/CA is simply the proportion of rated field current, and this is just the amount necessary to permit the machine to handle the P and Q represented by point P. If the load increases without any change in the field current, this causes a movement of operating point P along the arc PK. This path runs almost directly into the instability region (Farnham and Swarthout, 1953) of the generator, e.g minimum field current for stable operation. The final operating point would lie on the XY line, representing limits set by the turbine power. The figure also shows the effect of increased synchronous reactance x_d of the machine. This increase in x_d makes the machine reach the stability limits even faster. The maximum reactive power that can be delivered from this generator is defined by OD=CA-CO (e.g. as an synchronous condenser). With a synchronous reactanse x_d of 1.24 in per-unit, terminal voltage $V_t = 1.0$ in per-unit, and the given operating conditions in Figure 1, the rated field current [2] can be calculated to be 1.6 from

$$I_{f_N} = \sqrt{\left(\frac{V_t^2}{x_d} + \frac{Q_t}{S_N}\right)^2 + \cos\phi_N{}^2}. \quad (1)$$

2.2 Classical Control

The excitation (or field) current required to produce the magnetic field inside the generator, is provided by the exciter and is controlled by an Automatic Voltage Regulator (AVR) (Kundur, 1994). The AVR regulates the generator terminal voltage by controlling the amount of current supplied to the generator field winding by the exciter. Power System Stabilizers (PSS) are feed-forward supplementary control devices which are installed in generator excitation systems to increase damping of (power) oscillations. The specification of excitation systems is guided by IEEE standards 421 (IEEE, 2007). In this paper, a synchronous machine voltage regulator and exciter based on the IEEE type ST1A excitation and Kundur's (Kundur, 1994) generic PSS is used. This type represents a classical exciter model of static potential-source controlled-rectifier systems. This classical control structure is shown in Figure 2

There are two key factors that define an excitation system: the transient gain and the ceiling force ratio (IEEE, 2007). Because of a very high field forcing capability of the system, a field current limiter is employed to protect the generator rotor and exciter. The transient gain has a direct impact on small signal and dynamic stability. Too small a value may fail to give the desired performance, while too high a value (faster response) may result in instability during faults.

3 Concept and Formulation of MPC

MPC is an algorithm where an optimal control problem is solved at the current time, then a receding/sliding horizon technique is applied as time progresses. The predictive controller considers both past situations (given by state) and the changing of the system in a finite future time horizon. To solve the optimal control problem, an optimization routine is needed. In the optimization problem, an objective/criterion to be maximized/minimized is formulated together with constraints (Maciejowski, 2002).

Optimal control is an open loop optimization problem. If input disturbances and references change in the future, the controller has no knowledge about this change since no feedback is presented in the solution. Under such conditions optimal control problems may give good performance. To come around this challenge, *feedback* is introduced to the optimal controller. A way to do this is called Model Predictive Control (MPC) (Sharma, 2014).

[2] The rated field current is the direct current in the field winding of a machine, when operating at rated voltage, current and speed and at rated power factor for synchronous machines (Farnham and Swarthout, 1953).

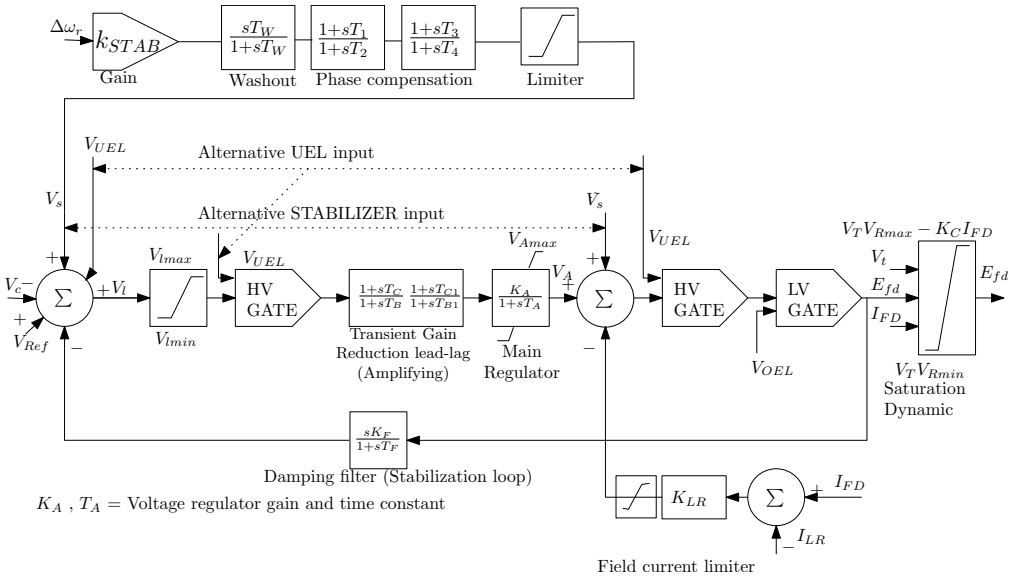

Figure 2. The classical static excitation control ST1A with PSS used in simulations. The PSS representation consist of a phase compensation block, a signal washout block and a gain block. The models are tuned according to Kundur (Kundur, 1994).

As mentioned above, MPC is optimal control with a sliding horizon strategy, e.g. a new optimal control problem is solved at every time step Δt.

Assume the initial state of the plant x_j is known, together with current/future references r_{j+1},r_{j+2},..,r_{j+N} and disturbances w_j, w_{j+1},..,w_{j+N-1}. By solving the optimal control problem, this leads to an optimal open loop control input sequence $u^*_{j|j}$, $u^*_{j+1|j}$,..., $u^*_{j+N-1|j}$. Subscript $k|j$ implies the control input at time k, when current state x_j is known. It is clear that $u^*_{k|j} = u^*_k(x_j, r_{j+1}, .., r_{j+N}, w_j, .., w_{j+N-1})$. The dependence of $u^*_{k|j}$ on $r_{j+1}, .., r_{j+N}, w_j, .., w_{j+N-1}$ gives feed forward from $r_{j+1}, .., r_{j+N}, w_j, .., w_{j+N-1}$. However, optimal control where $u_k = u^*_{k|j}$ does not give feedback since u_k only depends on x_j. To have feedback, we require that u_k depends on x_k. To achieve feedback, introduce receding horizon: set $u_j = u^*_{j|j}$. Then find or estimate x_{j+1} after u_j has been injected, shift/recede the optimal control horizon one step. The process is then repeated to compute $u^*_{j+1|j+1}, u^*_{j+2|j+1}, .., u^*_{j+N+1|j+1}$ by setting $u_{j+1} = u^*_{j+1|j+1}$ and we introduce feedback.

Because of feedforward the controller can react before known disturbances (or set point changes) affect the process. A model of the disturbance should then be included along with the model of the process while solving the optimal control problems at each time step.

3.1 MPC as Excitation Control

For the power system generator excitation control, the selected system outputs are the generator voltage and angular velocity. The manipulating input, u, is the generator field excitation voltage E_{fd} when it is used as a primary controller. Alternatively MPC is also used as a secondary controller to change set-point of the classical (primary) controller $u = V_{ref}$. In Figure 3, the control structure used in the simulations is shown. For transient stability, MPC works as primary control while during long-term stability analysis MPC was tested both for primary and secondary control. The control system can also change between classical and MPC control during simulation.

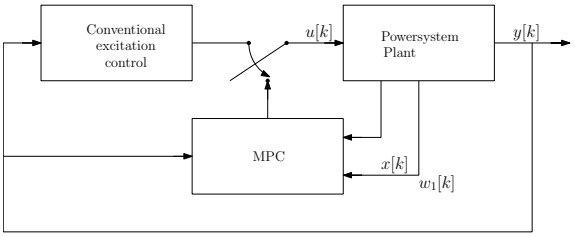

Figure 3. Structure of plant and controller. Here, MPC is a Multiple Input, Single Output (MISO) controller.

The performance index J is scalar and is computed as a summation of the square of the deviations between outputs and references, Δe, and the variations of the controlling inputs to the controlled system, Δu_c. Weighting factors $\mathbf{Q}$, $\mathbf{P}$ and $\mathbf{R}$ are included in J as tuning parameters.

$$J = \sum_{j=1}^{N_p} \Delta e_{V,j}{}^T \mathbf{Q} \Delta e_{V,j} + \Delta e_{\omega,j}{}^T \mathbf{P} \Delta e_{\omega,j} + \sum_{j=1}^{N_c} \Delta u_{c,j-1}{}^T \mathbf{R} \Delta u_{c,j-1} \quad (2)$$

where

$$\Delta u_{c,j} = u_{c,j} - u_{c,j-1} \quad (3)$$

$$\Delta e_{\omega,j} = \omega_{ref} - \omega_{,j} \quad (4)$$

$$\Delta e_{V,j} = V_{ref} - V_{t,j} \quad (5)$$

The control input is the field excitation voltage

$$u_{c_j} = [E_{fd_{c_j}}] \quad (6)$$

N_p and N_c are prediction and control horizon lengths. The inequality constraint on the controlled variable are $E_{fd_c} \in [E_{fd_{min}}, E_{fd_{max}}]$ where $E_{fd_{min}} = -3.2$ per-unit and $E_{fd_{max}} = +3.2$ per-unit (Two times the rated field current according to FIKS (Statnett, 2012)).

The control output

$$y_j = [V_{t,j}, \omega_{g,j}]^T \tag{7}$$

3.2 Modeling and Control Workflow

The modeling part in this paper is done with the *powerlib* library of *SimPowerSystems*™ built on the *Simscape*™ language, running within the *Simulink*® environment. *SimPowerSystems* provides component libraries and analysis tools for modeling and simulating electrical power systems. Since Simulink uses MATLAB as its computational engine, MATLAB toolboxes are available. In this paper, MPC is implemented using the MATLAB Optimization Toolbox and the *fmincon* solver with the *Active-Set* method.

For simulations, the phasor domain solution method with Simulink®variable-step solvers (ode23t and ode23tb) are used. The phasor solution method is mainly used to study electromechanical oscillations of power systems, which is the case study in this paper.

To further increase the speed of optimization, all simulations were done in *Accelerator* mode and with the *Fast Restart* command. The Accelerator mode generates and links code into a C-MEX S-function. The idea of *Fast Restart* is to perform the model compilation once and reuse the compiled information for subsequent simulations. Also the *SimState* function was used for easily integration within the optimization algorithm. A *SimState* is the snapshot of the state of a model at a specific time during simulation.

4 Tuning the MPC Controller

4.1 Time Response

The voltage controller needs to operate freely and without unnecessary restriction within performance limits of the generator and excitation system. A standard procedure for evaluating the response of the closed-loop excitation control system is to document its dynamic characteristics. A small-signal performance measure is expressed in terms of indices associated with time response. A step-response test is done on the regulator in open circuit conditions according to TSO. The mathematical model design to be used for the MPC tuning and also first-swing tests is a classical SMIB (Singel Machine Infinite Bus). This model consist of a three-phase salient-pole synchronous machine modelled in the dq rotor reference frame, three-phase transformer, transmission line and a voltage source as an inifinite bus as shown in Figure 4.

The model is a power plant in Norway: the 175 MVA hydro power plant Kobbelv aggregate 2 owned by Statkraft AS (G2 in Area 2 in Figure 11). The main data for this generator is given in Table 1

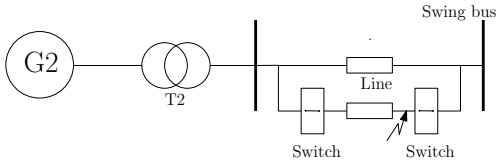

Figure 4. Singel Machine Infinite Bus (SMIB) for transient stability simulations.

Table 1. Main data for G2 in area 2.

Description	Parameter	Value	Unit
Rated power	S_N	175	MVA
Rated Power factor	$\cos\phi_N$	0.86	
Rated voltage	Vt_N	16.5	kV
Frequency	f	50	Hz
Number of polepairs	p	8	
Inertia constant	H	2.9	s

4.2 Open Circuit Conditions

The voltage regulator should be verified by the impulse response in open circuit conditions. For the voltage regulator, a 5% up and down step-response test on the voltage regulator should be carried out. The voltage should be measured over the generator terminals and the response should be non-oscillatory with a overshoot less than 15% of the impulse response itself. The results are shown in Figure 5.

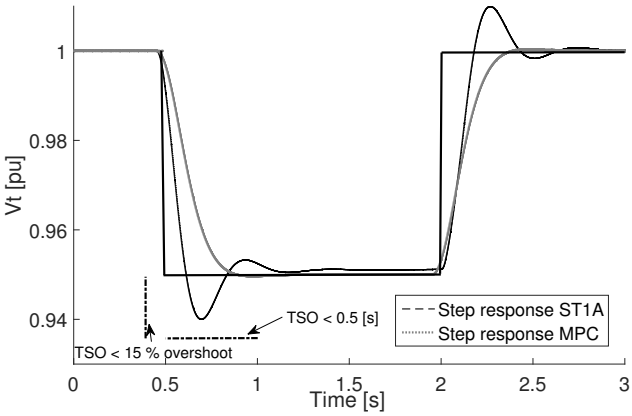

Figure 5. The figure is showing a open circuit small-signal time response test with respect to TSO requirement for both MPC and classical control ST1A. The settling time must be < 0.5 seconds for a 0.95 to 1 step-up and a 1 to 0.95 step-down from steady state value according to FIKS (Statnett, 2012). The overshoot shall be less than 15 % of the change. The MPC tuning parameters were $N_p = 5$, $N_c = 1$, $\mathbf{Q} = 300$, $\mathbf{P} = 5$, $\mathbf{R} = 0.01$ and $\Delta t = 0.05$.

5 First-swing Angle Stability Enhancement

First-swing angle stability (or transient stability) enhancement is necessary to avoid loss of synchronism. Two factors which indicate the stability are the angular swing (during and after a fault) and the critical clearing time t_{crit} [3] (or clearing angle δ_{crit}) of a fault (Grainger and Stevenson, 1994). The generator rotor angle swing normally peaks between 0.4 and 0.75 seconds. This short time demands a fast acting voltage regulator to boost the internal voltage through the field excitation. The steady-state power-angle characteristic presented in Figure 6 shows the highly non-linear relationship between interchange electrical power P_e and angular position δ of the rotors of the synchronous generators (The effect of AVR and damping windings (Kundur, 1994) are neglected).

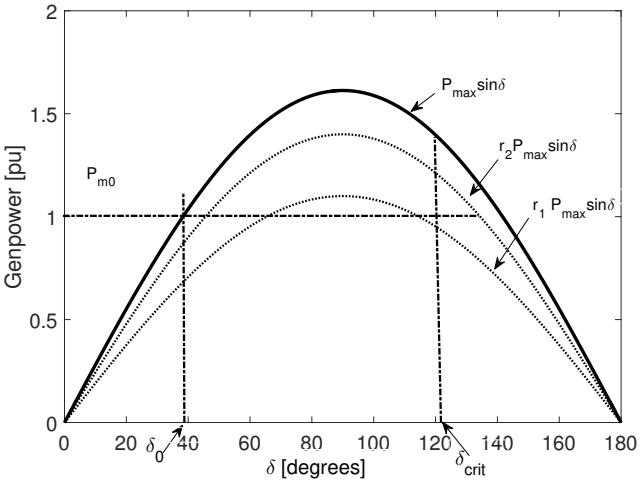

Figure 6. Plot of power-angle curves (Pre-fault P_{max}, during fault $r_1 P_{max}$ and post-fault $r_2 P_{max}$) for synchronous generator G2 Area 2 showing, initial mechanical power and electrical power $P_{m0} = P_e = 1pu$, inital angular position of the rotor $\delta_0 = 39$ degrees and the critical clearing angle calculated to $\delta_{crit} = 122$ degrees and corresponding critical clearing time $t_{crit} = 0.28$ seconds.

Position $\delta_0 < 90$ in Figure 6 is the initial operating point of a stable operation. The swing equation for the machine with constant flux linkage may be written in acceleration form as

$$\frac{H}{180f}\frac{d^2\delta}{dt^2} = P_m - P_e = 1.0 - P_{max} sin\delta \tag{8}$$

$$P_{max} = \frac{E_g \cdot V_{bus}}{x_s} \tag{9}$$

E_g is the synchronous machine transient voltage, x_s is the series transfer reactance between E_g and swing bus V_{bus}, and f is the electric frequency. In all the simulations,

[3] The critical clearing time is the maximum elapsed time from the initiation of the fault until its isolation such that the power system is stable.

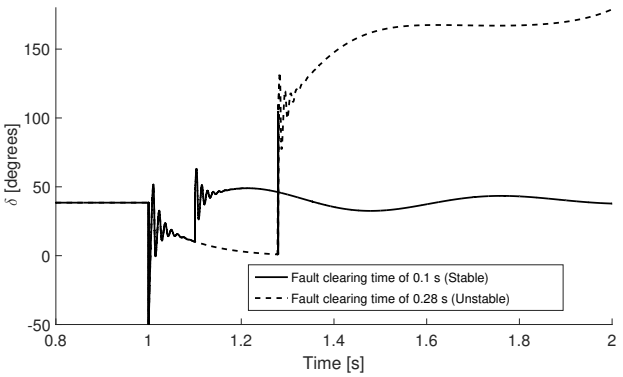

Figure 7. Plot of rotor angle δ affected by a three-phase fault under constant field voltage control for synchronous generator G2 in Area 2. The plot shows two different fault clearing times. The fault cleared after 0.28 seconds lead to loss of synchronism as calculated from t_{crit}.

P_m is kept constant. When P_m equals P_e, the machine operate at steady state synchronous speed. Both the inertia constant H and transient reactance of the machine x'_d has a direct impact on the first swing (transient) studies. A smaller H gives a larger angular swing. P_{max} decreases as the transient reactance increases since it forms a part of the overall series reactance. A decreased P_{max} constrains the machine to swing through a smaller angle from its original position before it reaches the critical clearing angle.

The MPC controller was tested and compared to classical control as shown in Figure 8 and Figure 9.

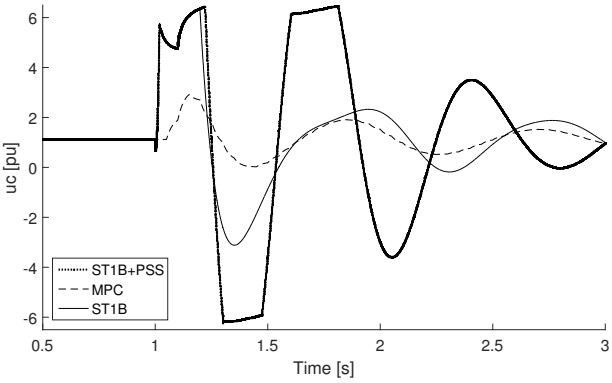

Figure 8. Change in field voltage E_{fd} as a function of time under disturbance of a three-phase arc fault for three different types of control actions. Clearing time was 0.1 second. Future disturbance is not known for the controller.

6 Long-term Voltage Stability Enhancement

6.1 Steady-state Voltage Stability

The steady-state voltage-power characteristics (also called onion surface) shown in Figure 10 for the SMIB, gives insight into the voltage stability problem (Larsson, 2000).

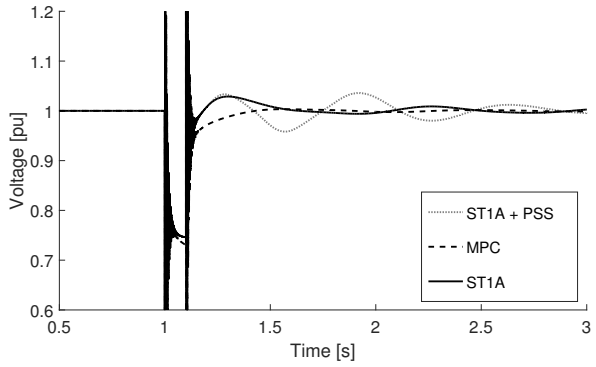

Figure 9. Change in terminal voltage V_t as a function of time under disturbance of a three-phase arc fault for three different types of control actions. Clearing time was 0.1 second. Future disturbance is not known to the controller.

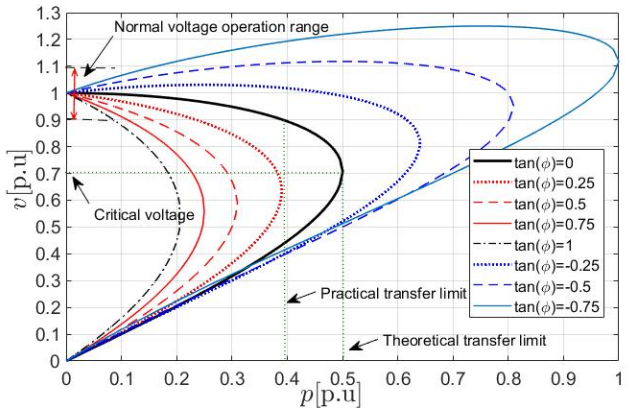

Figure 10. Normalized power(p)-voltage(v) curves (onion surface) for steady-state voltage stability analysis. The practical and theoretical transfer limits and the critical voltage is given for $\tan(\phi) = 0$.

The critical voltage V_c (voltage collapse) points out the theoretically stability limit of the SMIB. The most important factor to provoke a voltage collapse (blackout) is the load model as presented in (yvang et al., 2014) . A widely used dynamic load characteristic is an exponential load model with fractional load exponents combined with time constants for both active and reactive power (Cutsem and Vournas, 1998). If the voltage is lower than a specified value, the load impedance is kept constant. An impedance load model adapts to the voltage. However, a dynamic load that recovers over time combined with automatic tap-changers would stress the power system. When load recovers in a highly loaded system, the need for reactive power increases with I. This will automatically bring the system to the edge. In addition one needs to make sure that generator exciters are limited (Kundur, 1994).

6.2 Power System Simulator

Large-disturbance (e.g. loss of load or loss of generation) long term voltage stability simulations requires the examination of the dynamic performance of the system over a period of time sufficient to capture the interactions of such as tap-changers and field current limiters (Kundur, 1994). This means that it is not only sufficient to simulate a three phase fault with clearing of fault after some milliseconds as done with first swing simulations. After an arc fault the system will either be transiently unstable, partly or as a whole (collapse), or it will return to a stable point. Thus, additionally outage of a line or any reactive power source is of interest (Cutsem and Vournas, 1998). For Long Term Voltage Stability (LTVS) simulations, a more complex simulator was needed to test the MPC controller in contrast to the SMIB simulator in transient studies. A Dynamic Study Model has been developed based on the Nordic Model 2010 High Load Case (Norgesmodellen) from Statnett. The geographical area is in the North region of Norway containing four synchronous generators and one synchronous compensator. It also contains an tap-changer connected to a dynamic load for stressing the system. The model was tuned to operate near its capacity limit and could exhibit cascading failures which could lead to blackouts. The power system model is shown in Figure 11.

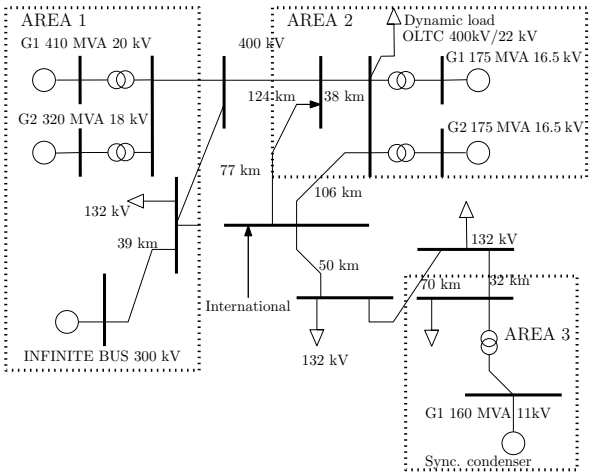

Figure 11. Power system simulator for long term voltage stability simulations based on the Nordic Model from Statnett. The system consists of three different Areas including four synchronous generators and one synchronous condenser. Power is also fed through the international transmission link.

6.3 LTVS Simulations

For LTVS simulations in this paper the international transmission link is disconnected demanding necessary reactive power to be delivered locally. The tap-changer is then trying to restore the voltage at load forcing the system to collapse. As expected from the steady state calculations, the power system have a blackout when part of the system is reaching the critical voltage limit around 0.7 per-unit as seen in Figure 12.

Results from simulations with MPC as primary control are shown in Figure 13 for different tuning parameters. Optimization is done at every $\Delta t = 1s$. A smaller Δt and a longer prediction horizon N_p gives better control but has a

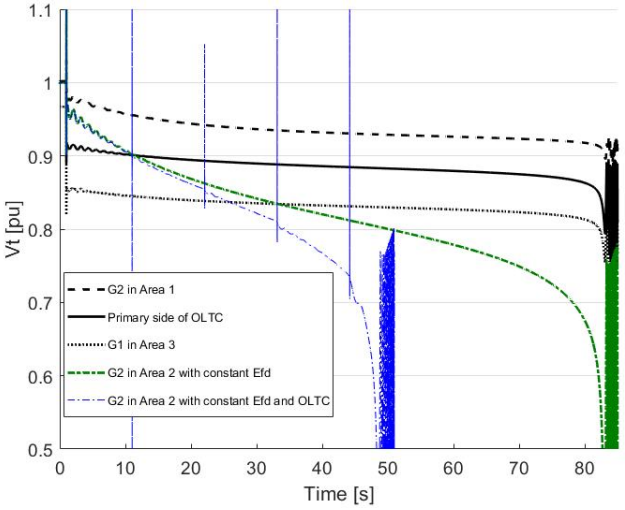

Figure 12. Voltage as a function of time for some selected buses in the power system with and without OLTC control on dynamic load. Area 1 Generator 1 and Generator 2 has constant field voltage. Area 2 Generator 1 and Area 3 Generator 1 has implemented classical control.

higher computational cost. The weighting factors are the same as earlier.

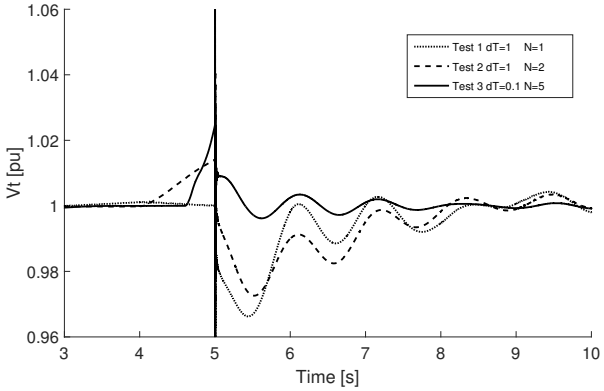

Figure 13. Voltage as a function of time where MPC control action are implemented at Area 2 G2 as primary control.

According to the TSO, the set-point voltage of the controller has to be between 0.9 and 1.05 per-unit value and can be set both locally and from a control center. For simulating such a scenario, MPC is used to change the set-point value $u = V_{ref}$. In this case, the set-point was changed for both generators in Area 2 for bringing the voltage at the On-Load-Tap Controller (OLTC) bus closer to 1 pu after the disturbance. In this simulation, saturation is also included in the dynamic model. Future disturbance is also known. Results are shown in Figure 14 and Figure 15 with different Δt, horizon N_p and tuning parameters.

7 Discussion

This investigation on transient and long term voltage stability considers the ideal (though unrealistic) situation where the internal MPC model exactly matches the real system (perfect MPC model). It is unrealistic to expect that the MPC controller could maintain a complete, accurate system representation. The degree to which MPC can tolerate model inaccuracy is core to practical power system implementation (Gong, 2008). A more realistic implementation could be an SMIB model representing the whole grid. Thus, state estimation should be done on the synchronous generator. In addition, the transfer reactance x_s in (9) needs to be estimated and the infinite bus voltage V_{bus} in (9) needs to adapt the actual voltage level in the system for a good predictive control action. The size of the inductor could be identified from the electromechanical first swing oscillations after a fault.

In these simulations, the full nonlinear model was used with MPC e.g. NMPC. NMPC requires extensive computing power to solve nonlinear constrained optimization problems in real time. In the case of transient stability, NMPC is too slow to avoid loss of synchronism. One other problem that occurs in simulating electrical circuits is that their equations often exhibit stiffness. In SimPowerSystems snubber resistors and capacitors are used across the switches to improve numerical stability. Ode 23tb was the fastest integrator in these simulations. However, with long term voltage stability when the MPC is acting only as set-point changing controller with a sampling time e.g every 5-10 second, NMPC could be feasible. In that case, a linear prediction model combined with C-code implementation should be used.

The MPC should also be tested for low frequency electromechanical oscillations in large interconnected power systems (e.g. both inter-area and local oscillations) (Kundur, 1994). This would determine more precise MPC tuning parameters applicable for both small- and large-signal stability.

The Simscape language is an object-oriented language based on MATLAB and is very attractive to use for power system modeling. One alternative is to integrate the open source object oriented Modelica modeling language with MATLAB through the FMI toolbox from Modelon. In that case the MATLAB optimization toolbox can be used to run MPC on a Modelica model through C code generation.

8 Conclusion

This paper investigates the use of Model Predictive Controll (MPC) for voltage (excitation) control of synchronous generators to enhance the stability of the power system. Simulation results show that a well tuned predictive controller combined with an internal model that exactly matches the real system, gives improved control action in all the simulations compared to classical control. Due to computational limitations, real time simulation for transient stability would not be possible with the strategy

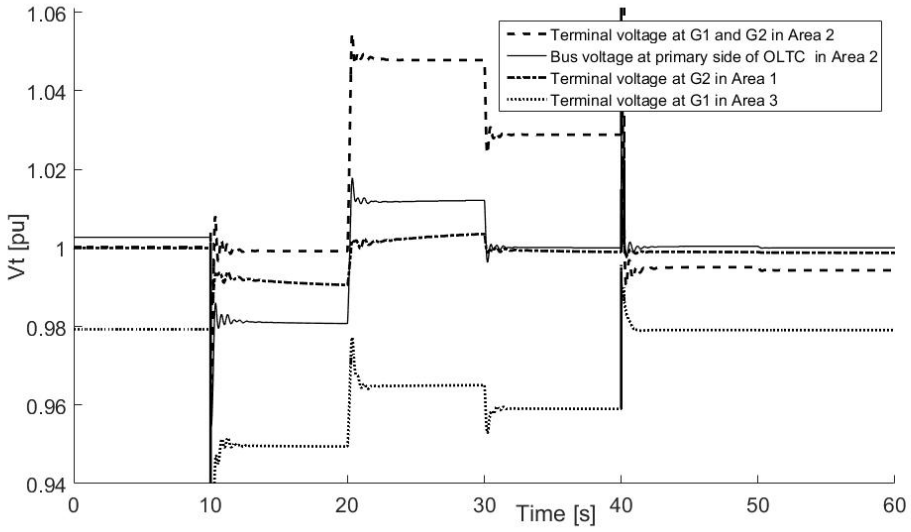

Figure 14. Voltage as a function of time where MPC is changing the set-point on classical control at G1 and G2 in Area 2 to bring voltage at primary side of OLTC bus closer to 1 pu. Optimization is done at every $\Delta t = 10s$ and the horizon is $N_p = 1$. The international transmission line in Figure 11 are disconnected at 10 seconds and reconnected at 40 seconds in this simulations. The MPC tuning parameters were $\mathbf{Q} = 300$, $\mathbf{P} = 5$, $\mathbf{R} = 0.01$.

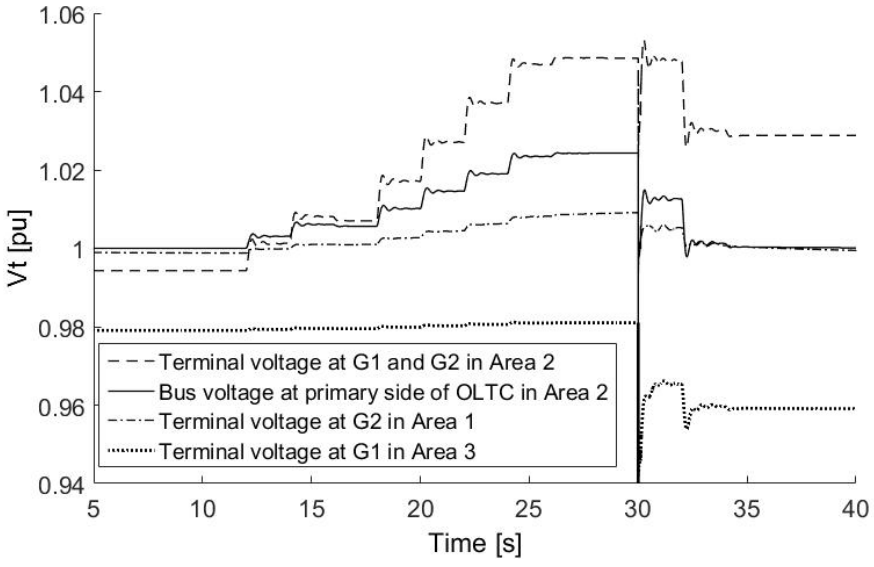

Figure 15. Voltage as a function of time where MPC is changing the set-point on classical control at G1 and G2 in Area2 to bring voltage at primary side of OLTC bus closer to 1 pu. Optimization is done at every $\Delta t = 2s$ and the horizon is $N_p = 10$. The international transmission line in Figure 11 are disconnected at 30 seconds in this simulations. The MPC tuning parameters were $\mathbf{Q} = 30$, $\mathbf{P} = 1$, $\mathbf{R} = 1$.

presented in this paper. However, a reduced power system model combined with C-code generation could be a feasible solution for faster NMPC action.

Modelling and Dynamic Simulation of Cyclically Operated Pulverized Coal-Fired Power Plant

Juha Kuronen Miika Hotti Sami Tuuri
Fortum Power and Heat Oy, Espoo, Finland, {juha.kuronen, miika.hotti, sami.tuuri}@fortum.com

Abstract

Pulverized coal-fired power plants are increasingly operated cyclically for the compensation of fluctuating load in the electric grid caused by intermittent production of wind and solar power plants. Dynamic simulation is a powerful tool for investigating the transient behavior of a power plant that is operated cyclically. New solutions, e.g. process changes and control strategies can be tested with a computer-aided dynamic simulation software. This paper introduces a model and dynamic model validation of a commercial pulverized coal-fired power plant that is used in grid load compensation. The model is developed using dynamic simulation software Apros, and it includes all the main processes and control loops of the plant, but also some significant simplifications have been made compared to the real plant process. The model is validated against measurement data from the plant. Simulated dynamic validation cases include typical load changes that are used in grid load compensation. The model can be used for further investigations regarding flexibility and controllability of the plant.

Keywords: modelling, dynamic simulation, cyclic operation, pulverized coal-fired power plant, validation

1 Introduction

The production of renewable energy, especially wind and solar power, has expanded in the past few years in Europe due to growing concern about the climate change, emission restrictions on the energy markets and renewable energy subsidies. The load level of solar and wind power plants depends strongly on weather conditions which vary depending on the season and daytime. The intermittent renewable energy production leads to fluctuating load in the electric grid, and to balance the grid load some power plants are forced to compensate the load fluctuations by continuously controlling the power output of the plant. This operation mode is called cycling. In Central Europe conventional steam power plants, typically pulverized coal-fired units, are participating in the compensation. Traditionally large coal-fired units have been designed for base load operation, but due to increased renewable energy production base load plants are more and more operated in varying load levels. This sets new challenges for the flexibility and controllability of these plants.

These challenges can be divided into three categories. Firstly faster load transients between operational points as well as faster and more flexible start-up and shutdown processes are needed. Secondly the plant needs to be operated on broader range and the technical minimal load limit has to be re-evaluated. Thirdly the thermo-economical optimization of the plant within the whole operational range need to be done, since the operation in full load is reduced. (Starkloff et al., 2015) In addition the rates of load transients, start-ups and shutdowns are limited by thermo-mechanical stress in boiler and turbine components. Uncontrollable stress reduces significantly the residual life of stress-prone plant components.

In order to respond to the load transient, flexibility, and thermo-economical optimization challenges, development and re-engineering work is typically needed in plants that are not designed for cyclic operation. This work may result e.g. in boiler heat surface constructional changes, burner upgrades or control strategy changes. New solutions can be easily tested with a computer-aided dynamic simulation tool. Hence modelling and dynamic simulation of pulverized coal-fired plants are increasingly important, and this topic has been covered in several recently published papers, e.g. (Starkloff et al., 2015; Richter et al., 2015; Krüger et al., 2015). This paper presents a dynamic simulation model of a commercial 750 MWe pulverized coal-fired power plant that is operated both in base load and cyclic operation mode. The model is validated against operational plant data during typical load changes of the plant.

It is always necessary to know the purpose of the model and the accuracy needed from the model. In this work the main purpose is to simulate load-varying operation of the plant. For this purpose the main process sections and control loops of the plant are included in the model. Water and steam temperatures, pressures and mass flows in the boiler should equate with the real process, so that the load change transients can be simulated accurately. Therefore the boiler section must be modelled carefully. Since a development of an exact plant simulator was not the aim of this work, the model

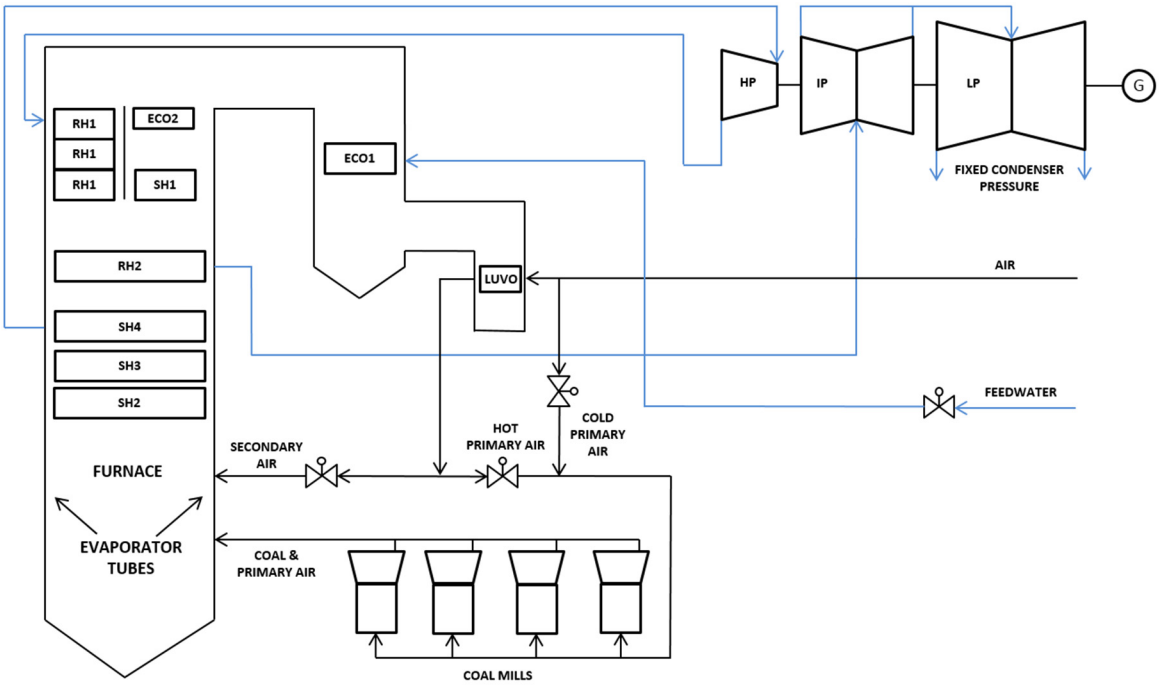

Figure 1. Schematic diagram of the plant model.

was adapted to the specific needs of the simulation experiments. In other words the process and control system models include considered simplifications compared to the real plant. For example feedwater section, including feedwater tank, pumps and preheaters, is not included in the model. The power plant process and control system were modelled in dynamic simulation software Apros.

The paper is structured as follows. After the introduction the simulation software Apros is introduced briefly in Section 2. The plant model is presented in Section 3. The validation results are discussed in Section 4 and the conclusions are given in Section 5.

2 Simulation Environment

Dynamic simulation software Apros was utilized for the modelling and simulation of the reference plant. Apros is a multifunctional software for full-scale modelling and dynamic simulation of power plants and industrial processes. Apros is the result of a quarter century's development work by VTT (Technical Research Centre of Finland) in co-operation with Fortum. It is used by multiple power plant operators, engineering companies, research institutes, safety authorities and universities all over the world.

Apros combines accurate physical process modelling with automation modelling. With Apros it is easy to design, test and see how the process and the control system work together, and the whole integrated system can be studied and optimized simultaneously in detail. The user has access to a set of predefined process component models that are conceptually analogous with concrete devices. The component libraries cover a comprehensive set of process and automation components such as pipes, valves, pumps, heat exchangers, tanks, measurements, controllers etc. One convenient feature in Apros is user component (UC) which can be utilized for creating own re-usable component structures. User component consists of basic Apros library components and possibly other user components. It can be easily re-used and shared with other Apros users.

In Apros, modelling is based on thermal hydraulics which is described using time-dependent conservation equations for mass, momentum and energy as well as correlations for friction and heat transfer (Technical Research Centre of Finland).

3 Plant Model

The reference plant is a commercial pulverized coal-fired unit. The plant is rather new and it represents state of the art technology. It is used both in base load and cyclic operation mode. The once-through boiler of the plant is ultra-supercritical with live steam temperature of 600 °C and live steam pressure of 290 bar. The gross power capacity of the plant is 800 MW and the net electric power is 750 MWe. The plant is also able to produce 90 MWth district heat for the surrounding region. The overview and scope of the plant model is illustrated in Figure 1. The following chapters introduce the plant model. The process is divided into three

process sections and the control system comprises of seven sections.

The simulation model construction and validation can be divided into four steps. Firstly the model scope and boundary conditions are considered and decided based on the use of the model. Then the actual model is built up in the modelling environment. After model build-up the model is tuned to various steady state operating points and the model parameters are tuned by comparing the model responses and plant measurement data. Lastly the dynamic validation is performed by simulating transients that are compared to measurement data. Once these steps are completed successfully the model is ready to be used in different types of simulation experiments.

3.1 Air and Fuel Feed

Air and fuel feed section includes air supply lines, air preheaters, air flow control valves, raw coal supply line, coal mills and coal-air line to the furnace as it is presented in Figure 2.

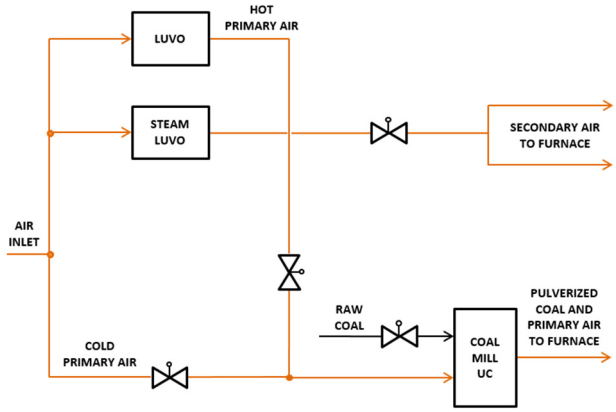

Figure 2. Air and fuel feed section model diagram.

In the model air is passed to the furnace in two phases, whereas in the real plant the number of air feed lines is larger. Primary air, which is fed through the coal mills, makes up about 30 % of all combustion air. Primary air is a mixture of cold and preheated hot air. Hot air is preheated with flue gases in the air preheater, and cold and hot air are mixed at the inlet of the coal mill to control the coal mill outlet temperature. Secondary air makes up the major part of the combustion air, around 70 %. Secondary air is preheated with extraction steam and mixed with fuel-rich primary air in the furnace to give a proper air-fuel ratio.

The coal mills of the plant are modelled in detail using the user component feature of Apros. Coal mill model is an important part of cyclically operated pulverized coal-fired power plant simulator, and a valid mill model improves the accuracy of the plant's transient simulation. Load changes, start-ups and shutdowns can be simulated realistically if the dynamics of the mill model corresponds to dynamics of a real mill. The roll-type coal mill operation is as follows. Raw coal is dropped from the feeder belt into the mill where it lands on the grinding table and is pulverized by rollers. Primary air is used as carrier gas for grinded coal particles. Inside the mill primary air, which is blown from the bottom of the mill, dries the moist coal, picks up the pulverized coal particles from the grinding table and transports particles to the classifier section. Only the finest coal particles escape the mill through the classifier, whereas heavier particles fall back to the grinding table. By modifying the rotation speed of the classifier the amount of escaping coal powder can be controlled.

The proposed coal mill model was first introduced by (Niemczyk et al., 2012). The coal mill UC is tuned to simulate the behavior of the four mills of the real plant. The model is a so-called graybox-model based on physical knowledge and parameter identification methods. Primary air flow and raw coal flow including moisture are the inputs of the mill component. The output is the mixed air-coal flow which is passed to the furnace. In the coal mill model two particle sizes, raw and pulverized coal are considered, and the model comprises of equations for mass balances of raw and pulverized coal in different sections of the mill, overall energy balance and pressure losses inside the mill. In the model the coal storage inside the mill is divided into three different sections: raw and pulverized coal on the grinding table and pulverized coal in the air. The dynamic behavior of the coal storage inside the mill is crucial during load changes. A schematic representation of the mill model is presented in Figure 3. A more accurate description of the mill model is given in (Niemczyk et al., 2012; Kuronen, 2015).

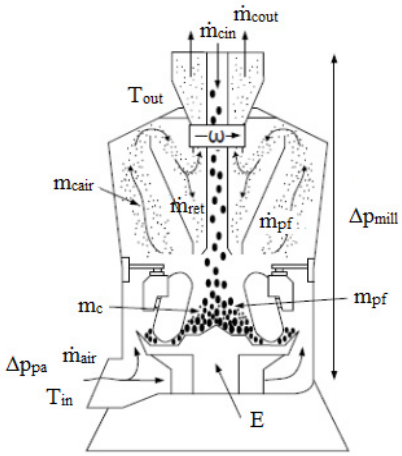

Figure 3. Schematic picture of a roll mill.

3.2 Boiler

The structure of the boiler model is illustrated in Figure 4. In the once-through boiler model the heat transfer between the combustion flames/flue gases and water-steam circuit is modelled by including all the real heat exchange surfaces into the model. These are

economizers, evaporator, superheaters and reheaters. In the real plant the lower part of the evaporator comprises of spiral tube structure and the upper part is constructed with straight tubes. Hence in the model the evaporator is also divided into two separate parts with different dimensions and heat transfer properties. Heat transfer areas and pipe dimensions are fixed according to plant documentation. The heat transfer coefficients, radiation emissitivies and view factors of the heat exchange surfaces are adjusted empirically. Also the water separator, which separates water and steam before the superheating section, and water sprayers, which are utilized in controlling the temperature of the superheated steam, are modelled.

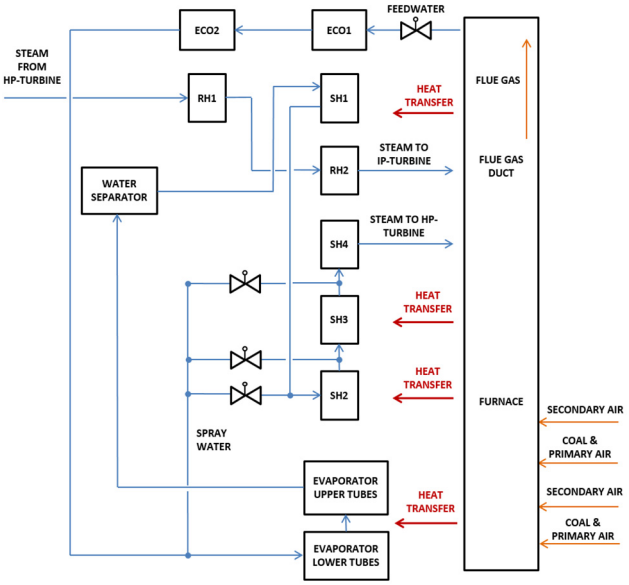

Figure 4. Boiler model diagram.

Flue gas section consists of the combustion chamber, burners and the flue gas duct. The dimensions of the combustion chamber and flue gas duct are equal to ones in the real plant.

3.3 Turbine Plant

Turbine plant model comprises of high-pressure (HP), intermediate-pressure (IP) and low-pressure (LP) turbines, steam extractions, turbine control valve and turbine shaft. Superheated steam flows from the final superheater to the HP-turbine through the turbine control valve, which is kept fully open, since the boiler is operated in sliding pressure mode. After the HP-turbine steam is reheated in two phases in the boiler and brought to IP- and LP-turbines. The mechanical power produced by the turbines is transformed to electric power via shaft and generator components.

The turbine plant model scope does not include a condenser, where the expanded steam is passed after the LP-turbine, but the pressure after the last LP-turbine section is fixed according to the real conditions in the plant condenser. The scheme of the turbine plant model is shown in Figure 5. Turbine sections are composed of turbine components, which are connected to a turbine shaft. After each turbine section, part of the steam is extracted to be taken to the water preheaters and district heat exchangers. Since the feedwater and district heat sections are not included in the model, extraction flows are constantly controlled and the flows alternate according to the operating point. Hence the right mass balance is maintained. Extraction mass flows in different operating points have been collected from the plant's process and information system.

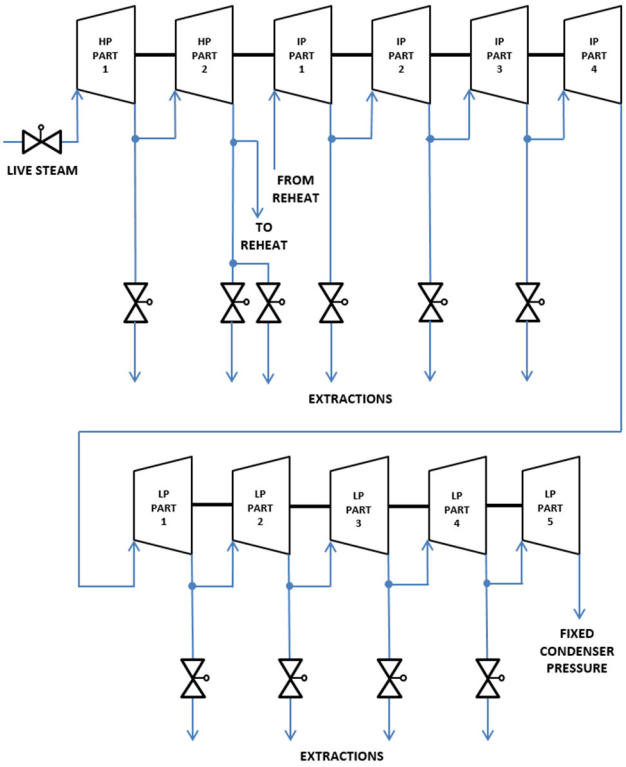

Figure 5. Turbine plant model diagram.

3.4 Control loops

All the main control loops of the plant are modelled and tuned in Apros. The advantage of Apros is that the process and control system can be modelled in the same simulation environment. The modelled control loops are:

- Block control
- Coal flow control
- Primary and secondary air control
- Live steam temperature control
- Reheated steam temperature control
- Feedwater control
- Extraction flow controls.

The co-ordination of turbine and boiler operation is realized by the block control (or unit control), which generates set point for the boiler and turbine to keep the desired load set point while maintaining the desired operating pressures and temperatures (Lamp et al., 2009). The user gives the gross power output set point

via block control and all the other main controlled variables get their set points as a function of the power set point. The user given set point signal is corrected with a power correction controller according to the deviation between the power set point and measured generator power. The block control diagram is presented in Figure 6.

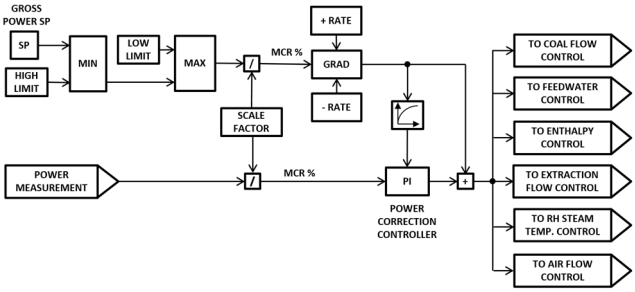

Figure 6. Block control diagram.

The coal flow set point is determined as a function of plant load and it is then adjusted with a heat value correction which takes into consideration the changing content of the raw coal. The coal composition depends on the type of the coal and plants utilize coals from different sources. The changing composition affects strongly on the coal flow control which is based on a function between plant load and coal mass flow. Heat value correction is based on the enthalpy difference between water at the inlet of the boiler and steam at the outlet of the boiler. Designed enthalpy difference is compared with measured one and the coal heat value in the control loop is corrected according to the enthalpy deviation.

The amount of primary air is controlled according to plant load level and coal flow. The mass flow of primary air is approximately two times bigger than coal mass flow. The temperature of the air-coal mixture at the outlet of the mill is controlled with the ratio of preheated and cold primary air. Secondary air flow is adjusted according to the total air demand, which is a function of the power level and coal flow set point. Secondary air set point is modified with O_2-control (oxygen-control), which adjusts the volume of oxygen in the flue gas to the desired level. Secondary air, primary air and coal mill temperature control loops are pieced together in air control diagram.

The live steam temperature is controlled by spraying saturated water among the live steam in three phases. Live steam temperature set point after the last superheater is kept constant in the model. For the first two attemperators the temperature set point is defined by the temperature difference across the attemperator. Reheated steam temperature is controlled correspondingly.

The feedwater control loop is presented in Figure 7. The set point for the feedwater flow is determined according to the load level and it is modified with enthalpy correction. Enthalpy correction factor is calculated according to deviation between the design and measured steam enthalpy after the evaporator. Since steam enthalpy is a function of temperature and pressure, enthalpy correction controls steam temperature and pressure after the evaporator section. Feedwater flow is adjusted with a control valve.

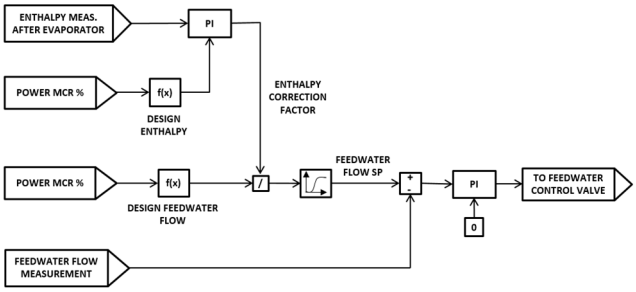

Figure 7. Feedwater control diagram.

Although feedwater preheaters, -tank, -pumps and condenser are not included in the model the extraction flows from the turbines are modelled to achieve the correct mass balance in the water-steam cycle. Extraction flow controls consist of multiple individual valve controls, and set points for the flows are set as a function of plant load level.

4 Model Validation and Simulation Results

The plant model was first validated in multiple steady state conditions between the gross power range of 50-100 %. When the steady state validation results showed good agreement the model was validated dynamically by simulating load changes that are typically performed during grid load compensation. The dynamic validation was done between the gross power range of 87-100 %. The dynamic validation results are presented in this section.

The gross power output is presented in Figure 8. The model response (red line) follows fairly well the measurement curve (blue line), but it does not overshoot or undershoot the set point curve (green line) as strongly as the measurement curve. The deviation between the curves is a consequence of multiple factors, since the inaccuracies of the whole model culminate on the power output response. Real controller tuning parameters and load-dependent set point functions of main variables were not known during the modelling, and it reflects as a deviation between the model and plant responses during load change transients. The high-frequency oscillation in the power curve as well as in feedwater curve is caused by measuring errors and backlash of valves. This type of oscillation is not needed to be included in the model.

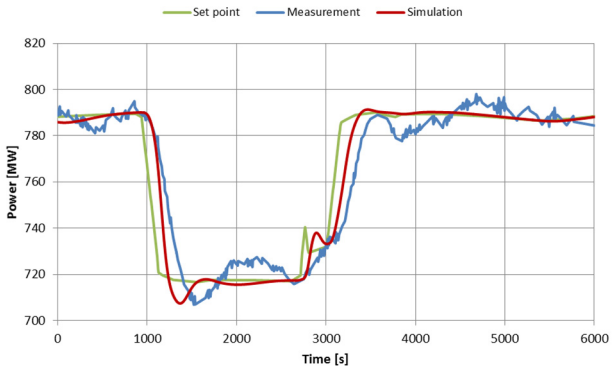

Figure 8. Gross power output.

The raw coal mass flow from the feeder to the coal mill is showed in Figure 9. Dynamically the raw coal flows are quite similar. There are notable peaks in the measured coal flow curve when the load changes are made. The model is able to reproduce the peak when the load is decreased, but there are slight difference between the curves, when the load is increased back to the original level. This originates from the more aggressive controller tuning at the plant. Also the coal flow controller is probably a bit more advanced in the plant control system, whereas in the model an ordinary PI-controller is used. The raw coal flow level is also a bit higher in the model, around 1 kg/s, depending on the operating point. The reason for this can be found from the load-dependent set point function which is a compromise among other variable set point functions. Differences in the coal flow reflect directly on the power output.

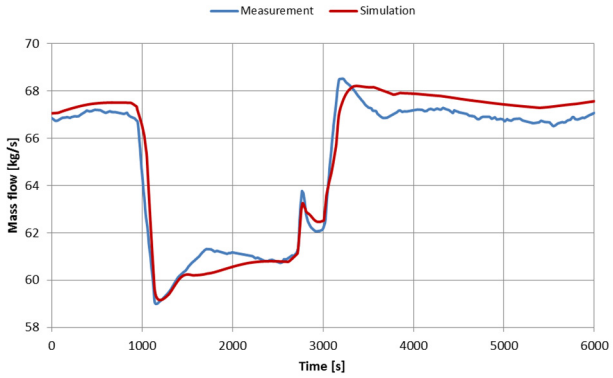

Figure 9. Raw coal mass flow into the coal mill.

The feedwater flow is presented in Figure 10. The simulated feedwater mass flow level is around two percent lower than the measured level. Once again the main reason is the load-dependent set point function which is most probably not the same one that is set in the plant control system. Also the absence of HP- and LP-preheaters, condenser, feedwater tank and the simplified extraction flow modelling have an impact on the feedwater flow in the model. However the curves are dynamically uniform if the high-frequency oscillation is not considered.

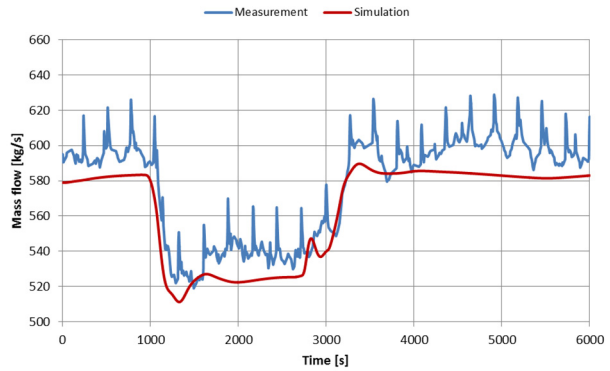

Figure 10. Feedwater mass flow.

The simulated total air mass flow is fairly well in line with the measurement as can be seen from Figure 11. Air controllers at the plant and in the model seem to be tuned quite similarly since the total air mass curves are rather close to each other under the load changes.

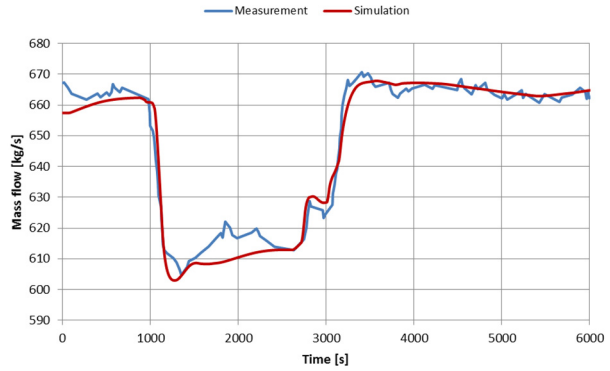

Figure 11. Total air mass flow.

Measured and simulated live steam temperatures after the final superheater are illustrated in Figure 12. The simulated temperature corresponds to the measurement, although the exact same dynamic behavior is difficult to achieve. The correspondence between the live steam temperatures indicates that the dimensions of the heat exchange surfaces and heat transfer coefficients in the boiler are substantially correct. Also the live steam temperature control maintains the temperature close to the set point (597 °C) during the load changes.

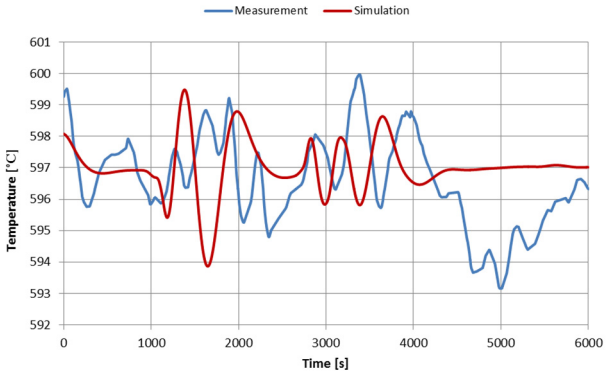

Figure 12. Live steam temperature.

5 Conclusions

Pulverized coal-fired power plants are increasingly participating in electric grid load control due to expanded intermittent renewable power generation. This sets new challenges related to flexibility and controllability of the coal plants since the plants are operated cyclically to maintain a steady load in the electric grid. For example process- and control strategy changes are often needed in base load plants which are not designed to be operated cyclically. New solutions can be designed and tested with time-variant dynamic simulation models.

This paper presented a dynamic simulation model of a full-scale commercial pulverized coal-fired power plant. The model was constructed and simulated in dynamic simulation software Apros. The model included the main processes and control loops of the real plant, but some considered simplifications were done to delimit the scope of the model. The model was validated both on steady-state and dynamic conditions. Based on the dynamic validation results, which were illustrated in this paper, the model responses corresponded fairly well to the plant measurements between the power range 87-100 %. Even if the model is a simplified version of the real plant, it can be already utilized e.g. for design and testing purposes.

In future the plant model can be developed in various ways. Firstly new subprocesses and control loops could be added to the model. Secondly re-tuning the control loops, defining appropriate time constants and load-dependent set point functions would increase the model accuracy. Thirdly a more comprehensive model validation on a broader power range should be performed, so that the model could be reliably simulated on the plant's whole operating range.

Abstract

The amount of grid-connected power electronic converters is increasing as the world's energy production shifts toward sustainable sources. Poor power quality and harmonic resonances have been reported which have been shown to be caused by grid-connected converters. Accurate modeling tools are required to characterize the conditions for instability and to design stable power-electronics-based power systems.

Unstable behavior can be identified by using models implemented in circuit simulators or using power-hardware-in-the-loop setups. The unstable resonance occurs when inverter control system interacts with the grid impedance. However, a very wide impedance-bank is required in the laboratory to test inverter stability when grid impedance is expected to vary significantly. Moreover, stability tests are often limited to cases where grid impedance is approximated as an inductance. This paper proposes a method for emulating the grid impedance in a hardware-in-the-loop setup which eliminates the need for bulky passive components and allows arbitrary grid impedance to be emulated. As a result, the inverter can be tested with a varying grid impedance to determine the exact conditions for unstable behavior. Moreover, the grid impedance can be changed online to emulate the behavior of a time-varying power grid in real time.

Keywords: hardware-in-the-loop, grid impedance, emulation

1 Introduction

The amount of grid-connected power electronic converters, such as wind and solar inverters is rapidly increasing as the amount of renewable power generation is ramped up (Bose, 2013). Stability of conventional power systems has been mainly determined by power balance, i.e., the produced power has to match the load power to keep grid frequency and amplitude within acceptable limits. However, the stability of modern power systems is challenged by the dynamic behavior of grid-connected power electronic converters, and especially, their small-signal characteristics (Wang et al., 2014; Messo et al., 2013).

Grid-connected converters have been shown to introduce stability issues when the penetration of renewables is significant (Enslin and Heskes, 2004). This has been shown to be mainly caused by poorly damped resonance formed together by inverter output impedance and the grid impedance (Sun, 2011; Wen et al., 2016; Suntio et al., 2017). Wind power inverters were found out to cause instability when connected to a series-compensated line (Belkin, 2010) and photovoltaic inverters have been reported to become unstable in a grid that has high inductance (Yang et al., 2014). Instability and resonance issues can be prevented if the inverter impedance is designed to have larger impedance than the grid or if both impedances resemble passive circuits (Harnefors et al., 2016).

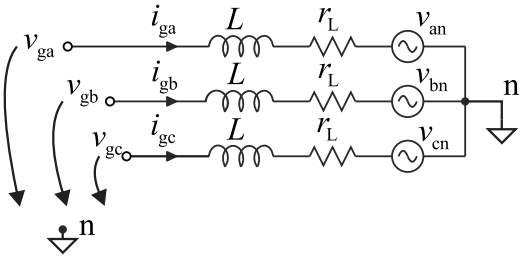

Figure 1. Three-phase grid impedance.

Immunity of a grid-connected inverter to impedance-based instability can be evaluated by connecting the inverter to the power system through an inductance which has sufficiently large value. A weak grid is usually approximated by a large inductance or combination of resistive and inductive elements (Gavrilovic, 1991). However, in reality the grid impedance can be hardly described as a lossy inductor since it may exhibit resonances (Jessen et al., 2015). In practice this means that one should have sufficient physical impedance-bank in the laboratory to test converters in different grid conditions. An interesting alternative is to use a real-time simulator paired with a linear amplifier to emulate the grid impedance which gives more freedom to define the nature of grid impedance, e.g., a series or parallel resonance. Promising results have been presented in the literature, such as in (Kotsampopoulos et al., 2015) where a real-time simulator was used to emulate part of the grid impedance in a hardware-in-the-loop simulation. However, the performance of the impedance emulation method was not validated by measuring the emulated impedance.

This paper proposes a method to emulate the grid

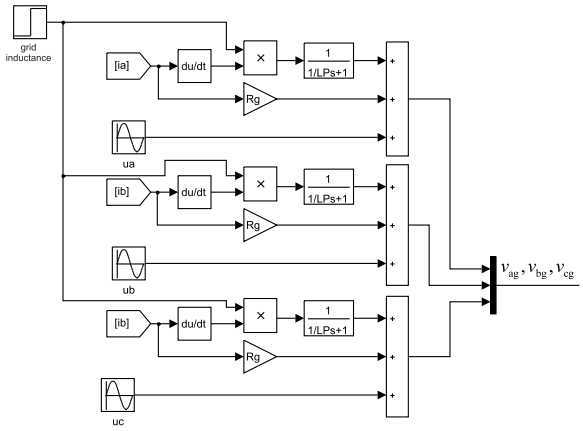

Figure 2. Simulink model to realize the grid impedance in Figure 1.

impedance behavior using power-hardware-in-the-loop (PHIL) setup, which can be used in characterizing impedance-based stability of grid-connected inverters. The method enables modifying the grid impedance online allowing stability studies of grid-connected converters in time-varying grid conditions. The limitations of PHIL-implementation due to sampling delay are also discussed. The delay is shown to introduce a considerable error in the phase of the emulated grid impedance.

The paper is organized as follows: Section II explains how a three-phase grid impedance is modeled in the MATLAB Simulink environment. Such model can be directly build into C-code and ran on a real-time simulator. Section III shows a simulation case where grid inductance is stepped up to destabilize a grid-connected inverter. The practical implementation of the grid impedance emulator and its limitations are discussed in Section IV where a dSPACE real-time simulator and a linear amplifier are used to emulate an inductive grid impedance. Final conclusions are summarized in Section V.

2 Grid impedance model

Circuit diagram of a three-phase grid impedance is as depicted in Figure 1 where v_{an}, v_{bn} and v_{cn} represent the ideal grid voltages. The grid is formed by three identical branches which have resistance and inductance. Grid voltages seen by a grid-connected inverter, i.e., v_{ga}, v_{gb} and v_{gc} at the PCC, can be solved by utilizing basic circuit theory and given according to (1).

$$\begin{aligned} v_{\mathrm{ga}}(t) &= L\frac{\mathrm{d}}{\mathrm{d}t}i_{\mathrm{ga}}(t) + r_{\mathrm{L}}i_{\mathrm{ga}}(t) + v_{\mathrm{an}} \\ v_{\mathrm{gb}}(t) &= L\frac{\mathrm{d}}{\mathrm{d}t}i_{\mathrm{gb}}(t) + r_{\mathrm{L}}i_{\mathrm{gb}}(t) + v_{\mathrm{bn}} \\ v_{\mathrm{gc}}(t) &= L\frac{\mathrm{d}}{\mathrm{d}t}i_{\mathrm{gc}}(t) + r_{\mathrm{L}}i_{\mathrm{gc}}(t) + v_{\mathrm{cn}} \end{aligned} \tag{1}$$

A three-phase grid impedance can be emulated using a linear amplifier where the reference voltages are calculated based on the measured grid currents according to (1). This is an interesting idea since practically the amplifier could be configured to resemble an arbitrary grid impedance which is very attractive for stability studies of grid-connected inverters and for quality control of power converters.

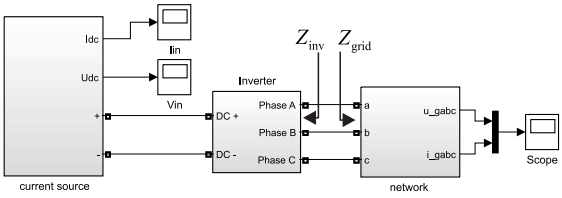

Figure 3. Overview of the grid-connected inverter.

A Simulink model according to to (1) was built to emulate the dynamics of grid impedance, as depicted in Figure 2. Moreover, a low-pass filter with a cut-off frequency of 10 kHz was used to filter out switching ripple from the output of the derivative block. The value of grid inductance can be changed online which emulates the behavior of a real power grid. Moreover, the model could be easily modified to enable online variation of frequency, phase angle and resistance. However, the scope of this paper is limited to changing the value of inductance.

3 Impedance-based instability studies

The grid model was connected to a switching model of a three-phase inverter as illustrated in Figure 3. The model is built using the SimScape component library. The inverter is fed from a DC current source and connected to three-phase voltage sources. The reference values of grid voltages at the PCC were calculated according to (1). The grid currents become unstable when the ratio of inverter output impedance and the simulated grid impedance fail to satisfy the Nyquist stability criterion, i.e., when impedance q-components $Z^{\mathrm{q}}_{\mathrm{inv}}$ and $Z^{\mathrm{q}}_{\mathrm{grid}}$ form together an undamped resonance. Derivation of the inverter impedance model and discussing the stability criterion are out of the scope of this paper but the reader is urged to see (Messo et al., 2015) that shows how the Nyquist stability criterion can be applied to three-phase impedances.

Figure 4 shows the impedance ratio $Z^{\mathrm{q}}_{\mathrm{grid}}/Z^{\mathrm{q}}_{\mathrm{inv}}$ on the complex-plane when grid inductance is selected as 2 mH and increased to 5 mH. The Nyquist stability criterion states that the system is unstable when the impedance ratio encircles the point (-1,0).Thus, the system is stable when grid inductance is 2 mH but becomes unstable when the inductance is increased to 5 mH.

The "Inverter" block in Figure 3 includes the actual power stage, AC filter and the control system. The inverter utilizes normal cascaded control scheme where DC voltage and AC currents are controlled to keep the DC voltage at a certain level and to feed power to the grid at unity power factor. The inverter utilizes a phase-locked-loop

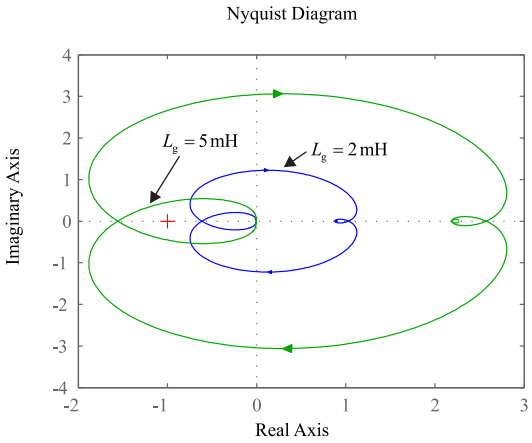

Figure 4. Ratio of inverter impedance and grid impedance on the complex-plane.

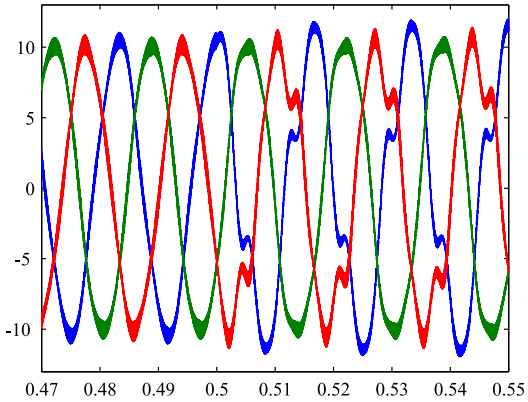

Figure 5. Grid currents become unstable due to increase in grid inductance from 2 to 5 mH at 0.5 s.

(PLL) to synchronize its output currents to grid voltages. The power stage and necessary measurements are built using the components found in the SimScape-toolbox as illustrated in Figure 6.

Phase-locked-loop makes the q-component of inverter output impedance resemble a negative resistance which can destabilize the inverter in a weak grid (Messo et al., 2013). The PLL was tuned to have a crossover frequency of 200 Hz which causes instability when grid inductance increases to 5 mH. Figure 5 shows simulated grid currents when the grid inductance is suddenly increased from 2 to 5 mH at 0.5 s and the inverter becomes unstable due to high-bandwidth PLL. The simulator could be constructed by adding grid impedance in the model as inductive components and connecting an extra 3 mH inductance at 0.5 s by using an ideal switch. However, in this case the simulation time is considerably longer. Therefore, using the proposed impedance model as in Figure 2 also enables smaller simulation time.

4 Practical implementation

The feasibility of grid impedance emulation method in a power-hardware-in-the-loop environment was tested by implementing the impedance model using a dSPACE real-time simulator and a three-phase linear amplifier PAS15000 manufactured by Spitzenberger. Photograph of the laboratory setup is as shown in Figure 7. The setup consists of a three-phase IGBT inverter supplied by a PV simulator feeding the three-phase linear amplifier through an isolation transformer.

The Simulink model for emulating inductive grid impedance is as shown in Figure 8. Ideal grid voltages were generated by three sine-wave sources phase shifted by 120 degrees. Voltage drop over the emulated phase inductance was obtained by multiplying the inductor current derivative by the desired inductance value. The output signal of the product block had to be low-pass filtered to avoid destabilizing the linear amplifier which is due to sampling delay of dSPACE. The impedance model was running on the same dSPACE-platform as the inverter control system. Therefore, the sampling frequency has to be set the same as inverter switching frequency (8-12 kHz).

Input impedance of the linear amplifier, i.e., the emulated grid impedance was measured in the dq-domain using the inverter as a perturbation source and by measuring the frequency response from grid current q-component to grid voltage q-component. The grid impedance q-component is the ratio of these components as given in (2). The measurement setup is as depicted in Figure 9. PRBS-injection was added in the reference value of inverter output current q-component. The grid current and voltage q-components were measured and the grid impedance was computed using the methods discussed in (Roinila et al., 2015). The currents and voltage were measured in the dq-reference frame tied to the inverter control system, i.e., by utilizing the grid voltage angle estimated by the PLL. The PLL crossover frequency was set to 2 Hz to avoid PLL from affecting the measured impedance at low frequencies.

$$Z_g^q = \frac{\hat{v}_{oq}}{\hat{i}_{oq}}. \tag{2}$$

The isolation transformer has some resistive losses and stray inductance which have to be measured first to evaluate which part of the grid impedance is caused by the transformer and which is realized by the impedance emulator. The grid impedance q-component was measured while the value of emulated inductance value was set to zero. The measured and fitted impedances are shown in Figure 10. The isolation transformer has resistance of 400 mΩ and inductance of approximately 600 μH. I.e., the phase is around 0 degrees at low frequencies with a constant magnitude and increases to 90 degrees at higher frequencies with magnitude increasing 20 dB per decade. It can be concluded that the impedance measurement is

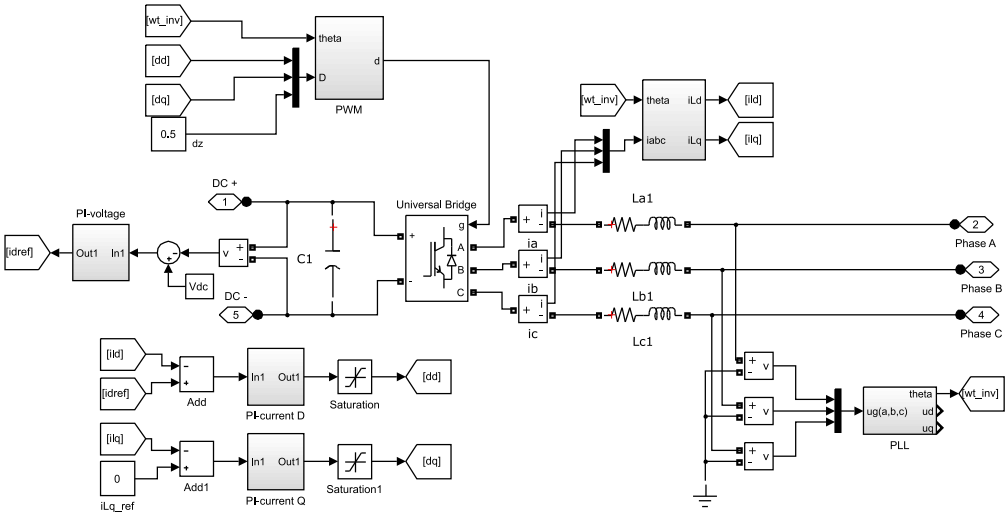

Figure 6. Inverter power stage with control system in Simulink.

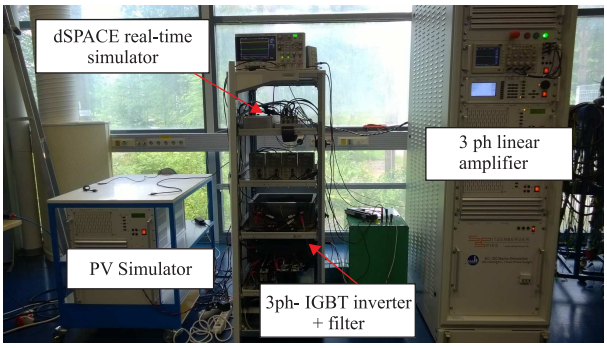

Figure 7. Three-phase inverter connected to a three-phase grid emulator.

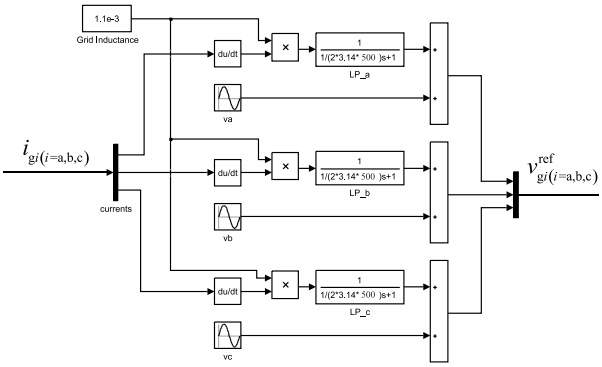

Figure 8. Impedance model implemented using the dSPACE real-time simulator.

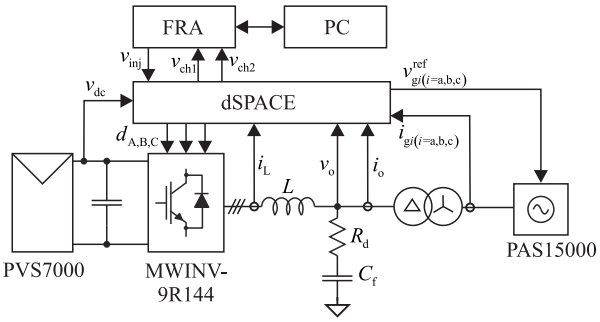

Figure 9. Setup for measuring the emulated grid impedance.

accurate up to few kilohertz after which the phase curve starts to drop due to sampling delay.

Figure 11 shows the measured grid impedance in green when the impedance emulator is activated. The inductance value was set to 1.1 mH and the low-pass filter was tuned to have a crossover frequency of 500 Hz allowing stable operation of the linear amplifier. The red dots illustrate the impedance of a series RL-circuit with resistance equal to 400 mΩ and inductance of 1.7 mH, i.e., the reference grid impedance includes the effect of isolation transformer. The magnitude of the emulated impedance follows the reference curve up to 400 Hz after which the impedance experiences an additional series resonance. Moreover, the phase starts to deviate from the reference value already around 50 Hz. The inaccuracy of emulated impedance is caused by the low-pass filter which was required for stable operation. A low-pass filter with a single pole starts decreasing the phase of the impedance already one decade below cut-off frequency, i.e., at 50 Hz. However, the low-pass filter is required for stability and cannot be set to higher frequency while sampling frequency is tied to inverter switching frequency. Reference of the grid impedance which includes the effect of transformer

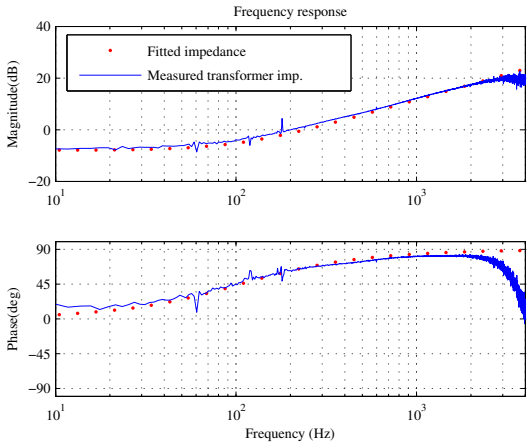

Figure 10. Measured transformer impedance q-component.

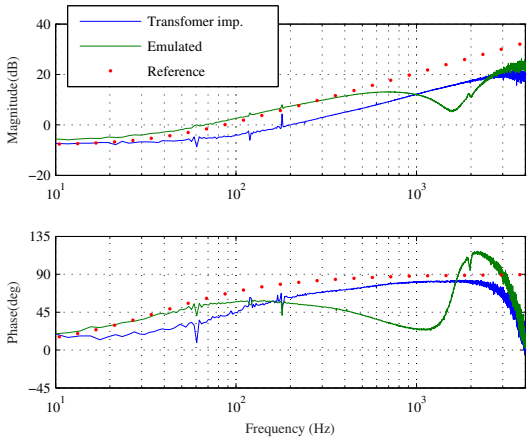

Figure 11. Measured grid impedance when impedance emulator is activated.

impedance is given as a function of frequency in (3).

$$Z_{\mathrm{g}}^{\mathrm{q}}(j\omega) = 0.4 + j\omega 1.7 \cdot 10^{-3} \tag{3}$$

Switching frequency of the inverter was increased to 12 kHz and, therefore, the sampling frequency of the grid impedance emulator was increased as well. The sampling delay was effectively reduced by a factor of 1.5. The higher sampling frequency allows stable operation of the linear amplifier with emulated inductance value of 900 μH when the low-pass filter was tuned to have cut-off frequency of 1 kHz. Using higher value of emulated inductance value or increasing the cut-off frequency would destabilize the linear amplifier. This should be avoided since very large high frequency currents would flow in the circuit. (Enough to trip current sensor with 50 A current limit!)

Measured grid impedance and its reference value are shown in Figure 12. The magnitude curve follows the reference curve up to almost 1 kHz. However, the phase curve begins to deviate from reference curve approximately after 100 Hz. This is expected since the low-pass

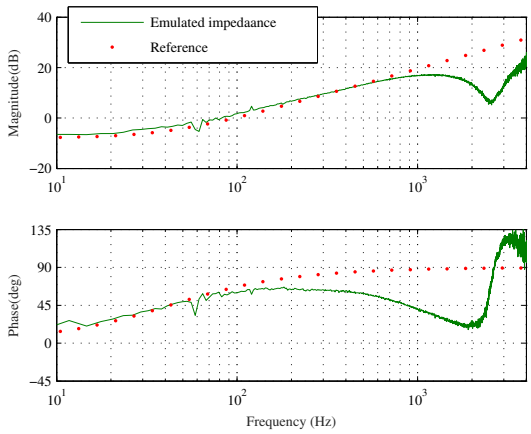

Figure 12. Measured grid impedance when impedance emulator is activated with higher sampling frequency.

filter has cut-off frequency of 1 kHz. It is not reasonable to increase the inverter switching frequency much higher since the IGBT switches require as much as 4 μs of blanking time to avoid shorting the DC capacitor. The reference curve for the emulated impedance is calculated according to (4).

$$Z_{\mathrm{g}}^{\mathrm{q}}(j\omega) = 0.4 + j\omega 1.5 \cdot 10^{-3} \tag{4}$$

Based on the measured impedances it can be concluded that the present impedance emulator is suitable for characterizing impedance-based instabilities occuring at low-frequencies in cases when grid inductance has a maximum value around 1 mH. The limitation arises from the low sampling frequency which causes the phase of emulated impedance to deviate from the reference value at frequencies higher than 100 Hz. Impedance-based interactions occurring at higher frequencies cannot be, therefore, reproduced. As a future research the sampling frequency of impedance emulator should be decoupled from the inverter control system which requires another real-time simulator for implementation.

5 Conclusions

The amount of grid-connected power electronic converters is increasing due to reduced price of renewable energy, such as wind and solar. At the same time stability of power grids is challenged by the inverter control functions, such as grid-synchronization algorithms. Evaluation methods to characterize stability issues introduced by grid-connected converters need to be developed to enable large-scale utilization of renewable energy.

The converter becomes unstable when its control system starts interacting with grid impedance which usually varies over time. In determining impedance-based stability, a large set of physical components is required in the laboratory to realize the variation in grid impedance. Moreover, contactors are required to change the grid

impedance to emulate load changes in the grid which complicates the test setup and increases cost.

This paper studies a grid impedance emulation method using a dSPACE real-time simulator and three-phase linear amplifier which eliminates the need for bulky and expensive passive components. In the proposed method grid impedance is modeled inside the real-time simulator which allows changing the value of grid impedance online. Performance of the impedance emulation method is studied by measuring the input impedance of the impedance-emulator by using a three-phase IGBT inverter to generate the small-signal excitation in its output currents. The impedance emulator is shown to be very sensitive to sampling delay which degrades the phase behavior of the emulated grid impedance. Moreover, the delay easily destabilizes the linear amplifier when large grid inductance is to be emulated. This issue should be treated with caution since very large high-frequency currents can flow in the circuit. Future work will include implementing the grid impedance emulation method by an additional real-time simulator in order to achieve higher sampling frequency and smaller delay.

Abstract

Heat transfer and pressure loss characteristics of a fin and tube heat exchanger are numerically investigated based on parametric fin geometry. The cross-flow type heat exchanger with circular tubes and rectangular fin profile is selected as a reference design. The fin geometry is varied using a design aspect ratio as a variable parameter in a range of 0.1-1.0 to predict the impact on overall performance of the heat exchanger. In this paper, geometric profiles with a constant thickness of fin base are studied. Three-dimensional, steady-state CFD model is developed using commercially available Multiphysics software COMSOL v5.2. The numerical results are obtained for Reynolds number in a range from 5000 to 13000 and verified with the experimentally developed correlations. Dimensionless performance parameters such as Nusselt number, Euler number, efficiency index, and area-goodness factor are determined. The best performed geometric fin profile based on the higher heat transfer and lower pressure loss is predicted. The study provides insights into the impact of fin geometry on the heat transfer performance that help escalate the understanding of heat exchanger designing and manufacturing at a minimum cost.

Keywords: fin and tube heat exchanger, numerical modelling, fin profile, conjugate heat transfer, turbulent flow, pressure loss

1 Introduction

Fins are the extended surfaces used in heat exchangers to enhance the heat transfer rate between heat transfer surfaces and the flowing fluid (Cengel et al., 2012). The increment in the heat transfer performance through fin surfaces is widely employed in many industrial applications. Application of waste heat recovery systems has received tremendous attention during the last decade due to the resulting saving of primary fuel, increased energy efficiency and lower greenhouse gas emissions. Heat exchangers are one of the important components of these waste heat recovery systems. During past few years, H-type finned and tube heat exchangers have been studied both experimentally (Yu et al., 2010; Chen and Lai, 2012; Chen et al., 2014) and numerically (Tong, 2007; Zhang et al., 2010; Jin et al., 2013). The studies mainly focused on examining the heat transfer and flow resistance characteristics for a reference design of the H-type finned tube bundles. In addition, combined heat and mass transfer analysis on H-type design with three types of finned tube namely-dimple finned tube, longitudinal vortex generators (LVGs) finned tube, and finned tube with compound dimples and LVGs together was conducted (Wang and Tang, 2014; Zhao et al.,2014).

The implementation of fins on the primary heat surface enhances the complexity, volume, and weight which make the design and construction of fin surfaces of vital importance in heat exchanger applications. Very limited research on different fin types or geometry profiles is available due to restricted experimental conditions and numerical challenges. This limitation overshadows the current knowledge of design factors that influence the heat transfer and pressure loss characteristics. Hence, it becomes imperative to study the different fin geometric profiles to determine the optimal fin design for a given H-type fin and tube heat exchanger application.

In this paper, we used Computational Fluid Dynamics (CFD) to obtain the solution of governing equations of physical phenomena in a cross-flow type fin and tube heat exchanger. The parametric study of fin geometry is conducted using air as a working fluid considering the 'rectangular' fin as reference geometric profile. Heat transfer and pressure loss characteristics in a fin and tube heat exchanger with different geometric fin profiles are predicted and compared with the reference fin profile geometry.

2 Numerical model development

2.1 Heat exchanger design

The heat exchanger used in the present study is fin and tube type. The design entails circular tubes and rectangular fins which are attached to the set of two tubes with a fixed gap in between. This particular design is also called 'H-type' finned tube heat exchanger due to the typical arrangement of fins on tubes resembling the letter 'H'. An orderly arrangement of the single units

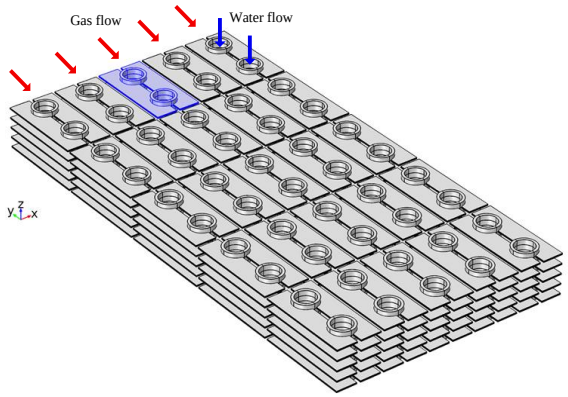

Figure 1. Double fin and tube (or H-type) heat exchanger configuration.

results in the complete heat exchanger configuration which can be scaled for desired applications based on the heat transfer rate and allowable pressure loss. Figure 1 shows the pictorial view of fin and tube heat exchanger configuration used in the present study. The design typically used in waste heat recovery applications such as marine boilers, where hot exhaust gas flows over the finned tube bundle, and cold water flows inside the tubes as can be seen in Figure 1. The heat transfers from hot exhaust gases, by convection through fins and conduction within fin and tube thickness, to the water inside the tubes for steam generation for other application purposes

2.2 Computational geometry

The geometry of the fin and tube heat exchanger simulated in the present study is shown in Figure 2. In order to save the computational effort, the geometry to be studied is reduced to one-half of the single unit. The computational geometry is divided into three domains- fin, tube and gas; and boundaries- inlet, outlet, and symmetry. The geometric dimensions of the heat exchanger design are given in Table 1.

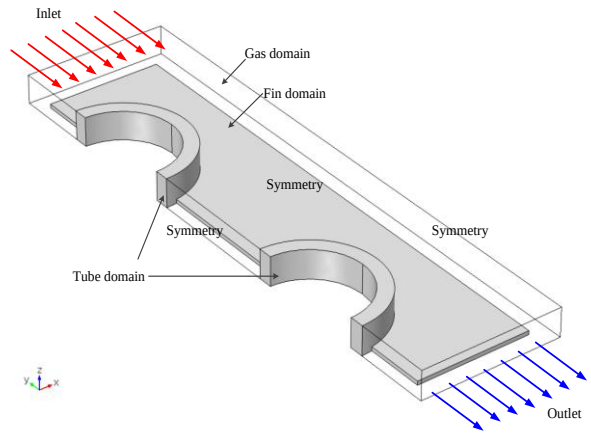

Figure 2. Computational geometry used in the present investigation.

Table 1. Design parameters and operating conditions for a single unit of the exchanger.

Parameter	*Symbol*	*Value*	*Unit*
Length of the fin	L_f	0.145	m
Width of the fin	W_f	0.070	m
Thickness of the reference fin base	$\delta_{fb,r}$	0.002	m
Thickness of the reference fin tip	$\delta_{ft,r}$	0.002	m
Width of the gap between fins	δ_a	0.007	m
Inner diameter of the tube	D_i	0.030	m
Outer diameter of the tube	D_o	0.038	m
Tube pitch	p_t	0.077	m
Length of the gas domain	L_g	0.155	m
Width of the gas domain	W_g	0.080	m
Fin pitch	p_f	0.015	m
Temperature at gas inlet	T_{in}	573.15	K
Pressure at gas outlet	p_{out}	0.0	Pa
Temperature of inner tube wall	T_w	453.15	K

2.3 Formulation of the fin geometric profile

In the present work, the geometry of the fin is varied using aspect ratio (α) as a profile parameter which is defined as the ratio of thickness of fin tip (δ_{ft}) to the thickness of fin base (δ_{fb}) and can be expressed as-

$$\alpha = \frac{\delta_{ft}}{\delta_{fb,r}} \quad (1)$$

The rectangular geometry of the fin is considered as a reference profile to simplify the analysis and geometric complexity, and the thickness of fin base is kept constant as of reference rectangular fin ($\delta_{fb,r}$) while the thickness of the fin tip is subjected to a variation (Figure 3). The aspect ratio is varied in a range α=1.0-0.1 transforming the reference rectangular fin profile (at α=1.0) into the trapezoidal profile (at α= 0.7, 0.5, 0.3) which eventually resembles a triangular profile (at α=0.1). With the change in aspect ratio, total heat transfer area, the thermal contact area between the fin and tubes and, the weight of the heat exchanger unit (computational geometry) changes as shown in Figure 4.

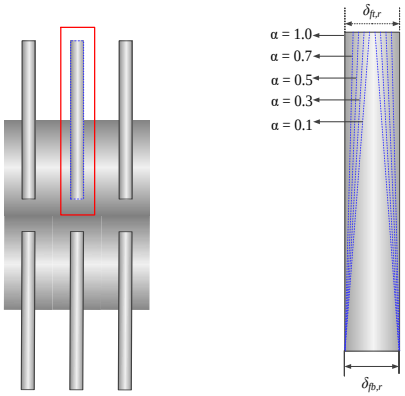

Figure 3. Computational geometry used in the present investigation.

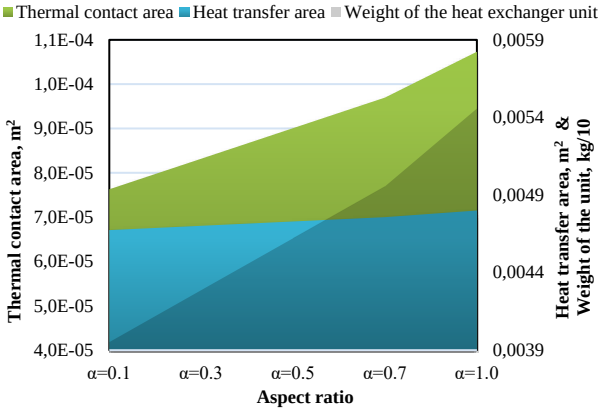

Figure 4. Computational geometry used in the present investigation.

2.4 Governing equations

3D CFD model is developed using commercially available Multiphysics software COMSOL v5.2. Following assumptions are made in the present model-

- Steady state flow and heat transfer
- Incompressible flow
- Negligible thermal contact resistance
- Temperature dependent fluid property
- Constant inner tube wall temperature
- No periodic boundary condition (i.e. model is valid for the first unit of the heat exchanger as shown in Figure1).

The mass and momentum balance for flow in the gas domain and energy balance in terms of heat transfer are given as-

$$\nabla \cdot \mathbf{u} = 0 \qquad (2)$$

$$\rho(\mathbf{u}\cdot\nabla)\mathbf{u} = \nabla\cdot[-p\mathbf{I} + \mu(\nabla\mathbf{u} + (\nabla\mathbf{u})^T)] + \mathbf{F} \qquad (3)$$

$$\rho C_p \mathbf{u}\cdot\nabla T + \nabla\cdot\mathbf{q} = \mathbf{Q} \qquad (4)$$

where, $\mathbf{q} = -k\nabla T$

Based on the mass flow rate and the heat exchanger configuration, the Shear Stress Transport (SST) model

Table 2. Design parameters and operating conditions for a single unit of the exchanger.

Initial	*Condition*
Gas domain	$\mathbf{u}=0\,;\,p=0\,;k=\left(\frac{10\cdot\mu}{\rho(0.1\cdot l_{ref})}\right)^2\,;\,\varepsilon=\frac{C_\mu k_{init}^{3/2}}{0.1\cdot l_{ref}}\,;\,\omega_{init}=\frac{\sqrt{k_{init}}}{0.1\cdot l_{ref}}$
All domains	$T = 298.15\ K$
Boundary	*Condition*
Inlet	$T=T_{in};\ u=0, v=-u_{in}, w=0$
Wall	$\mathbf{u}\cdot\mathbf{n}=0;\nabla k_e\cdot\mathbf{n}=0\ ;\ \varepsilon=\frac{C_\mu^{3/4}k_e^{3/2}}{\kappa_v\delta_w}$
Inner tube wall	$T=T_w$
Outlet	$p=p_{out}, -\mathbf{n}\cdot\mathbf{q}=0\ ;\ \nabla k_e\cdot\mathbf{n}=0\ ;\ \nabla\varepsilon\cdot\mathbf{n}=0$
Symmetry	$\mathbf{u}\cdot\mathbf{n}=0\ ;\ -\mathbf{n}\cdot\mathbf{q}=0\ ;\ \nabla k_e\cdot\mathbf{n}=0\ ;\ \nabla\varepsilon\cdot\mathbf{n}=0$

is adopted. The governing equations of two-equation SST model are formulated in terms of k and ω as (Mentor, 1994)-

$$\rho\frac{\partial k}{\partial t} + \rho\mathbf{u}\cdot\nabla k = P - \rho\beta_o k\omega + \nabla\cdot((\mu+\sigma_k\mu_T)\nabla k) \qquad (5)$$

$$\rho\frac{\partial \omega}{\partial t} + \rho\mathbf{u}\cdot\nabla\omega = \frac{\rho\gamma}{\mu_T}P - \rho\beta\omega^2 + \nabla\cdot((\mu+\sigma_\omega\mu_T)\nabla\omega) + 2(1-f_{v1})\frac{\rho\sigma_{\omega 2}}{\omega}\nabla\omega\cdot\nabla k \qquad (6)$$

The default model parameters used to solve the governing equations are defined in the Appendix. Table 2 lists initial conditions for a steady state simulation (Mentor et al., 2003) and boundary conditions used to solve the computational model and achieving preliminary results numerically.

3 Model validation

3.1 Experimental validation

The validation of numerical results is performed using the experimentally developed correlations by Chen et al. (2014) and a comparison is shown in Figure 5.

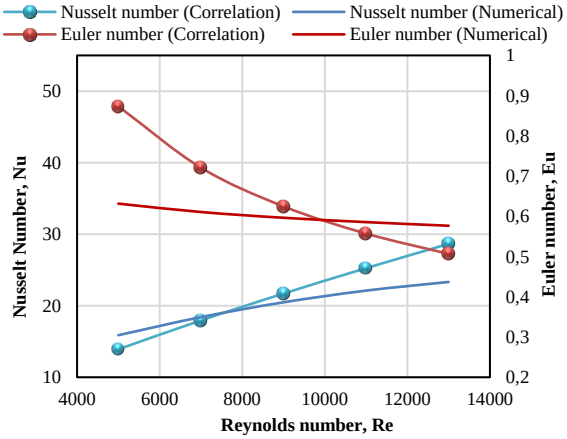

Figure 5. Computational geometry used in the present investigation.

Correlations for the Nusselt number and Euler number given by (7) and (8) are valid for Reynolds number range of 5000-18000 with a relative error of 2.79% and 3.70%, respectively. The average percent deviation of numerically predicted Nusselt and Euler numbers from the correlation values is calculated to be 5.61% and 5.72%, respectively. The deviation accounts for the assumptions in the present study or and the experimental errors in developing the correlations. These deviations are in acceptable range and hence, the results are assumed accurate enough to predict the physical behavior.

$$Nu = 0.053Re^{0.756}\left(\frac{D_o}{p_f}\right)^{-0.212}\left(\frac{L_f}{p_f}\right)^{-0.294}\left(\frac{W_f}{p_f}\right)^{0.155} \quad (7)$$

$$Eu = 19.14Re^{-0.57}\left(\frac{L_f}{D_o}\right)^{1.32} \quad (8)$$

3.2 Mesh independence test

Mesh independence test is made on the reference fin using temperature difference across the gas domain as an objective property. Five different meshes with 375860, 657449, 997272, 1716992 and 2130500 elements are used in the simulation. The test result suggests the mesh with 1716992 elements as a good choice in regards with the accuracy and computational time.

4 Results and discussion

The results predicted from the present study are discussed in this section. Table 3 expresses the dimensionless parameters used to evaluate the performance of the heat exchanger design. The Nusselt number and Euler number are used to assess the heat transfer and pressure loss characteristics of the heat exchanger with different fin geometric profile. As observed in Figure 6, the Nusselt number increases with the Reynolds number which shows thermal performance increases as the flow velocity increases. Moreover, the Nusselt number is higher for α=1.0, i.e., for rectangular

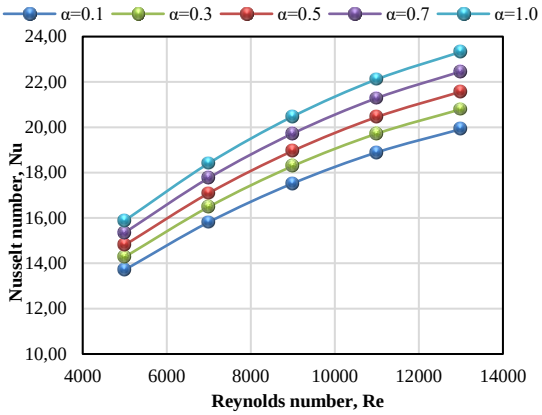

Figure 6. Variation of the Nusselt number with respect to Reynolds number.

fin profile and then decreases as α approaches to 0.1 where the fin geometric profile becomes nearly triangular. This effect results from the decreasing flow velocity as α varies from 1.0 to 0.1, which further decreases the convective heat transfer. Variation in Euler number with Reynolds number for different fin geometric profiles can be seen from Figure 7. Euler number decreases as α varies from 1.0 to 0.1, which is a clear demonstration of reduced pressure loss on a transition of rectangular fin profile (α=1.0) to triangular profile (α=0.1). At Re = 13000, Euler number for α=0.1 decreases by 7.23% than α=1.0.

In order to evaluate the overall performance of the heat exchanger in terms of both, heat transfer and pressure loss, efficiency index (Table III) is calculated. Figure 8 shows a variation in efficiency index with respect to Reynolds number for different fin geometric profiles. The efficiency index increases with the Reynolds number and so thus the overall performance of the heat exchanger design. As observed, efficiency index increases as α goes down from 1.0 to 0.1. which dictates that the fin with tapered geometric profile performs better in comparison to the conventional rectangular fin geometric profile.

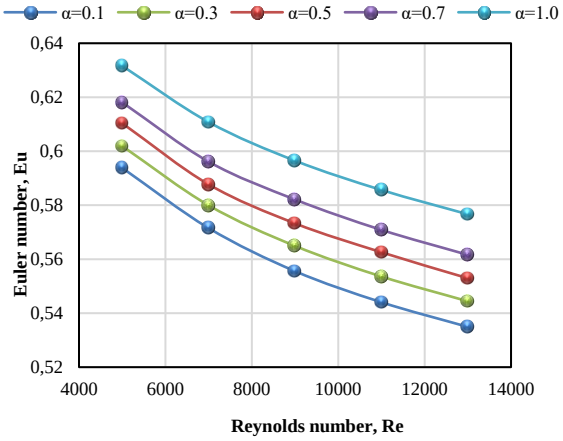

Figure 7. Variation of the Euler number with respect to Reynolds number.

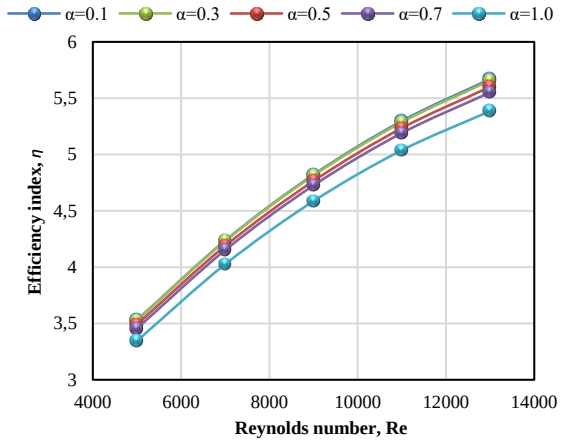

Figure 8. Variation of the efficiency number with respect to Reynolds number.

This trend of efficiency index explains that as α varies from 1.0 to 0.1, the pressure reduction is dominant than that of increment in thermal performance. In addition, the heat exchanger with α=0.1 and α=0.3 shows nearly equivalent performance. For instance, at Re=13000 efficiency index at α=0.1 is only 0.23 % higher than α=0.3. Heat transfer through the fin can be predicted from the temperature gradients on the fin surface.

Figure 9 shows temperature gradients on the fin surface of different geometric profiles. The dissipation of the heat from hot gas to the fin is evident from the higher temperatures away from fin and tube interface where the heat is conducted from the fin to the tube wall resulting in lower temperatures in those regions. Relatively, higher temperature gradients on the fin surface with α=0.1 are evident of lower heat transfer rate due to the lower temperature difference between the gas and the fin which further reduces the heat transfer performance.

To determine the impact of different fin profiles on the overall performance, a dimensionless parameter called 'area-goodness factor' is used. It is defined as a ratio of Colburn j factor to the friction factor, f of the heat exchanger design with respect to the reference fin geometry (Table III). Figure 10 shows the comparative performance of the heat exchanger with different fin geometric profiles at Reynolds number range 5000-13000. It can be observed that fin at α=0.1 (i.e., nearly triangular geometric profile) has the highest performance factor in comparison to the other fin profiles under similar operating conditions.

In many industrial applications of fin and tube heat exchangers such as waste heat recovery, aerospace, air-conditioning, automobile radiator, marine vessels, the available volume space and heat exchanger unit weight is a primary design consideration. Therefore, to investigate the most suitable geometric fin profile, the reduction in the weight of the heat exchanger unit as the fin geometric profile varies from α=1.0 to α=0.1 is determined and is shown in Figure 11. As α reduces from 1.0 the weight of the heat exchanger unit (considered one-half in the present study, see Figure 2) reduces and accounts for approximately 28 % reduction when α=0.1. Based on the results and discussion, it can be observed that fin geometric profile at α=0.1 when fin has nearly triangular geometric profile shows better performance with less weight than the reference rectangular fin geometry at α=1.0.

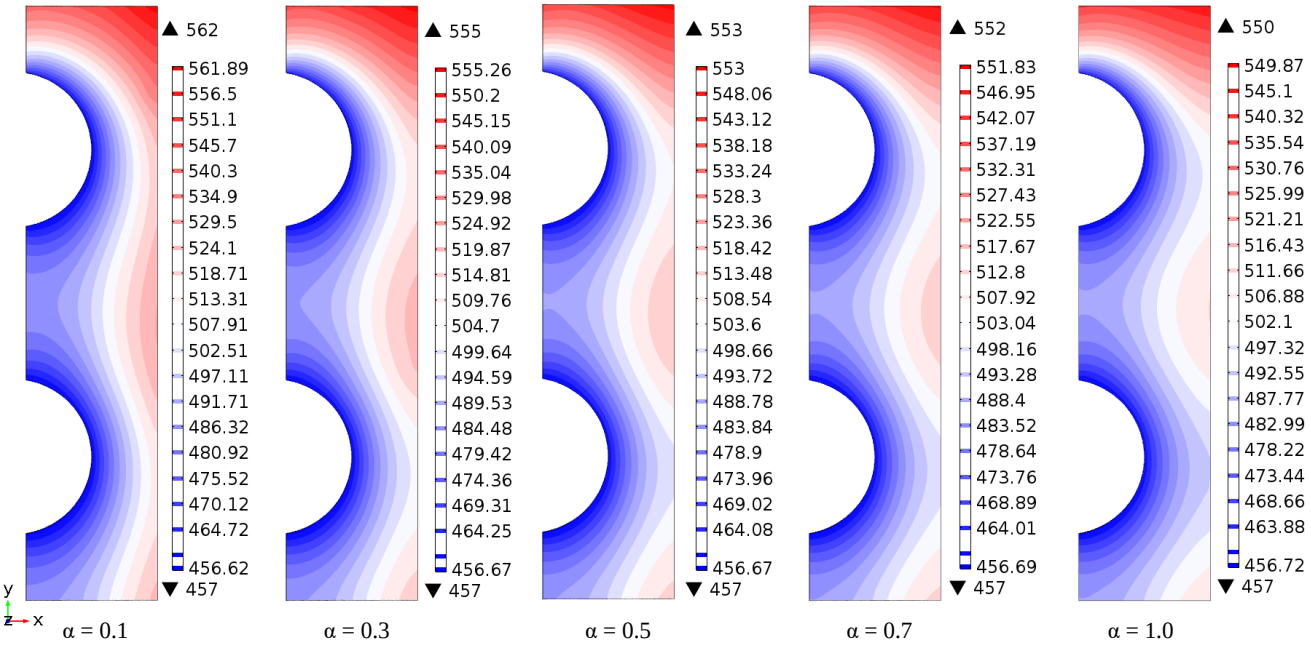

Figure 9. Temperature gradients on the fin surface of different geometric profiles.

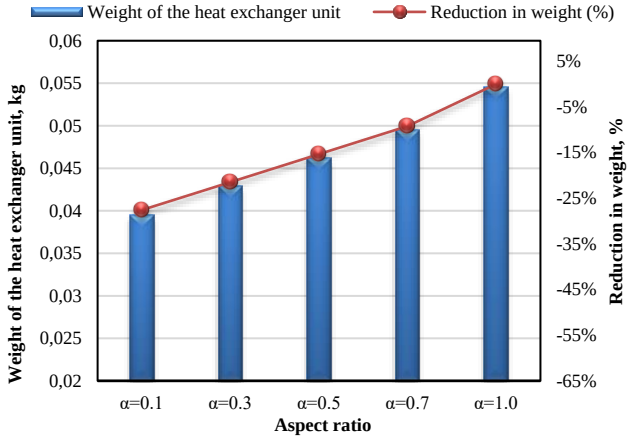

Figure 11. Comparison of the change in weight of heat exchanger unit with different geometric fin profile.

5 Conclusions

In the present study, the impact of different fin geometric profiles on the heat transfer performance and pressure loss in a fin and tube heat exchanger design are analyzed. The numerical study concludes that the fin with triangular at α=0.1 profile can enhance the heat transfer with reduced pressure loss in comparison to the conventional rectangular fin profile, α=1.0. Furthermore, the fin with α=0.1 reduces the heat exchanger weight up to 28 % which is always desirable in the industrial applications of fin and tube heat exchangers. The work presented in this paper encourages the further investigation of different possible fin geometric profiles to optimize the material and manufacturing cost which are the main controlling factors in designing a fin and tube heat exchangers at the industrial scale.

Appendix

In (5), $P = \min(P_k, 10\rho\beta_o k\omega)$ (i)

where, $P_k = \mu_T(\nabla\mathbf{u} : (\nabla\mathbf{u} + (\nabla\mathbf{u})^T) - \frac{2}{3}(\nabla\cdot\mathbf{u})^2 - \frac{2}{3}\rho k\nabla\cdot\mathbf{u}$ (ii)

The turbulent viscosity is, $\mu_T = \frac{\rho a_1 k}{\max(a_1\omega, Sf_{v2})}$ (iii)

where, S is the characteristic magnitude of the mean velocity gradients,

$S = \sqrt{2S_{ij}S_{ij}}$

The other model constants are given in terms of interpolation functions as,

$\phi = f_{v1}\phi_1 + (1 - f_{v1})\phi_2$ for $\phi = \beta, \gamma, \sigma_k, \sigma_\omega$ and $f_{v1} = \tanh(\theta_1^4)$

$$\theta_1 = \min\left[\max\left(\frac{\sqrt{k}}{\beta_o\omega l_\omega}, \frac{500\mu}{\rho\omega l_\omega^2}\right), \frac{4\rho\sigma_{\omega 2}k}{CD_{k\omega}l_\omega^2}\right] \quad \text{(iv)}$$

where, lw is the distance to the closest wall.

$$CD_{k\omega} = \max\left(\frac{2\rho\sigma_{\omega 2}}{\omega}\nabla\omega\cdot\nabla k, 10^{-10}\right) \quad \text{(v)}$$

$$f_{v2} = \tanh(\theta_2^2) \text{ and } \theta_2 = \max\left(\frac{2\sqrt{k}}{\beta_o\omega l_\omega}, \frac{500\mu}{\rho\omega l_\omega^2}\right) \quad \text{(vi)}$$

The other default model parameter values are,

$\beta_1 = 0.075, \gamma_1 = 5/9, \sigma_{k1} = 0.85, \sigma_{\omega 1} = 0.5,$

$\beta_2 = 0.0828, \gamma_2 = 0.44, \sigma_{k2} = 1.0, \sigma_{\omega 2} = 0.856,$

$\beta_o = 0.09, a_1 = 0.31$ (vii)

The Reynolds number is calculated as: (viii)

$$Re = \frac{\rho u_{\max} D_o}{\mu}$$

The gas-side convective heat transfer coefficient is determined by overall heat transfer coefficient as:

$$\frac{1}{U} = \frac{1}{h_g} + \frac{A_t}{A_i}\left(\frac{1}{h_i} + \frac{(D_o - D_i)}{2K}\right) \quad \text{(ix)}$$

On further simplification,

$$\frac{1}{UA_t} = \frac{1}{h_g A_t} + \frac{1}{h_i A_i} + \frac{1}{\left[\frac{2KA_t}{(D_o - D_i)}\right]} \quad \text{(x)}$$

Since the heat transfer coefficient inside the tube is high (~10^4 W/m^2.K), the second term in Eq. (x) is omitted. The above equation can be further simplified without losing accuracy as the tubes being analyzed are of small thickness (~10^{-3} m) and higher thermal conductivity (~50 W/m.K) which makes the third term very small and hence negligible. This results in a much more straightforward expression,

$$\frac{1}{UA_t} = \frac{1}{h_g A_t} \quad \text{(xi)}$$

$$U = h_g \quad \text{(xii)}$$

Overall heat transfer coefficient can be determined as:

$$U = \frac{Q_t}{A_t \Delta T_{lm}} \quad \text{(xiii)}$$

$$\text{where, } \Delta T_{lm} = \frac{(T_w - \bar{T}_{in}) - (T_w - \bar{T}_{out})}{\ln\left[\frac{(T_w - \bar{T}_{in})}{(T_w - \bar{T}_{out})}\right]} \quad \text{(xiv)}$$

Voltage Stability Assessment of the Polish Power Transmission System

Robert Lis

Faculty of Electrical Engineering, Wroclaw University of Science and Technology, Poland,
Robert.Lis@pwr.edu.pl

Abstract

PSE S.A. is the sole Transmission System Operator in Poland and, as such, responsible for the provision of reactive power resources for maintaining the voltage within predefined limits. This paper describes the problems associated with the investigation of voltage stability of transmission power grid. Voltage problems are the result of heavy loading of transmission lines and transformers. Voltage instability has been responsible for voltage damage in some parts of Polish Power Transmission System (PPTS) on 26 June 2006. The voltage criteria used for voltage security assessment should require, that the worst bus voltage at post-contingency N-1 and sometimes N-2, must be approximately greater than 0.95 p.u. for generator buses and 0.9 p.u. for others. At the stage of planning, the active power transfer margin may be used as a proximity measure of voltage collapse.

Keywords: power system control, reactive power control, load flow control, voltage stability

1 Introduction

The idea of P-V and Q-V curve is used to determine the maximal reactive margin at load buses to avoid voltage instability. Sometimes the voltage stability study may be limited to identify the violation of the bus voltage constraints. In this paper the p-q curve for the critical bus voltage magnitude is created. Using this p-q curve the probability of the critical voltage violation is estimated for uniformly distributed active and reactive power at a given load bus. The p-q curve is created on the basis of bus impedance, which can be measured or calculated. To illustrate the usefulness of p-q idea the simple numerical example is presented. The paper describes also the importance of reactive power control basing on the failures and control problems in the PPTS during a dry summer period.

Assessing and mitigating problems associated with voltage security remains a critical concern for many power system planners and operators. Since it is well understood that voltage security is driven by the balance of reactive power in a system, it is of particular interest to find out what areas in a system may suffer reactive power deficiencies under some conditions and to obtaining information regarding how system voltage stability can be improved most effectively. Operation near the voltage stability limits is impractical and a sufficient power or voltage margin is needed. Practically, the idea of P-V and Q-V curve is used to determine the minimal margin to avoid voltage collapse (Chayapathi et al., 2013; Khoi et al., 1999; Lis, 2013).

Voltage stability is concerned with the ability of a power system to maintain acceptable voltages at all buses in the system under normal conditions and after being subjected to a disturbance (Taylor, 1994). As an example, Table 1 shows the voltage limits, which should be fulfilled in PPTS (Lis, 2013). According to their idea, the Thevenin's impedance is equal to the bus load impedance at the point of voltage collapse. In this paper the idea of using Thevenin's impedance to bus voltage study is extended by taking into account the bus load.

Table 1. Voltage Criteria in PPTS.

No.	*Bus*	*Normal Conditions*	*N-1 and N-2 Contingencies*
1	Generation buses 110 kV	1.0000p.u. - 1.1100 p.u.	0.9545 p.u. - 1.1100 p.u.

From the point of view of monitoring and control the following transmission constraints are the most important: thermal limit of lines of transmission subsystem, voltage stability limit of transmission subsystem and angle stability limit of transmission subsystem. Voltage problems occur in heavily stressed

power systems. Then, the voltage stability limit may be sometimes more drastically important than thermal limits. This is the case of the voltage collapse in PPTS on June 26, 2006.

This paper is devoted to the analysis of voltage limits. The main question is how far we are from the voltage instability and how to consider the randomness of loads. The original p-q curve is applied here to solve such a task. The idea of using p-q curve for voltage collapse analysis was presented in this paper. The p-q curve for the critical bus voltage magnitude is created. Using this p-q curve the critical voltage violation is estimated for uniformly distributed active and reactive power at a given load bus.

The p-q curve is created on the basis of bus impedance. The mathematical background of the proposed idea is presented. To illustrate the usefulness of p-q idea the simple numerical example is presented.

1.1 Country-Wide Absence of Electrical Supply– a Blackout

The quality of the electrical energy supply can be evaluated basing on a number of parameters (Abril et al., 2003; Yorino et al., 2003; Shubhanga et al., 2002). However, the most important will be always the presence of electrical energy and the number and duration of interrupts. If there is no voltage in the socket nobody will care about harmonics, sags or surges. A long term, wide-spread interrupt - a blackout leads usually to catastrophic losses. It is difficult to imagine that in all the country there is no electrical supply. In reality such things have already happened a number of times.

One of the reason leading to a blackout is reactive power, that went out of the control. When consumption of electrical energy is high, the demand on inductive reactive power increases usually at the same proportion. In this moment, the transmission lines (that are well loaded) introduce an extra inductive reactive power. The local sources of capacitive reactive power become insufficient. It is necessary to deliver more of the reactive power from generators in power plants. It might happen that they are already fully loaded and the reactive power will have to be delivered from more distant places or from abroad. Transmission of reactive power will load more the lines, which in turn will introduce more reactive power. The voltage on customer side will decrease further. Local control of voltage by means of autotransformers will lead to increase of current (to get the same power) and this in turn will increase voltage drops in lines. In one moment this process can go like avalanche reducing voltage to zero. In mean time most of the generators in power plants will switch off due to unacceptably low voltage what of course will deteriorate the situation.

In continental Europe, most of the power plant are based on heat and steam turbines. If a generation unit in such power plant is stopped and cool down it requires time and electrical energy to start operation again. If the other power plants are also off - the blackout is permanent (Bhattacharya et al., 2001, 2002; Chicco et al., 2013).

The difficulties showed up on summer 2006. The prediction for power consumption on this day was 18200 MW (in the morning peak) what was much higher compared with June in last year or previous years. This power was planned to be supplied from 75 generation units. Above these, there were a hot power reserve of 1350 MW (in this 237 MW second-reserve, 656 MW minute-reserve) and a cold reserve of about 2600 MW. In the north-east Poland there is not any grid-generation. The closest to this region is Ostroleka Power Plant (P. P.), which in that time from three 200 MW units has two in operation and one set off for maintenance. In early morning of the Jun 26th one unit in Power Plant Patnow had to be switched off and before noon four other units (two in Kozienice P. P. and two in Laziska P. P.) were switched off as well. All these unites were the main supplier to the north-east region of Poland. At 7 o'clock 570 MW of power was lost. At the same time the consumption prediction appeared to be wrong - the consumption was 600 MW higher and there was also much higher demand on reactive power. At 13 o'clock there was an unbalance of 1100 MW. In mean time one unit (in Dolna Odra P. P.) had been activated. However further activation from cold-reserve required more time (about 6 hours) because of technological reasons.

Unusual heat wave spreading throughout the country caused deterioration of the operational conditions in power plants. Due to lack of sufficient amount of cooling water and exceeded water temperature levels, the generating capacities of some power plants systematically decreased. That situation concerned mainly the power plants located in the central and northern part of Poland, the loadings of some transmission lines reached the acceptable limits what in turn cause the necessity of generation decrease in power plants located outside the mentioned region. The control of reactive power became critical (Hatziadoniu et al., 2003; Lu et al., 2002).

2 Prepare Bus Load Flow Equations Using Thevenin's Circuit

Thevenin's theorem states that in the linear electric circuit the effect of the load change at a given bus can be represented by a simple circuit with *emf* $\underline{E}_T$ and the bus impedance $\underline{Z}_T$. The basic circuit resulting from Thevenin's theorem is shown in Figure 1. Knowing the Thevenin's bus impedance $\underline{Z}_T = R_T + jX_T$, load bus voltage V, active P and reactive bus power Q one can calculate the magnitude of Thevenin's *emf* using the following formula:

$$E_T = \sqrt{\left(V + \frac{PR_T + QX_T}{V}\right)^2 + \left(\frac{PX_T - QR_T}{V}\right)^2} \quad (1)$$

Using complex notification:

$$\underline{V} = V_a + jV_b \quad and \quad V = \sqrt{V_a^2 + V_b^2} \quad (2)$$

$$\underline{E}_T = E_a + jE_b \quad and \quad E_T = \sqrt{E_{Ta}^2 + E_{Tb}^2} \quad (3)$$

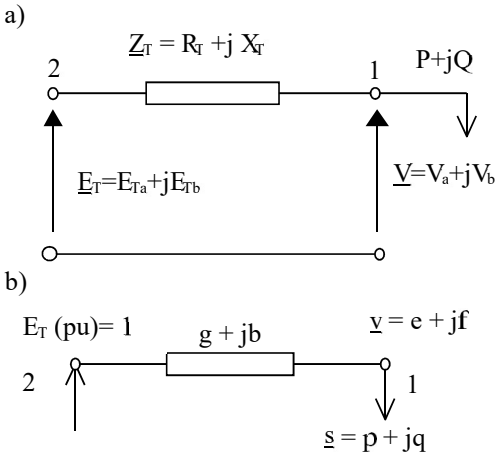

Figure 1. The scheme of 2-bus Thevenin's network, a) simple Thevenin's circuit, b) scheme for load flow study.

The complex admittance of branch connecting load bus with Thevenin's *emf* bus equals:

$$G_T + jB_T = 1/(R_T + jX_T) \quad (4)$$

The load flow equations for load bus have the following form:

$$P = V^2 G_{11} + (V_a E_a + V_b E_b) G_{12} + (-V_a E_b + V_b E_a) B_{12} \quad (5)$$

$$Q = -V^2 B_{11} - (V_a E_a + V_b E_b) B_{12} + (-V_a E_b + V_b E_a) G_{12} \quad (6)$$

where $$G_{11} = G_T \quad and \quad G_{12} = -G_T \quad (7)$$

$$B_{11} = B_T \quad and \quad B_{12} = -B_T \quad (8)$$

Let the bus 2 with Thenenin's *emf* be the slack bus. Then I have

$$E_a = E_T \quad and \quad E_b = 0 \quad (9)$$

and $$P = V^2 G_{11} + V_a G_{12} + V_b B_{12} \quad (10)$$

$$Q = -V^2 B_{11} - V_a B_{12} + V_b G_{12} \quad (11)$$

or $$P = V^2 G_T - V_a G_T - V_b B_T \quad (12)$$

$$Q = -V^2 B_T + V_a B_T - V_b G_T \quad (13)$$

To simplify all considerations the load bus per unit system is introduced as follows

$$Z_b = Z_T = \sqrt{R_T^2 + X_T^2} \quad (14)$$

$$V_{base} = E_T \quad (15)$$

$$S_b = E_T^2 / Z_b \quad (16)$$

where symbol *b* means the base value. Dividing both side of load flow equations by S_b I obtain:

$$p = v^2 g - eg - fb \quad (17)$$

$$q = -v^2 b + eb - fg \quad (18)$$

where $$p = P / S_b \quad and \quad q = Q / S_b \quad (19)$$

$$v = V / E_T \quad (20)$$

$$e = V_a / E_T \quad and \quad f = V_b / E_T \quad (21)$$

$$g = G_T Z_T \quad and \quad b = B_T Z_T \quad (22)$$

Note that the following relations exist in the new bus load per unit system:

$$r + jx = R_T / Z_T + jX_T / Z_T \quad (23)$$

$$z^2 = r^2 + x^2 = \frac{R_T^2}{Z_T^2} + \frac{X_T^2}{Z_T^2} = 1 \quad (24)$$

$$\underline{y} = 1/\underline{z} = 1/(r + jx) = (r - jx)/z^2 = r - jx \quad (25)$$

$$\underline{y} = g + jb \quad (26)$$

And finally $$g = r \quad and \quad b = -x \quad (27)$$

Hence the load flow equations in load bus per unit are as follows:

$$p = v^2 r - er + fx \quad (28)$$

$$q = v^2 x - ex - fr \quad (29)$$

2.1 The P-Q Curve for the Critical Bus Voltage Magnitude

From the point of view of voltage stability the voltage magnitude at a given bus must be in the range of upper and lower voltage limit

$$V_{lower} \le V \le V_{upper} \tag{30}$$

Especially the lower value is the critical value V_{cr} from the point of view of avoiding voltage instability in the power system. Hence the bus voltage must be greater then the critical value

$$V > V_{cr} \tag{31}$$

Using the new per unit system I can write

$$v > v_{cr} \tag{32}$$

where $$v_{cr} = V_{cr} / E_T \tag{33}$$

According to the above assumptions load flow equations for load bus critical solutions (e,f) depend on the critical voltage magnitude vcr. The load flow equations can be analyzed as a critical p-q curve composed of (p,q) values, which are related to the critical bus voltage magnitude vcr .

To find the formula of the critical p-q curve I must eliminate the rectangular components of *e* and *f* from the load flow equations (28) and (29). To find *e* I can make the following multiplications

$$rp = r^2 v^2 - r^2 e + rxf \tag{34}$$

$$xq = x^2 v^2 - x^2 e - rxf \tag{35}$$

and the following addition

$$rp + xq = z^2 v^2 - z^2 e \tag{36}$$

For $z = 1$ I have finally

$$e = v^2 - (rp + xq) \tag{37}$$

To find *f* I can made the following multiplications

$$xp = rxv^2 - rxe + x^2 f \tag{38}$$

$$rq = rxv^2 - rxe - r^2 f \tag{39}$$

and the following subtraction

$$xp - rq = z^2 f \tag{40}$$

For $z = 1$ I have finally

$$f = xp - rq \tag{41}$$

Substituting the obtained formula of *e* and *f* to the formula of v_{cr} I have as follows

$$v_{cr}^2 = e^2 + f^2 \tag{42}$$

$$v_{cr}^2 = (v_{cr}^2 - (rp + xq))^2 + (xp - rq)^2 \tag{43}$$

$$\begin{aligned} v_{cr}^2 &= v_{cr}^4 - 2v_{cr}^2 (rp + xq) \\ &\quad + (rp + xq)^2 + (xp - rq)^2 \end{aligned} \tag{44}$$

$$\begin{aligned} v_{cr}^2 &= v_{cr}^4 - 2v_{cr}^2 rp - 2v_{cr}^2 xq \\ &\quad + r^2 p^2 + 2rxpq + x^2 q^2 \\ &\quad + x^2 p^2 - 2rxpq + r^2 q^2 \end{aligned} \tag{45}$$

$$v_{cr}^2 = v_{cr}^4 - 2v_{cr}^2 rp - 2v_{cr}^2 xq + p^2 + q^2 \tag{46}$$

Hence, I obtain the following formula of p-q curve for a critical voltage magnitude v_{cr}

$$p^2 + q^2 - 2v_{cr}^2 rp - 2v_{cr}^2 xq + v_{cr}^4 - v_{cr}^2 = 0 \tag{47}$$

From the above formula I can obtain the quadratic equations for the specific *p*

$$q^2 - 2v_{cr}^2 xq + p^2 - 2v_{cr}^2 rp + v_{cr}^4 - v_{cr}^2 = 0 \tag{48}$$

An example of p-q curve is shown in Figure 2. The p-q curve can be transformed into P-Q curve after multiplication *p* and *q* by S_b .

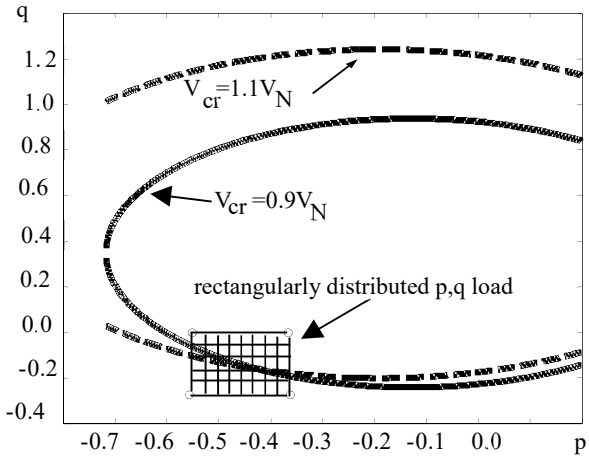

Figure 2. The example p-q curve at a load bus. Symbol V_N means the nominal voltage.

Equation (48) is quadratic and has two real solutions according to the value of the equation discriminant Δ:

$$\Delta = 4v_{cr}^4 x^2 - 4p^2 + 8v_{cr}^2 rp - 4v_{cr}^4 + 4v_{cr}^2 \tag{49}$$

$$\Delta = 4v_{cr}^4 x^2 - 4p^2 + 8v_{cr}^2 rp - 4z^2 v_{cr}^4 + 4v_{cr}^2 \quad (50)$$

$$\Delta = 4v_{cr}^4 x^2 - 4p^2 + 8v_{cr}^2 rp - 4r^2 v_{cr}^4 - 4x^2 v_{cr}^4 + 4v_{cr}^2 \quad (51)$$

$$\Delta = -4p^2 + 8v_{cr}^2 rp - 4r^2 v_{cr}^4 + 4v_{cr}^2 \quad (52)$$

$$\Delta = 4v_{cr}^2 - 4(p^2 - 2v_{cr}^2 rp + r^2 v_{cr}^4) \quad (53)$$

$$\Delta = 4v_{cr}^2 - 4(p - v_{cr}^2 r)^2 \quad (54)$$

$$\sqrt{\Delta} = 2\sqrt{v_{cr}^2 - (p - rv_{cr}^2)^2} \quad (55)$$

and finally I obtain two parts of p-q curve

$$q_{1,2} = 0.5\left(2v_{cr}^2 x - / + \sqrt{\Delta}\right). \quad (56)$$

The lower part of the p-q curve is associated with the consumed power, because a reactive consumed power at bus is treated in load flow equations as a negative value

$$q_{lower} = v_{cr}^2 x - \sqrt{-p^2 + 2v_{cr}^2 rp + v_{cr}^2 - v_{cr}^4 r^2} \quad (57)$$

The upper part of the p-q curve relates to positive values, i.e. to reactive generation at a given bus

$$q_{upper} = v_{cr}^2 x + \sqrt{-p^2 + 2v_{cr}^2 rp + v_{cr}^2 - v_{cr}^4 r^2} \quad (58)$$

2.2 The Probability of the Violation of the Critical Voltage

Let's assume that the load at bus is uniformly distributed between their min and max

$$p_{min} \le p \le p_{max} \quad (59)$$

$$q_{min} \le q \le q_{max} \quad (60)$$

The probability of the violation of the critical voltage magnitude at load bus can be calculated using the outside area and the rectangular area, see Figure 3. To find the probability of the violation of the critical voltage the lower part of p-q curve should be used, Figure 3. Using the geometrical definition of probability:

$$p_{vcr} = S_{outside} / S \quad (61)$$

where S means the area of rectangular

$$S = (p_{max} - p_{min})(q_{max} - q_{min}) \quad (62)$$

The outside area equals

$$S_{outside} = S - S_{ABCD} \quad (63)$$

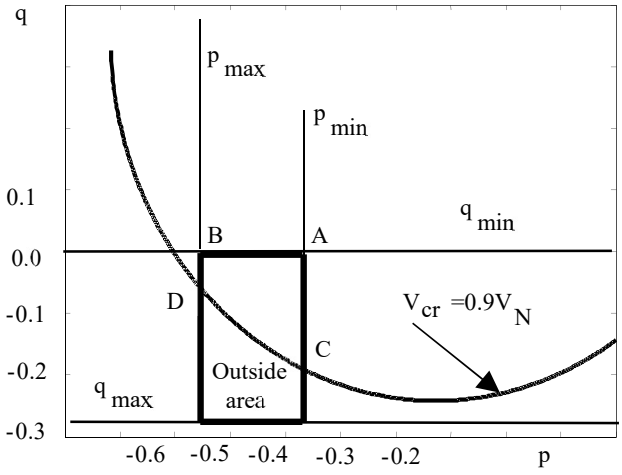

Figure 3. The p-q curve and the rectangularly distributed load.

The area of *ABC*D figure can be computed using the definite integral formula in the following way

$$S_{ABCD} = S1 - S2 = \int_{p\,max}^{p\,min} q_{min}\,dp - \int_{p\,max}^{p\,min} q_{lower}\,dp \quad (64)$$

where

$$S1 = \int_{p\,max}^{p\,min} q_{min}\,dp = q_{min}\,p\,\Big|_{p\,max}^{p\,min} = q_{min}(p_{min} - p_{max}) \quad (65)$$

and

$$\begin{aligned} S2 = {} & v_{cr}^2 x(p_{min} - p_{max}) + \\ & - \frac{(-p_{min} + v_{cr}^2 r)}{2}\sqrt{W_{min}} + \\ & + \frac{(-p_{max} + v_{cr}^2 r)}{2}\sqrt{W_{max}} + \\ & + \frac{v_{cr}^2}{2} arcsin\frac{(-p_{min} + v_{cr}^2 r)}{v_{cr}} + \\ & - \frac{v_{cr}^2}{2} arcsin\frac{(-p_{max} + v_{cr}^2 r)}{v_{cr}} \end{aligned} \quad (66)$$

Finally we can make the following substitution:

$$W_{min} = -p_{min}^2 + 2v_{cr}^2 rp_{min} + v_{cr}^2 - v_{cr}^4 r^2 \quad (67)$$

$$W_{max} = -p_{max}^2 + 2v_{cr}^2 rp_{max} + v_{cr}^2 - v_{cr}^4 r^2 \quad (68)$$

3 Numerical Example

Thevenin's complex impedance seen from the 400 kV load bus has been obtained by the load flow study in 400/220 kV transmission grid:

$$\underline{Z}_T = R_T + jX_T = (-125.12 + 31.40)\ \Omega.$$

The bus voltage magnitude at the analysed load bus determined by load flow computation equals: V = 410

kV, while the nominal voltage has the following value V_N = 400 kV. The critical voltage magnitude equals:

$$V_{cr} = 0.9V_N = 360 \text{ kV}.$$

The minimal and maximal active and reactive load at the analysed bus equal

$$P_{min} = 400 \text{ MW} \quad \text{and} \quad P_{max} = 600 \text{ MW};$$
$$Q_{min} = 0 \text{ MVAR} \quad \text{and} \quad P_{max} = 300 \text{ MVAR}.$$

Knowing the Thevenin's bus impedance $\underline{Z_T} = R_T + jX_T$, load bus voltage V, active P and reactive bus power Q I calculate the magnitude of Thevenin's *emf*:

$$E_T = \sqrt{\left(V + \frac{PR_T + QX_T}{V}\right)^2 + \left(\frac{PX_T - QR_T}{V}\right)^2} = 572.9\text{kV}.$$

To simplify all considerations the load bus per unit system is introduced: $Z_b = Z_T = \sqrt{R_T^2 + X_T^2} = 342.1\ \Omega$;

$$V_{base} = E_T = 572.9 \text{ kV};$$
$$S_b = E_T^2 / Z_b = 959.4 \text{ MVA}.$$

The value of analyzed variables in load by per unit systems are as follows:

$$p_{min} = P_{min} / S_b = \text{-0.4169};$$
$$p_{max} = P_{max} / S_b = \text{-0.6254};$$
$$q_{min} = Q_{min} / S_b = 0;\ q_{max} = Q_{max} / S_b = \text{-0.3127};$$
$$v_{cr} = V_{cr} / E_T = 0.6284;$$
$$r = R_T / Z_T = \text{-0.3657};\ x = X_T / Z_T = 0.9307.$$

Now can calculate the probability of the violation of the critical voltage magnitude. The rectangular area:

$$S = (p_{max} - p_{min})(q_{max} - q_{min}) = 0.0652.$$

The inside area: $S_{ABC} = \int_{p_{min}}^{p_{max}} (q_{lower} - q_{min})dp = 0.0270.$

The outside area $S_{outside} = S - S_{ABCD} = 0.0382.$

The probability of the violation of the critical voltage magnitude: $p_{vcr} = S_{outside} / S = 0.58$ □

4 Conclusions

The proposed p-q curve method is simple and may be based on local measurements of bus impedance. It enables calculating the probability of voltage limit violation at a given load bus. The greater the probability the weaker the bus is from the point of view of voltage stability.

To find the formula of p-q curve a new load bus per unit system must be introduced. The transformation from p-q curve to P-Q curve can be easily made by multiplication p and q value by the base power of the analyzed load bus.

The probability of voltage limit violation is estimated as the quotient of relevant area outside and inside the specific p-q curve.

The slower forms of voltage instability can be analyzed as steady state problem using power flow simulation. Snapshot in time following an outage may be simulated and P-U curves computed to assess voltage stability margin.

The main difficulties of the modelling of the power system concern load modelling and therefore conservative constant load hypothesis are used in computation.

Abstract

The formation of agglomerates in a refuse derived fuel (RDF) fired circulating fluidized bed (CFB) boiler has been investigated by implementing a dynamic model of the combustion process. The nature of refuse derived fuel, which is complex in composition, leads to an increased tendency for agglomerate formation. Notwithstanding the fact that a robust control scheme is essential in preventing the decrease in boiler efficiency from accelerated agglomerate formation. Therefore, a mechanism for detecting agglomeration through a physical model by looking at the minimum fluidization is presented. As agglomerates form between the fuel ash and bed sand the average diameter of the sand will increase and therefore the minimum fluidization velocity. Samples of bed material have been sieved and measured from a 160 MW circulating fluidized bed boiler fired with refuse derived fuel to determine bed material size distribution. The findings have been correlated and match an increase in the minimum fluidization velocity during a seven day sampling period where the bed material size distribution increases above the average sand diameter.

Keywords: circulating fluidized bed, agglomeration, detection, RDF

1 Introduction

The role of waste management in the 21st century is essential in maintaining the excessive amount of waste produced each year in the world. Most developed countries have modern routines and guidelines for dealing with municipal solid waste (MSW) by sorting out recyclable, toxic, and organic materials. Some of these countries are utilizing MSW for producing refuse derived fuels (RDFs). These are used in waste incinerators for the purpose of producing heat and power. When compared to other alternatives, such as land-filling, waste incineration is more reliable and environmentally friendlier (Hernandez-Atonal et al., 2007).

Due to the complex nature of RDF, a viable option for thermal waste treatment is to use them as a source of fuel in circulating fluidized bed (CFB) boilers to produce heat and power, simultaneously solving waste and energy issues. CFB boilers are unique in design and allow for a high degree in fuel flexibility, high combustion efficiency, lower emissions, and relatively fast response to load change (Basu and Fraser, 2015; Hernandez-Atonal et al., 2007; Gungor, 2009), and therefore can handle the complexities of RDF.

Typically, CFBs operate at a combustion temperature between 750 °C and 900 °C and use sand to fluidize the bed material. However, a large portion of the combustible material in RDF contain high levels of alkali and chlorine compounds, which both have low melting and low vaporization temperatures (Pettersson et al., 2013), and can react with the fluidizied sand to form low melting eutectics. It is crucial to maintain the operating temperature within limits. Else there is a significant risk of sand-ash reactions which can lead to agglomeration, slagging, and in the worse case scenario complete defluidization. The variability of RDF's composition, and therefore heating value, can lead to the temperature deviating above the boiler's limits for short periods, in the form of hot zones. The latter can increase the propensity of agglomerate formation either through ash melting or the ash coating of sand. Once agglomerates form they reduce the boiler's efficiency because the fluidized median is hindered and requires increasingly more air to properly combust the incoming fuel.

A dynamic model of an RDF fired CFB has been modeled after a 160 MW industrial installation. Bed samples for a one week period have been taken and analyzed for any increase in the bed material particle diameter. The model has proven to be capable of detecting agglomerate formation off-line, showing an increase in the minimum fluidization during a period of time when there was a corresponding significant increase in particle diameter.

2 Literature Review

2.1 Circulating Fluidized Bed Boilers

The schematic illustrated in Figure 1 is that of a CFB. Its a type of boiler that uses sand as the fluidizing median, where a degree of solid reflux is achieved allowing for a more uniform temperature throughout the boiler. Major advantages include stable combustion at low temperatures (750-900°C), uniform temperature distribution, large solid-gas exchange area, ability to handle problematic fuels with a large variability in size, moisture content,

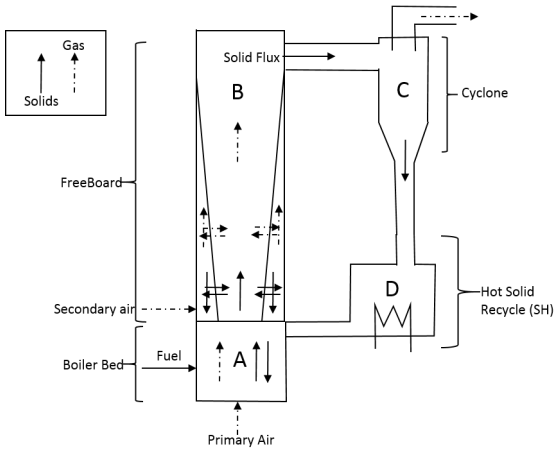

Figure 1. Circulating Fluidized Bed Boiler.

and heating value. They are capable of high heat transfer coefficients between bed and heat exchanger surfaces (Werther, 2007; Scala and Chirone, 2004).

When the fuel enters the boiler it begins to heat, where water is evaporated, volatiles begin to be released through devolatilization, ignition begins, and fragments begin to form. During this process more char becomes available for combustion. Primary air enters the bed of the boiler and entrains the sand and fuel. Above the bed is the freeboard, where secondary air is injected to allow for a higher combustion efficiency and it has been shown to reduce CO concentrations (Hernandez-Atonal et al., 2007). At the top of the boiler the flue gas along with a net solid flux of solids are carried to the cyclone which allows for the flue gas to be utilized in the convective section and separates fly ash from hot solids (sand and ash). The hot solids then pass through a heat exchanger to utilize their high enthalpy content, and then the cooled solids which contain unburnt char are recirculated back into the bed via the loop seal to be fully combusted.

2.2 Characteristics of RDF

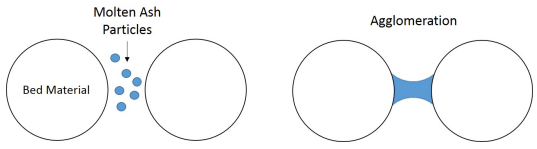
RDF is a byproduct of home and industrial waste, but before it can be fired it needs to be sorted and treated. The waste comes into the sorting facility were it is first chopped and shredded into credit card size pieces. Metals are removed by using high power magnets and the remaining mixture passes over a large wind-sifter, which allows for heavier objects such as glass and ceramics to dropout of the mixture. The separated items are sent to recycling, where what is left can be classified as RDF, and is ready for transport into the boiler.

We can characterize what remains in the fuel as either biomass-based (climate neutral) or fossil-based, where the fossil-based constituents are typically plastics and textiles. Due to the sorting process, determining the proportions of biomass vs. fossil based portions through manual sorting is impractical. There are three established methods for determining the biomass-based portion, and therefore the fossil based portions of RDF: The Selective Dissolution Method, The Balance Method, and the The ^{14}C-Method (Staber et al., 2008). The downside is that these methods are impractical for real-time applications.

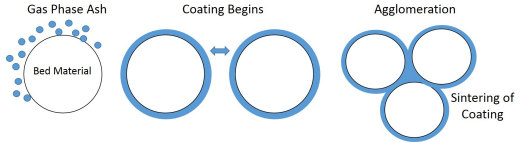
2.3 Agglomeration

The development of agglomerates, the binding of bed particles, is highly dependent upon the characteristics of the fuel's ash content, particle-to-particle interactions and the hydrodynamics in the boiler. As the bed material is fluidized ash can melt and bridge bed material together, as illustrated in Figure 2a. Alternatively, ash can lead to a buildup on bed material and create a sticky coating, as illustrated in Figure 2b, which causes more particles to stick together. Therefore, the likelihood of agglomeration formation is dependent upon ash characteristics and has been the topic in many studies looking at biomass and waste fuels (Elled et al., 2013; Lin et al., 2003; Scala and Chirone, 2008; Bajamundi et al., 2015; Ryabov et al., 2003). Proper fluidization is also needed to inhibit the likelihood of agglomeration. If particle mobility and mixing are below optimal it will not only cause a reduction in heat and mass transfer of the bed material (Liu et al., 2012), but the viscous materials can bond together and can lead to permanent bonds depending upon the residence time.

In a study by (Lindberg et al., 2013) they stated that the predominant ash forming elements are K, Na, Ca, Mg, Fe, Al, Si, P, S, Cl, C, H, and O. The main ash characteristics that can lead to agglomeration come from Na and K, alkali metals. When agglomerates form they disrupt the dynamics in the boiler and if the temperature exceeds the melting temperature of the particles for too long the sticky outer layer of bed material can form permanent bonds (sintering), which can lead to slagging or in worst case scenarios complete defluidization. In a study by (Chirone et al., 2006) they report that bed agglomerates begin to form near burning char because of the higher temperatures and this increases the formation of melt, or the particles stickiness. This is especially problematic because it can lead to the formation of eutectics and the escalation of adhesive forces during sintering. Eutectics formed can have melting points as low as 401 °C and 552 °C for $Na_2S_2O_7$ and $Na_3K_2Fe_2(SO_4)_6$ respectively (Dunnu et al., 2010).



(a) Agglomeration from ash melting.



(b) Agglomeration from ash coating.

Figure 2. Prominent modes of Agglomeration.

Agglomerates are a common occurrence in fluidized beds, but a well controlled boiler can control the fluidazation velocity or temperature well enough to break these clusters apart before sintering takes place. Presented in (Skrifvars et al., 1994; Yan et al., 2003), they discuss how the oxygen concentration in the boiler is linked to the risk of sintering, where regions of higher oxygen content can lead to hot spots. Two mechanisms, flue gas recirculation and air flow, can be used to prevent the likelihood of hot spots. Flue gas recirculation into the boiler bed will help in reducing the oxygen content as well as bed temperature. Maintaining a consistent air flow rate, depending upon the quality of the fuel, for fluidizing the bed material can also help in facilitating a well mixed combustion median in order to reduce hot spots.

A wide range of methods for agglomeration detection, when fired with biomass, have been compared and can be grouped into three categories: on-line detection, experimental methods (controlled agglomeration tests), and theoretical evaluations (fuel ash analysis), (Gatternig, 2015). The last two methods seem reasonable when considering a fuel that is relatively homogeneous, but RDF is a complex and difficult fuel to model and predict melting points, and ash composition because of its composition variability. In most industrial fluidized bed boilers it is routine to take random fuel samples to check for composition consistency. These samples could be used in agglomeration indexes (Visser, 2004; Vamvuka et al., 2008) that look at, among other elements, Na and K in the fuel to determine the likelihood of agglomerate formation. However, this approach assumes that the fuel characteristics will remain the same year after year, but in reality RDF composition is based on the consumers and such an assumption is unrealistic. Also, this method only considers a fraction of the predictability of agglomeration by looking at fuel composition and neglects fuel-ash-bed material interactions, and therefore can give a bit of insight into agglomeration tendencies and should be used cautiously. Another method for agglomeration detection is through advanced multicomponent/multiphase thermodynamic modeling (Lindberg et al., 2013), but there is currently a lack of comprehensive thermodynamic databases for ash compounds and the phases formed during combustion.

Therefore, online detection is the most suitable way to predict agglomeration when RDF is used. Current methods used for the early detection of agglomeration have been explored by looking at pressure drops and temperature fluctuations. However, at this point, the probability of defluidization is already prevalent and leaves no options for the operator but to shutdown the plant, and is not a suitable form of early detection. An alternative method, suitable for early detection, of agglomerates on a small-scale in fluidized beds has been proposed by (Nijenhuis et al., 2007). They were able to develop an early agglomeration recognition system that detects very small changes in hydrodynamic multiphase systems, and allow detection of agglomeration up to 60 minutes before occurring.

The method proposed by the authors in this paper for the detection of agglomerates is based on the minimum fluidization needed to fluidize the bed material. As the diameter of the bed material increases so will the amount of air need to fluidized the bed material in order to operate the boiler within the proper temperature limits. Hence modeling the minimum fluidization can be used in early warning detection of minimal to extreme agglomerate formation.

3 Methodology

The dynamic model used has been calibrated and validated using data from a RDF fired CFB, boiler 6, at MälarEnergi, in Västerås, Sweden. It was possible to back calculate the mass flow rate of fuel by conducting a heat balance on the boiler's heat exchangers. By this method it was determined that 16.8 kg/s of RDF are fed into the boiler, taking the thermal efficiency of the boiler into consideration, this corresponds to MälarEnergi's reported value of 30 tonne/hour. The model is designed to allow for the real input of primary air, secondary air, and flue gas recirculate mass flows and corresponding temperatures. It is assumed that the mass flow rate of the fuel and its respective LHV are constant.

3.1 Description of Model

A model has been designed in DYMOLA using Modelica programming language. The reason for having a dynamic model is to be able to capture the transient behavior of RDF through the combustion process. With the end goal of being able to have a model that has the ability to not only monitor agglomeration, but to also be used for emissions tracking, decision support, and fault detection. The Modelica modeling language allows users to build model libraries with ability to reuse component blocks and to easily change parameters to match any complex dynamic system.

Individual component blocks were made for the CFB-loop, also represented in Figure 1, for the boiler bed, freeboard, cyclone, and hot cycle recirculate (super heater (SH)) respectively. Multiple functions have been been written in order to accurately represent the thermodynamic properties for all in-coming streams, bottom and fly ash, bed material,and flue gas.

3.2 Mass and Energy Balances

The model is based on mass and energy balances (equations 1 and 2) used for the freeboard and bed of the boiler, cyclone, and superheater following that of a similar approach to that presented in (Basu and Fraser, 2015; Gungor, 2009). Where i represents the control volume in the CFB-loop (A, B, C, D) in Figure 1, m is the mass, H is the enthalpy, α is the percentage of combustion, and $\dot{Q}$ is the heat released during combustion.

$$\frac{d(m_i)}{dt} = \Sigma \dot{m}_{in,i} - \Sigma \dot{m}_{out,i} \tag{1}$$

$$\frac{d(m_i H_i)}{dt} = \dot{m}_{in,i} H_{in,i} - \dot{m}_{out,i} H_{in,i} + \alpha \dot{Q}_{released,i} \quad (2)$$

It was possible to calculate the enthalpies of all constituent parts in the energy balance, equation 3, where T_i is the temperature in the control volume and T_{ref} is reference temperature taken at 289.15K.

$$\frac{d(H_i)}{dt} = Cp_i(T_i - T_{ref}) \quad (3)$$

The fuel composition and flow rate is constantly changing, and in turn so is the boiler bed and flue gas temperature, so a series of functions have been developed to calculate the specific heat for each element in the control volume in the energy balance. In this way, instead of assuming constant values, the model has the capability of more accurately simulating temperature profiles for the bed and freeboard of the boiler. The function developed for calculating the specific heat (Cp) of the gas follows the practices of (Wester, 1987), equation 4.

$$Cp = \frac{1}{T - T_{ref}} \int_{T_{ref}}^{T} \sum_{n=-1}^{n=7} a_c^n \left(\frac{T}{1000} \right)^n \quad (4)$$

The coefficients for a_c^n represent air, N_2, O_2, CO_2, and water vapor. The gas thermophysical properties and composition were calculated by using flue gas stoichiometric calculations. The flue gas composition is found to primarily be comprised of CO_2, H_2O,O_2, and N_2. Where the model uses the ultimate analysis of the fuel as input, calculates the amount of excess air in the system, and then the flue gas composition can be used to calculate the specific heat, equation 5, as well as viscosity and density at the operating temperature.

$$\begin{aligned} Cp_{gas} = {} & [N_2]Cp_{N_2} + [O_2]Cp_{O_2} \\ & + [CO_2]Cp_{CO_2} + [H_2O]Cp_{H_2O} \end{aligned} \quad (5)$$

The solids contained within each control volume consist of fuel, sand, ash, and char, as shown in equation 6. Where α, β, γ, and δ represent the percentage of fuel, sand, ash, and char respectively that are in the control volume i.

$$C_{p,solids,i} = \alpha \cdot C_{p,fuel} + \beta \cdot C_{p,sand} + \gamma \cdot C_{p,ash} + \delta \cdot C_{p,char} \quad (6)$$

The functions for fly and bottom ash were developed by using chemical compositions found in (Chang et al., 1997). Where they analyzed the chemical composition and determined the compounds and corresponding percent composition of ash, and found that CaO, SiO_2, Al_2O_3, Fe_2O_3, ZnO, MgO, Cr_2O_3 were the major components (in decreasing order). Specific heat correlations for the compounds were developed from (Abu-Eishah et al., 2004; Karditsas and Baptiste, 1995; Madelung et al., 1999), therefore temperature dependent ash specific heat values could be estimated, equation 7.

$$C_{p,ash,i} = \Sigma \left(\xi_j \cdot C_{p,j} \right) \quad (7)$$

where i represents either fly or bottom ash, ξ is the compound percentage in the ash, and j is the compound. With the calculation of Cp_{gases} and Cp_{solids} and corresponding mass flows equations 2 and 3 can be used to determine the boiler temperature.

3.3 Hydrodynamics

CFBs operate at a higher gas velocity and therefore the gas and solids within the boiler act like a fluid. In the bed of a CFB boiler there is a dense emulsion phase, where the gas moves through the inventory as large bubbles. At the top of the bed, where the secondary air input is, the bubbles burst dispersing inventory and unburnt char into the freeboard. The addition of this secondary air, theoretically, allows for a dilute well-mixed phase throughout the freeboard. The freeboard is typically further segregated into a core and annulus. The core is where the gas and solids flow upward, fine particles are carried out of the bed, and coarser particles tend to form clusters and then fall back down in the annulus region as a thin film, where the further up in the freeboard the smaller the annulus region becomes, as shown in Figure 1.

The minimum amount of air velocity required to fluidized the bed material is called the minimum fluidization velocity u_{mf} and is the velocity at which the drag of the fluidized median (sand) is equal to the weight of the bed material. Following the method used in (Kunii and Levenspiel, 2013) the minimum fluidization can be determined, equation 8.

$$\begin{aligned} & \frac{1.75}{\varepsilon_{mf}^3 \phi} \cdot \left(\frac{d_p U_{mf} \rho_g}{\mu_g} \right)^2 + \frac{150(1-\varepsilon_{mf})}{\varepsilon_{mf}^3 \phi^2} \cdot \frac{d_p U_{mf} \rho_g}{\mu g} = \\ & \frac{d_p^3 \rho_g (\rho_p - \rho_g) g}{\mu_g^2} \end{aligned} \quad (8)$$

Where ε_{mf} is the void fraction at minimum fluidizing conditions, ϕ is the sphericity of the sand, d_p is the average diameter of sand particles, ρ is either the density of the fluidizing median or sand, μ_g is the viscosity of the fluidizing median, and g is gravity.

As the amount of air is increased into the boiler the minimum fluidazation velocity of the gas will reach the superficial velocity (U_s) and is affected by the amount of gas, density and size in a given control area. Typically values for industrial CFBs is in the range of 5-10 m/s, (Basu and Fraser, 2015). This velocity carries bed material, ash, and unburnt char up into the freeboard, where a portion of these circulate within the boiler but there is also a net solid flux, G_s that leaves the boiler to be recirculated back through the loop-seal. Where G_s is equal to the amount

of solids going up in the boiler minus the solids circulating within the boiler. A correlation between G_s and operational conditions was presented by (Guan et al., 2010), equation 9, where G_s is in the rang of 200 and 400 kg/m^2, which is within the operating limits of the designed CFB.

$$\frac{G_s d_p}{\mu_g} = 547 Ar^{0.248} \left(\frac{U_s}{\sqrt{gD}} \right)^{0.375} \left(\frac{D}{H} \right)^{0.195} \quad (9)$$

Where Ar is Archimedes number, D is the diameter of the freeboard, and H is the height of the freeboard.

4 Results and Discussion

4.1 Validation

The model has been constructed to predict the performance of a 160 MW CFB boiler. The model has been designed to predict the bed and flue gas temperatures. The validity of the model has been determined by comparing data from boiler 6 at MälarEnergi. Figure 3 illustrates a simulation, for a week, of the flue gas temperature as it exits to the cyclone. The accuracy of the model is quite good initially, less than a few percent. However, it can be seen that when there is sudden increase or decrease the model tends to underestimate, or overestimate, the respective temperature. Since the model is currently designed using a constant fuel mass flow rate and heating value it is reasonable to believe that this is attributing to the deviation in the predicted temperature. The model's profile is able to follow that of the actual profile, but if the quality of the fuel coming into the boiler is poor this would be reflected in a substantial drop in the temperature profile.

4.2 Agglomerate Prediction

There is a lot in the literature about methods used to predict CFB failure from agglomeration, but typically these do not take into account the impact of the combustion environment (Yan et al., 2003) like gas to particle interactions and alkali vapor condensing.

Agglomeration prediction has been studied to a lengthy extent where fossil and biomass fuels are concerned. The standard procedure in industry for predicting agglomeration is determined from pressure drops and temperature changes (Gatternig, 2015), but it has already been mentioned that this is not suitable for early detection. For early detection, using plant process parameters, it is possible to detect agglomeration by looking at the minimum fluidization velocity, where a small increase shows that the diameter of the circulating bed material is increasing.

This is because with the onset of agglomerates and then sintering, the minimum fluidization required to fluidized the bed material will slowly increase. Therefore, agglomeration can be monitored by modeling process parameters, while operators can still keep an eye on pressure drops in the boiler bed and temperature fluctuations.

As mentioned the composition of RDF can vary from hour to hour. However, the composition of sand, with an average diameter in the range of $0.40 < d_p < 0.63$, is known and as agglomerates form this will require a higher minimum fluidization. Figure 4 confirms the presence of a relationship between the bed particle size increasing and the required increase in the minimum fluidization. Where the bed material size distribution was obtained from Mälarenergi, daily average, and the minimum fluidization is the model's prediction, taken on a daily average. This method allows for the detection of a a small change in the bed material average diameter with a suitable amount of time for the operator to make the decision to add fresh sand to the boiler before there is a subsequent formation of further agglomeration, slagging, or possibly complete defluidization.

Figure 5 illustrates the main elemental composition in g/kg TS of the bed material samples over the week in question. Because the ash melts are coating the sand particles it is reasonable that the main composition comes from silica, with an average value of 301 g/kg TS. However, a portion of the silica could come from glass fines in the fuel mix, but this value is unknown. It should also be noted that all of these elements, as stated before, are predominant ash forming elements. Therefore, it can be quantified that the agglomeration of the sand has occurred due to either ash melting or ash coating.

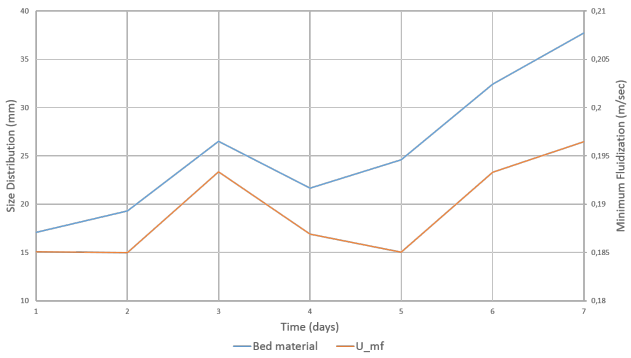

Figure 4. Bed Material Size Distribution $0.4 < d_p < 0.63$ mm Correlates to the Minimum Fluidization.

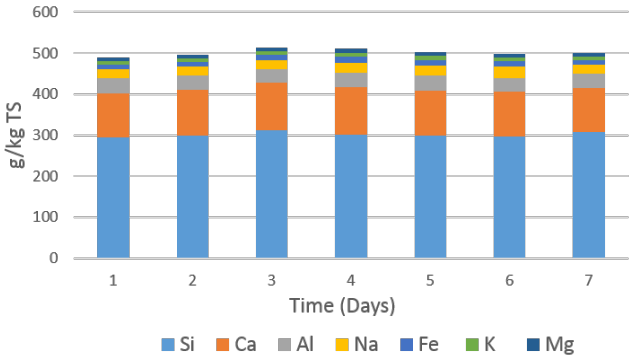

Figure 5. Primary elemental composition of the bed material during the study period.

5 Conclusions

The model presented shows the ability to determine the agglomeration of bed material while off-line. This has been accomplished by building a dynamic model using process parameters as input to model and calculate the minimum fluidization velocity required to maintain a boiler operating temperature within the range of 750 °C and 900 °C. It should be noted that during the seven days there were periods where the fluegas temperature dropped below 750 °C and can be attributed to the possibility of poor fuel. The simulated results show that an increase in minimum fluidization velocity corresponds to an increase in bed material share that is greater than the average diameter of the sand used, $0.40 < d_p < 0.63$. Since agglomeration is prevalent no mater what the fuel source is, it is possible to implement this model as a means for real-time detection of agglomerate formation as a means for decision support to operators.

Compared to other CFB models. The library developed in this study can potentially be reused for any CFB installation through the ease of the drag-and-drop nature of object-oriented programming. The model presented has the ability to handle the transient behavior of RDF, not only for modeling agglomeration, but to also capture the dynamics of the temperature fluctuation in the boiler, hence the possibility for real-time emissions monitoring. Decision support and fault detection can also be implemented by formulating a probabilistic distribution through Bayesian nets. Only one model is needed to monitor multiple aspects of the combustion process in CFBs.

Acknowledgment

The author would like to thank Linda Svensson, Allmyr Marianne, and Lisa Granström for their assistance in data acquisition and process information on block 6 at Mälarenergi, Västerås. The authors would also like to thank Erik Dahlquist at Mälardalen University for his leadership and guidance. Funding for this work comes from The PolyPo Project within the Future Energy Research Profile at Mälardalen University.

Nomenclature

Acronyms

CFB	circulating fluidized bed
RDF	Refuse derived fuel

Greek Symbols

ε_{mf}	Void fraction at minimum fluidization
μ	Viscosity, $\frac{kg}{ms}$
ϕ	Sphericity
ρ	density, $\frac{kg}{m^3}$

Roman Symbols

Ar	Archimedes number, $\frac{\rho_p(\rho_p-\rho_g)gd_p^3}{\mu^2}$
Cp	Specific heat, $\frac{kJ}{kgK}$
d_p	Particle diameter, m
g	Gravity, $\frac{m}{s^2}$
G_s	Net solid flux, $\frac{kg}{m_s^2}$
H	Enthalpy, $\frac{kJ}{kg}$
h	Height of the freeboard, m
m	mass, kg
Q	Heat released, KW
T	Temperature, K
U_{mf}	Minimum fluidization velocity, $\frac{m}{s}$
U_s	Superficial Velocity, $\frac{m}{s}$

Subscripts

g	Gas
i	Corresponding control volume
p	Particle
ref	Reference temperature, ambient

Abstract

Renewable resources such as solar and wind are most commonly connected to a utility grid through inverters. The stability and system characteristics of such systems can be defined by the ratio of grid impedance to the inverter output impedance. Since the impedances vary over time with numerous operation conditions, real-time measurements are required to verify the stability. The impedance measurement technique based on maximum-length-binary-sequence (MLBS) injection and Fourier techniques has been proven to be an efficient option for online analysis of grid-connected systems. This paper shows how a hardware-in-the-loop simulation based on dSPACE can be implemented for stability analysis of a grid-connected inverter using the MLBS injection. The method makes it possible to modify the inverter control characteristics and grid conditions online, thereby providing means for various stability and control design studies for grid-connected systems. We have presented a measurement example based on a three-phase grid-connected inverter and used this example to demonstrate the implementation.

Keywords: frequency response, power system measurements, spectral analysis, signal design, real-time systems

1 Introduction

The most common way to connect renewable resources such as wind turbines or photovoltaic generators to a power grid is through inverters. As the penetration of the inverter-connected systems increases, it has globally important effect on the grid's performance. Consequently, interaction issues between the grid-parallel inverters and power grids have been topics of extensive research in recent years (Cespedes and Sun, 2014b; Lu et al., 2015; Hu et al., 2015). One of the most important topics has been the harmonic resonance generated due to the mismatch between the inverter's output impedance and grid impedance. This is commonly known as the harmonics-related power-quality problem, which has had a significant effect on overall energy efficiency and even grid stability (Sun, 2011). Recent studies have shown that the instability can be avoided by measuring the impedances of the grid and inverter, and based on the measurements, adaptively changing the inverter parameters (Cespedes and Sun, 2014a).

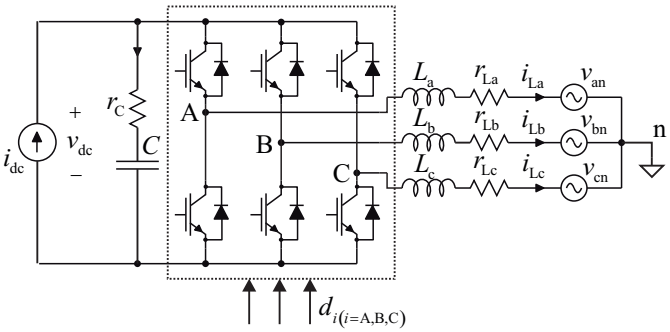

Figure 1. Grid-connected renewable energy inverter.

The impedance measurements of grid-connected systems using a broadband excitation and Fourier techniques have become a popular method in recent years (Barkley and Santi, 2009; Cespedes and Sun, 2014a; Roinila et al., 2013). This method involves injecting an external current on top of the normal output current of the inverter or grid, measuring the resulting voltage responses, and applying Fourier analysis to extract the frequency components in both the voltage and current. The grid or inverter impedance is then determined by the ratio between the voltage and current at different frequencies. The most common excitation types have been impulse (Cespedes and Sun, 2014a) and maximum-length binary sequence (MLBS) (Roinila et al., 2014), from which the MLBS has shown superiority over the impulse. The MLBS is a deterministic and periodic signal. Hence, the effect of external noise can be computationally reduced, and multiple periods can be applied through spectral averaging to further increase the signal-to-noise ratio (SNR). As a result, the amplitude of the excitation can be kept at a much lower level than the amplitude of many other types of excitations. Due to the binary form of the MLBS, the injection is extremely easy to implement, even with a low-cost application, the output of which can only cope with a small number of signal levels.

This paper considers real-time impedance measurements of a grid-connected system using hardware-in-the-loop (HIL) simulation based on dSPACE software

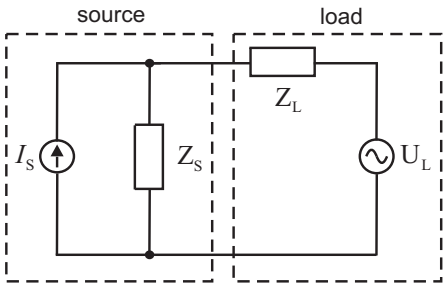

Figure 2. Interconnected source-load subsystem.

and Matlab/Simulink. dSPACE is widely used in real-time analysis and control of various power-electronics applications including three-phase grid-connected systems (Ghani et al., 2009), digitally controlled power converters (Monti et al., 2003), and back-to-back converters (Deshpande et al., 2012). Matlab/Simulink provides a functionality that generates a C-code from the Simulink model. Using dSPACE's real-time interface (RTI), the C-code can be automatically implemented into the I/O board of dSPACE. This method makes it possible to modify the grid characteristics and the inverter's controller parameters online, which in turn enables various stability and control design studies for grid-connected systems in time-varying conditions.

This paper will show the implementation of a real-time impedance measurement of a grid-connected system using dSPACE. No external signal generator or data-acquisition units are required; the signal generation, injection and computations are all performed in dSPACE. We show the implementation steps, starting from generating the MLBS. As the paper does not consider dSPACE in detail, the reader should have a basic knowledge of the software.

The remainder of this paper is organized as follows. Section 2 briefly reviews the theory behind the stability analysis of grid-connected systems and the synthesis of the MLBS. Section 3 gives an example of a grid-connected system operated by dSPACE, and provides guidelines for generating the MLBS and obtaining the system characterizing responses. Section 4 draws conclusions.

2 Theory

2.1 Stability of Grid-Connected System

Figure 1 depicts a three-phase inverter for direct interfacing of a photovoltaic generator. The inverter is comprised of six power electronic switches, a DC capacitor, and threephase inductors. The inverter controls its switches between conducting and non-conducting mode with sinusoidal control voltages in order to transform DC from the renewable energy source into the three-phase AC required by the power grid.

The stability of a inverter-connected system can be easily assessed in the frequency domain by constructing a small-signal state-space representation for the interfacing inverter and the load subsystem. The stability analysis can

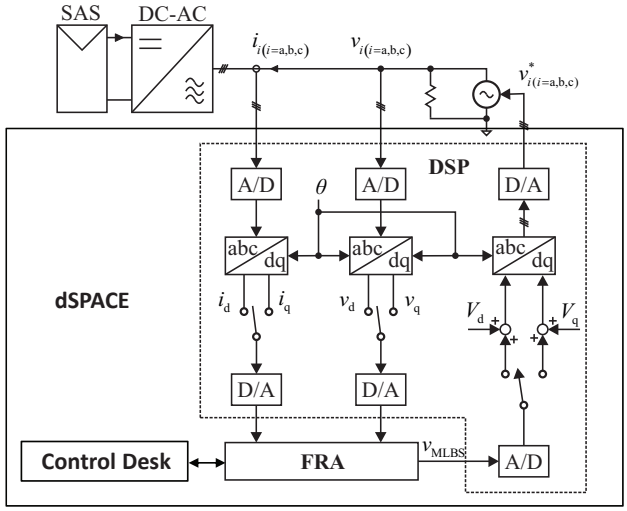

Figure 3. Circuit diagram of three-phase grid-connected inverter connected to real-time spectrum analyzer based on MLBS.

be conducted by applying the Nyquist stability criterion to the impedance ratio in an interface (Wang et al., 2014).

Figure 2 shows a simple example of a single-phase system in which the system consists of one source powering a single load. The source is modeled by a Norton equivalent circuit, as a current source I_S in parallel with the source impedance Z_S. The load voltage is denoted by U_L and the load impedance by Z_L. This combination applies for a grid-parallel inverter in which the grid acts as a voltage-type load and the inverter resembles a controlled current source. Assuming that the source is stable when unloaded and that the load is stable when powered by an ideal source, the stability and other dynamic characteristics of the interconnected system can be determined from the transfer function

$$G(s) = \frac{1}{1 + Z_L(s)/Z_S(s)} \tag{1}$$

The interconnected system is only stable if the impedance ratio $Z_L(s)/Z_S(s)$ satisfies the Nyquist stability criterion. Power systems that are more complex can be represented in the same form and analyzed similarly by putting together multiple sources into a source subsystem and loads into a load subsystem. In general, a grid-connected inverter does not suffer from resonance phenomena caused by impedance-based interactions if the output impedance of the inverter is shaped so that it has a larger magnitude than grid impedance at every frequency.

Three-phase inverters can be modeled in the DQ domain by using direct (d) and quadrature (q) components (Yazdani and Iravani, 2010). The output impedance can be represented in the matrix form shown in (2). The cross-coupling impedances Z_{qd} and Z_{dq} can usually be neglected in stability analysis because they are typically very small in magnitude. Analogous to single-phase systems, the stability of a three-phase system can be determined from the transfer functions in (3) and (4) by applying the Nyquist

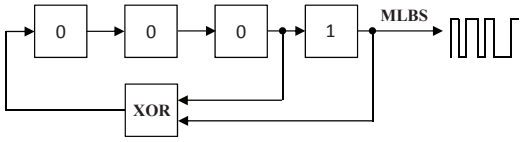

Figure 4. Shift register with XOR and feedback.

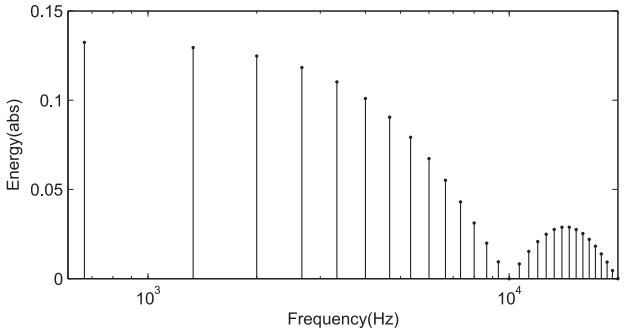

Figure 5. Power spectrum of 15-bit-length MLBS generated at 10 kHz.

stability criterion. Both impedance ratios have to satisfy this criterion for stable operation.

$$\mathbf{Z}_{\mathrm{S}} = \begin{bmatrix} Z_{\mathrm{d}} & Z_{\mathrm{qd}} \\ Z_{\mathrm{dq}} & Z_{\mathrm{q}} \end{bmatrix} \tag{2}$$

$$G_{\mathrm{d}}(s) = \frac{1}{1 + Z_{\mathrm{L}}(s)/Z_{\mathrm{d}}(s)} \tag{3}$$

$$G_{\mathrm{q}}(s) = \frac{1}{1 + Z_{\mathrm{L}}(s)/Z_{\mathrm{q}}(s)} \tag{4}$$

2.2 Maximum-Length Binary Sequence

Pseudo-random binary sequence (PRBS) is a periodic broadband signal based on a sequence of length N. The most commonly used signals are based on maximumlength sequences (MLBS). Such sequences exist for $N = 2^n - 1$, where n is an integer. These are popular because they can be generated using feedback shift-register circuits. (Godfrey, 1993)

Figure 4 shows an example of a shift-register circuit for generating an MLBS of a length $2^4 - 1 = 15$. The feedback is generated from stages 3 and 4. The register can be started with any number other than 0,0,0,0. In practice, the values 0 and 1 are mapped to -1 and +1 to produce a symmetrical MLBS with an average close to zero.

Figure 5 shows the form of the power spectrum of the MLBS generated by the shift register shown in Figure 4. The sequence is generated at 10 kHz and has signal levels ± 1 V. The power spectrum has an envelope and drops to zero at the generation frequency and its harmonics. The MLBS x has the lowest possible peak factor $|x|_{\mathrm{peak}}/x_{\mathrm{rms}} = 1$ regardless of its length, which means that the sequence is well suited to sensitive systems that require small-amplitude perturbation. .

Due to the deterministic nature of the sequence, the signal can be repeated and injected precisely and the SNR can be increased by synchronous averaging of the response periods.

3 Implementation in dSPACE

This section provides the main steps and guidelines for the frequency-response-measurement procedure using dSPACE. The steps are shown through an example in which the output impedance is measured from a threephase grid-connected inverter.

3.1 System Setup

Figure 3 shows the setup of the system under study. The goal is to measure the d- and q-components of inverter's output impedance. A similar approach can be used to measure the grid impedance or any other system-characterizing frequency response, but the example only considers the output-impedance measurement. The system comprises the power stage and real-time frequency-response analyzer (FRA) based on the MLBS injection. The powerstage components are the photovoltaic generator, the inverter, and the three-phase grid emulator. The details of the power-stage components are omitted because they are not within the scope of this paper.

The MLBS is implemented in dSPACE and runs parallel with the inverter control functions. The "Control Desk"-block in Figure 3 depicts a PC, which is used to modify the MLBS parameters such as the length of the injected signal and its amplitude. The MLBS is injected to the d- or q-component of the grid reference voltage. The perturbed three-phase currents and voltages of the inverter are transformed into their corresponding d- and q-components and collected by the FRA.

The measurements of the d- and q-components of the impedance require two separate measurement cycles; one for injecting and collecting d-components and one for q-components. It should be emphasized that various transfer functions can be measured without disconnecting the system. The possible variables can be defined in dSPACE and can be switched in the "Control Desk" -block. For example, the effect of different control loops on a specific transfer function can easily be analyzed online.

Figure 6 is a diagram of the real-time spectrum analyzer including the generation of the MLBS, the sequence injection, and data collection. All the rectangular boxes denote the Simulink blocks that are used for dSPACE. The shift register is implemented by unit-delay blocks. The output of exclusive-or (XOR) replaces the first bit of the sequence through feedback. The generation frequency of the injection is set by the delay value of the unit-delay blocks.

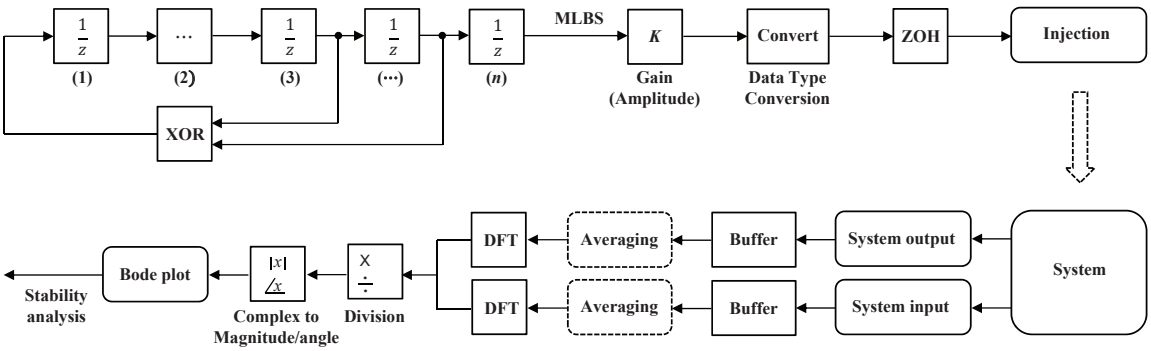

Figure 6. Diagram of the excitation generation, injection and data collection.

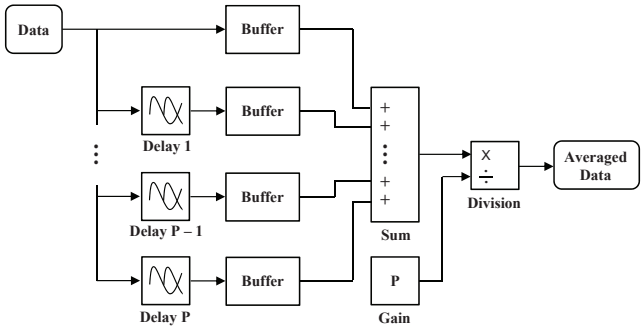

Figure 7. Diagram of the averaging procedure of measured data.

The MLBS is amplified by an adjustable gain (K), after which the sequence is converted from logical numbers to realworld numbers. The zeroorder-hold block is required by dSPACE. The presented concept allows continuous and repeating generation and injection of the MLBS into the system.

The presented implementation also makes it possible to change the injection amplitude in real time. Hence, depending on the noise level and nonlinearities, the amplitude can be experimentally adjusted so that the produced injection energy is high enough. The injection amplitude cannot be too high because the grid-connected systems are typically highly sensitive to external signals and nonlin-earities may easily arise.

The measurements of input and output data are continuously collected and buffered. Once the data is buffered a DFT matrix is applied to perform the Fourier transform (Sundararajan, 2001). The reason for the use of the DFT matrix is that the length of the buffered data is $2^n - 1$ (length of the MLBS). A readily available FFT-block could be used but the block only accepts a data sequence of length 2^n. Therefore, the fast Fourier transform is not applied in the implementation.

The Fourier transformed output data is divided by the input data resulting in the complex transfer function. The Bode plot is obtained by computing the magnitude and phase from the complex data. The refresh rate of the Bode plot is $2^n/f_\mathrm{s}$, where n is the length of the shift register and f_s is the sampling frequency.

The effect of external noise can be reduced by applying averaging. Figure 7 shows the diagram for moving average. Input and output data are delayed by $i \cdot f_\mathrm{s} 2^n$, where $i = 1, 2, \ldots, P$ where P denotes the number of injection periods.

3.2 Experiment

The applied MLBS injection is generated through a 7-bit-length shift register, resulting in an 127-bit-long sequence. The sampling frequency f_s and injection generation frequency f_g are set to 8 kHz and 4 kHz, respectively. Using the specified values for injection length and generation frequency, the frequency resolution is fixed to $f_\mathrm{g}/2^n = 4\mathrm{kHz}/127 \approx 31\mathrm{Hz}$. The measurement system is built in Matlab/Simulink as shown in Figure 6, after which the model is transferred to dSPACE as C-code.

Figs. 8 and 9 show a sample measurement of the d- and q-components of the inverter's output impedance. The curves are averaged over 12 injection periods. Hence, the time for one measurement cycle took approximately 0.38 s. Because a moving average was applied (Figure 7), a new Bode plot was obtained after each injection period. Therefore, the refresh rate of the Bode plot was approximately 31 Hz. The reference responses are obtained by sine sweeps. Due to long measurement time of the sine-sweep technique (approximately 10 min in the application), the method cannot be applied in practice. The figure shows that the results obtained by the MLBS accurately follow the reference, showing only a few decibels and degrees of error. No external data-acquisition devices were used in the experiment. The signal generation, injection and computations were all performed in dSPACE.

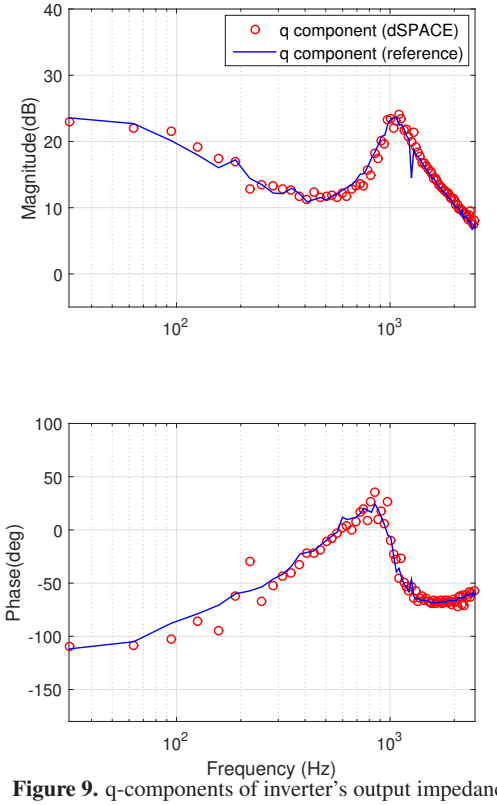

Figure 9. q-components of inverter's output impedance.

4 Conclusions

This paper has presented methods for real-time stability analysis of grid-connected systems using hardware-in-the-loop simulation based on dSPACE and Matlab/Simulink. The MLBS broadband injection was used to measure the output impedance of a three-phase grid-connected inverter. Due to the low peak factor, the amplitude of the injection can be kept relatively small compared to other types of excitations, thereby guaranteeing normal system operation during the identification. Other advantages include straightforward generation of the sequence.

A dSPACE implementation for generating the injection and data acquisition was shown. The proposed methods allow continuous monitoring of system performance and real-time adjustments of the injection properties. The method also makes it possible to modify the inverter control characteristics and grid conditions online, which provides means for analysis under time-varying conditions. Due to fast injection and measurement time, the presentedmethod is useful for various on-line and real-time measurements in, for example, adaptive control of three-phase inverters, and stability analysis of grid-connected systems.

Semi-Discrete Scheme for the Solution of Flow in River Tinnelva

Susantha Dissanayake Roshan Sharma Bernt Lie

Department of Electrical Engineering, IT, and Cybernetics, University College of Southeast Norway, Porsgrunn, Norway, {roshan.sharma, bernt.lie}@usn.no

Abstract

The Saint-Venant equation is a mathematical model which could be used to study water flow in an open channel, river, etc. The Kurganov-Petrova (KP) method, which is a second-order scheme, is used to solve the Saint-Venant equations with good stability. The water flow of a river between two hydropower stations in Norway has been simulated in this study using MATLAB and OpenModelica. The KP scheme has been used to discretize the Saint-Venant equations in the spatial domain, yielding a collection of Ordinary Differential Equations (ODEs). These are then integrated with time using the variable step-length solvers in MATLAB: ode23t, ode23s, ode45, and fixed step-length solvers: The Euler method, the second and fourth order Runge Kutta method (RK2 and RK4). In OpenModelica built-in, variable step-length DASSL solver has been used. From the simulation, it was observed that all solvers produce more or less similar results. Volumetric flowrate calculation indicated numerical oscillation with variable step-length solvers in MATLAB. The results indicated that it is reasonable to match the order of space and time discretization.

Keywords: semi-discrete KP scheme, OpenModelica, MATLAB

1 Introduction

By the year 2020, the 20-20-20 goal is to be achieved within the European Union: 20% efficiency in the improvement of power utilization, 20% reduction of carbon dioxide emission and 20% increment of renewable sources in the total energy mix (Blindheim, 2015). Subsequently, the utilization of renewable energy sources such as wind, hydro, and solar have to be optimized. Hydropower is a source of kinetic energy, which is extracted from flowing water. It is one of the mature renewable energy technologies in the current energy sector.

Norway is prominent in the production of hydropower as one of the renewable energy sources (Blindheim, 2015). Even though reservoir based power production technologies are well developed, power generation based on run-of-river systems are also common. As several hydropower stations are installed at different locations along the same river length, water flow between different hydropower stations influence their operations. When the upstream station (first station) increases its power production, volumetric flow of water out from the first station increases, thus the downstream power station (second station) has to increase the power production in order to utilize the water resource efficiently (Vytvytskyi et al., 2015).

Hence, it is vital to have an understanding of the propagation of the water flow from one station to the other, the change of water level at the second dam, the speed of the wave that hits the second dam, etc. Water flow modeling is also useful in other areas, e.g., managing water resources efficiently in agriculture, manage municipal drinking water distribution system and other applications in addition to power generation.

In this study, the flow of water in river Tinnelva in Southeast Norway between two hydropower stations are being considered. One power station is located at Årlifoss, and the other station is located at Grønvollfoss (downstream). The aim is to study the use of a semi-discrete scheme for the solution of flow in river Tinnelva. Objectives are to find an accurate and robust scheme for use in the control algorithm.

The paper is arranged as follows. The basic introduction to the governing equation and computational fluid dynamics (CFD) will be given in Section 2. Introduction to the KP numerical scheme will be provided in Section 3. Section 4 focuses on computer simulation. The Saint-Venant equation and the Kurganov-Petrova (KP) scheme as numerical scheme were used in simulation in order to compute final water level at Grønvollfoss dam. MATLAB and OpenModelica are being used as simulation software, and both built-in, variable step-length solvers and fixed step-length solvers are being used for the time integration. Parameters, assumptions, simplifications of the complex river system are also introduced in Section 4. Simulation results will be discussed in Section 5 together with numerical stability analysis.

2 Governing Equation for Flow Modeling

Conservation of properties of fluid flow, such as mass, energy, and momentum equations are important principles in fluid dynamics (Versteeg and Malalasekera, 2007). For the study of wave propagation, water flow, tsunami, etc. mathematical models have been derived based on the continuity equation and the momentum balance (Fayssal et al., 2015).

The Saint-Venant equation or commonly known as the 1-Dimensional (1D) shallow water equation, is used for

decades for simulation of water flow in open channels, rivers, etc. (Benkhaldoun et al., 2015). Basic conservation laws, such as momentum and mass conservation provide the base for the Saint-Venant equation which has been derived by integrating the momentum equation over the vertical coordinate (Benkhaldoun et al., 2015). This model provides stable solutions even at hydraulic jumps. The Saint-Venant equation can be posed as follows (Sharma, 2015).

$$\frac{\partial U}{\partial t}+\frac{\partial F}{\partial x}=S \tag{1}$$

where U vector is the vector of conserved variables

$$U=(A,Q)^T \tag{2}$$

F is the vector of fluxes

$$F=\left(Q,\frac{Q^2}{A}+gI_1\cos(\phi)\right)^T \tag{3}$$

and S is the source term

$$U=(z,q)^T, \tag{4}$$

$$F=\left(q,\frac{q^2}{z-B}+\frac{g}{2}(z-B)^2\right)^T, \tag{5}$$

$$S=\left(0,-g(z-B)\frac{\partial B}{\partial x}+\frac{gn^2q|q|(w+2(z-B))^{\frac{4}{3}}}{w^{\frac{4}{3}}}\frac{1}{(z-B)^{\frac{7}{3}}}\right). \tag{6}$$

Here, z is the water level above a datum, B is the bottom elevation from the datum, q is volumetric flow rate per unit width, w is the width of the river, n is Mannings roughness coefficient, and g is acceleration due to gravity. The S terms reflect source terms: including expressions of friction which give resistance against flow.

3 KP Numerical Scheme

In computational Fluid Dynamics (CFD), The Finite Volume Method (FVM) is based on averaging the Control Volume (CV) (Kurganov and Tadmor, 2000). As FVM average each CVs, discontinuities may occur at CV interfaces. This problem was recognized as the Riemann problem (Kurganov and Levy, 2002). In order to handle the Riemann problem, the Riemann solvers were developed (Kurganov and Tadmor, 2000). However, by the emerging of computer-based complex calculations, fast convergence with higher accuracy has to be accomplished. Subsequently, several novel techniques that could eliminate Riemann solvers were developed. The KP scheme was one of the developments which could handle discontinuities at CV interfaces without the Riemann solvers (Kurganov and Tadmor, 2000). The KP scheme is semi-discrete in nature: discretization in space and Ordinary Differential Equation (ODE) solvers in MATLAB and OpenModelica can be used to solve the resulting differential algebraic equations.

Kurganov and Petrova have developed a new scheme which could be considered as an extension/further development of the Nessyahu-Tadmor (NT) scheme (Kurganov and Tadmor, 2000). The NT scheme was developed to average the CV value by using the non-smooth Riemann fans over a fixed length $\triangle x$ (Nessyahu and Tadmor, 1990). In the KP scheme development, instead of averaging the non-smooth parts of the Riemann fans, precise local velocities of wave propagation have been considered along with small CVs of variable size (Kurganov and Tadmor, 2000). When the CV interface has discontinuities, a staggered CV concept can be introduced to eliminate the problem (LeVeque, 1999). During the transient, the local velocities are usually different at each side of a CV interface. Therefore, altered staggering at both sides of the CV is reasonable. Thus, the size of the virtual CVs are defined for a small time ($\triangle t$) by considering the local velocity of wave propagation. For each non-uniform CVs, a piecewise linear reconstruction has been done over the solution domain. Later the linear reconstructed values have been projected to the original uniform CVs while assuming the limits $\triangle t \to 0$ (Kurganov and Tadmor, 2000).

In the KP scheme, properties are indexed by a plus (+) and minus (-) with reference to the direction of the property flux. The local speed of discontinuity propagation has been calculated by considering the Jacobi matrix of the governing equations. In order to achieve higher resolution and a well-balanced scheme, the Total Variant Diminishing (TVD) concept together with the flux limiter concept has been used. The standard *minmod* limiter has been used in the original development of the KP scheme; many alternative flux limiters can be used just as well (Kurganov and Tadmor, 2000).

The KP scheme does not use the Riemann solvers. Hence, computational time can be reduced. Numerical viscosity with the KP scheme is lower compared to the NT scheme (Kurganov and Tadmor, 2000).

The KP scheme discretizes the Saint-Venant equation spatially, yielding a collection of ODEs in time. These ODEs can be written as follows,

$$\frac{d}{dt}\bar{u}_j=-\frac{H_{j+\frac{1}{2}}(t)-H_{j-\frac{1}{2}}(t)}{\triangle x}, \tag{7}$$

where $\bar{u}_j$ is the cell center average values, $H_{j\pm\frac{1}{2}}(t)$ are the central upwind numerical fluxes at the cell interfaces, defined as:

$$H_{j+\frac{1}{2}}(t)=\frac{a^+_{j+\frac{1}{2}}F\left(u^-_{j+\frac{1}{2}},B_{j+\frac{1}{2}}\right)-a^-_{j+\frac{1}{2}}F\left(u^+_{j+\frac{1}{2}},B_{j+\frac{1}{2}}\right)}{a^+_{j+\frac{1}{2}}-a^-_{j+\frac{1}{2}}}+\frac{a^+_{j+\frac{1}{2}}a^-_{j+\frac{1}{2}}}{a^+_{j+\frac{1}{2}}-a^-_{j+\frac{1}{2}}}\left(u^+_{j+\frac{1}{2}}-u^-_{j+\frac{1}{2}}\right), \tag{8}$$

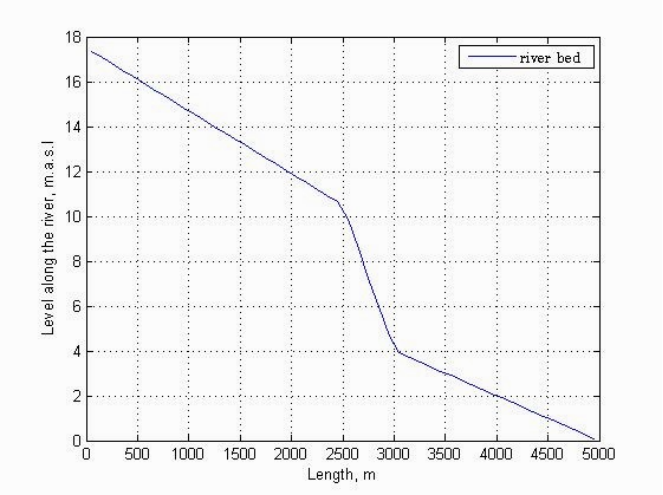

Figure 1. Bottom topography of the river.

$$H_{j-\frac{1}{2}}(t) = \frac{a^+_{j-\frac{1}{2}} F\left(u^-_{j-\frac{1}{2}}, B_{j-\frac{1}{2}}\right) - a^-_{j-\frac{1}{2}} F\left(u^+_{j-\frac{1}{2}}, B_{j-\frac{1}{2}}\right)}{a^+_{j-\frac{1}{2}} - a^-_{j-\frac{1}{2}}} + \frac{a^+_{j-\frac{1}{2}} a^-_{j-\frac{1}{2}}}{a^+_{j-\frac{1}{2}} - a^-_{j-\frac{1}{2}}}\left(u^+_{j-\frac{1}{2}} - u^-_{j-\frac{1}{2}}\right), \quad (9)$$

where $a^{\pm}_{j\pm\frac{1}{2}}$ are the one-sided local speeds of propagation and $u^{\pm}_{j\pm\frac{1}{2}}$ are property fluxes at indexed positions (Sharma 2015).

4 Simulation of the River Flow

In river Tinnelva, two hydropower stations, one at Årlifoss, and the other at Grønvollfoss are being operated by Skagerak Energi. The river reach is 5km in length. In the study, the bottom topography of the river has been divided into three sections of different slope, and the width of the river is assumed to be constant (180 m) during the whole reach of interest. The assumed bottom topography of the river is illustrated in Figure 1. The section from 2.5 km to 3 km has a steeper bed compared to the other sections (Vytvytskyi et al., 2015).

Due to different operational conditions, the volumetric outflow of water at the Årlifoss station is varying. The volumetric flow rates and other quantities are displayed in Table 1.

Other than the spatial discretization done by the KP scheme, time discretization methods in fixed step-length: The Euler method, the second order, and the fourth order Runge Kutta (RK2 and RK4) and the built-in variable step-length solvers: ode solvers in MATLAB (ode23s, ode23t, ode45) and the DASSL solver in OpenModelica, have been used. In addition to the water level computation, the numerical stability of each solver has been analyzed. Here, only for the numerical stability analysis, the variable step-length ode15s solver has been used.

Table 1. Results analysis.

Length	5 km
Number of CV	200
Time steps ($\triangle t$)	0.25 s
Volumetric flow in	120 m^3/s
Volumetric flow out	120 m^3/s
Volumetric flow increased	160 m^3/s
Width of the river	180 m
Initial water level at the dam	17.5 m
Mannings friction factor	0.04 $s/m^{1/3}$
Gravitational constant	9.81 m/s^2

5 Results and Discussion

Results of the simulation study and numerical stability analysis will be discussed in the following sub sections.

5.1 Simulation Results

The built-in variable step-length solvers: ode23t and ode23s have second-order accuracy (Gladwell et al., 2003). Fixed step-length solvers: The Euler method, the RK2 method, and the RK4 method have first order, second order, and fourth order accuracy respectively (Gerald and Wheatley, 2004; LeVeque, 1992). ode45 and ode15s have higher order; higher than a second order of accuracy (Gladwell et al., 2003).

The simulation results using fixed step-length solvers (the Euler method, the RK2 method and the RK4 method) with fixed step length ($\triangle t$ = 0.25 second) show very similar behaviors as shown in Figure 2.

An exploded view of Figure 2 in the time range of 35 min to 37 min is shown in Figure 3. In the exploded view, the Euler method shows some deviation from the other two solutions. However, this deviation is very small.

Both RK2, RK4 and the Euler method algorithms show accuracy up to fourth significant digits in their final solu-

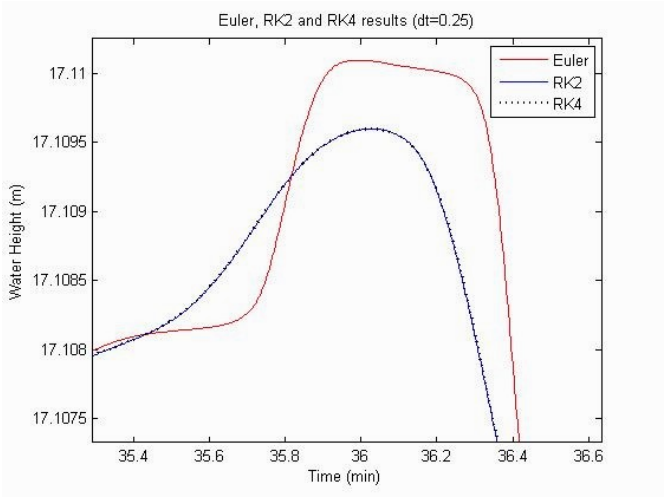

Figure 3. Exploded view of fixed step-length solvers (Euler method, RK2, RK4).

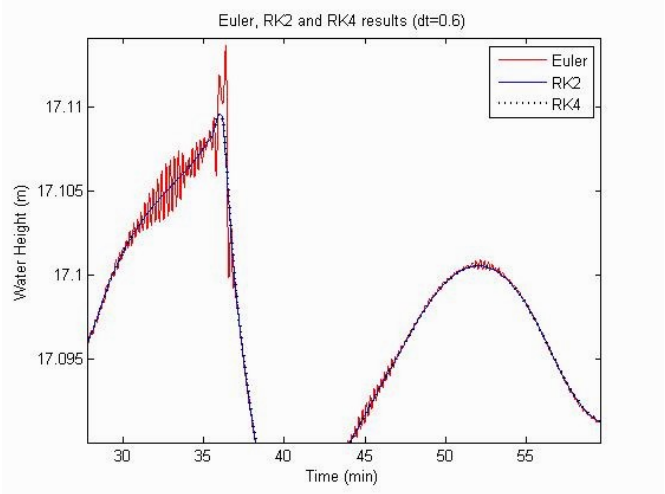

Figure 4. Fixed step-length solvers the Euler method, RK2, RK4 at $\triangle t$ = 0.6 s.

tions.

The solution obtained using the Euler method is highly dependent the choice of the step length; $\triangle t$. When $\triangle t$ is set to 0.6 seconds, the Euler method shows some oscillation in its solution (Figure 4).

With $\triangle t$ set to 0.7 seconds, the solution becomes unstable. While The Euler method shows higher oscillatoric behavior and unstable solutions when $\triangle t$ increases ($\triangle t \geq$ 0.7s) the RK2 and RK4 methods produce stable solutions. However, increment of $\triangle t$ has necessarily to be agreed with the CFL condition (Silvester et al., 2015; LeVeque, 1992) which is commonly written as,

$$C = \frac{u\triangle t}{\triangle x} \leq C_{max} \tag{10}$$

Here C is dimensionless number u refers the magnitude of the velocity, $\triangle x$ refers the length of CV. For the upwind scheme, $C_{max} = 1$ (Silvester et al., 2015).

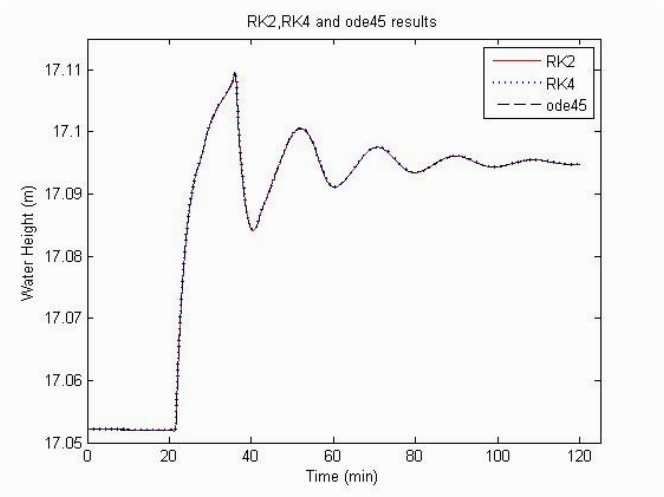

Figure 5. The RK2, RK4 method and ode45 solver results at $\triangle t$ = 0.25 s.

The standard KP scheme is a second order scheme in spatial discretization (Kurganov and Tadmor, 2000). Higher order time integrators: the RK4 method and ode45 were used to solve second order ODEs returned by spatial discretization of the Saint-Venant equation.

The idea was to check whether the higher order time integrators; higher than the second order, have a significant influence on solving second order ODEs more accurately.

According to the observations, both RK2 and the RK4 schemes show very similar solutions. Hence, this denotes that the higher order time integrators have the minor influence on the accuracy when it uses to solve lower order ODEs. The selection of an order of the time discretization that exceeds the order of the spatial discretization does not necessarily produce a more accurate solution (Liu and Tadmor, 1998). Consequently, in order to acquire a reasonably accurate solution, the order of the time discretization should be of either lower or the same order as the order of the spatial discretization.

When comparing variable step-length ode45 solvers in MATLAB with fixed step-length solvers: RK2 and RK4, all solvers produce very similar results (Figure 5). In exploded view (Figure 6), the variable step-length solver ode45 shows some minor oscillatory behavior. Even though the exploded view shows a small deviation, the results of the all three solvers (ode45, RK2, and RK4) compute the end-time water height at the Grønvollfoss dam accurately up to the fourth significant digit.

Results of all fixed step-length solvers: The Euler method, RK2, RK4 and all variable step-length solvers: ode23s, ode23t, ode45 are shown in Figure 7. The computed final water height of each different solver are similar (Figure 7), however, when it considers closely zooming in, it is possible to see minor deviations.

OpenModelica simulation by using the built-in DASSL solver shows a similar pattern compared to the solutions of the MATLAB solvers as shown in Figure 8. Table 2 sum-

marizes other observations of the simulation study. Time consumed by each solver, minimum and maximum time step of variable step-length solvers and steady water level for all solvers are tabulated in the Table 2.

5.2 Simulation Results for Numerical Stability Analysis

In this section, results of numerical stability analysis will be discussed. For ease of comparison, the six solvers, which were used, have been divided into two groups based on their order of the accuracy. Thus, ode23s, ode23t and the RK2 method were classed into group 01, which are of second order in accuracy. The RK4, ode45 and ode15s solvers were classed into the group 02, which are of higher order in accuracy in time discretization than group 01.

The results of the volumetric flow rate calculation for the lower order group (group 01) are plotted in Figure 9. From the observations, the ode23s and ode23t solvers show higher oscillation in volumetric flow rate calculations than RK2.

For the results of the group 02 solvers, Figure 10, it can be clearly seen, that the oscillatory nature increases with increasing order of the time discretization. The solution using variable step-length ode solvers are more oscillatory compared to the fixed step-length solvers RK4 for the volumetric flowrate calculations. ode45 shows higher oscillation while ode15s show relatively smaller oscillations for the volumetric flow rate calculation.

As a whole, it could be observed that built-in variable step-length ode solvers show a relatively oscillatory nature for the volumetric flow rate calculations.

6 Conclusions

Based on the simulated results, it can be concluded that a higher order in the time discretization than the order in the spatial discretization does not necessarily produce more accurate solutions, consequently, matching orders of both

spatial and time discretization is a good idea. Choice of $\triangle t$ necessarily has to be agreed with the CFL condition in order to achieve convergence with satisfactory accuracy in the final solution. For a selected $\triangle t$, which is higher than 0.7s, the Euler method produces oscillatory solution apart from the chosen $\triangle t$ satisfies the CFL condition. However, the RK2 and RK4 methods are quite stable while the Euler method shows oscillations. The numerical stability analysis indicated that the higher order variable step-length solvers are more oscillatory compared to higher order fixed step-length solvers. Final water height at Grønvollfoss dam is more or less similar with compared to different computations with variable step-length solvers and fixed step-length solvers. Results of the simulation study highly depend on the assumption made prior to simulation. The studied KP scheme has been found to be efficient and robust, and in a form suitable for use in control algorithm.

Simulation of Glycol Processes for CO_2 Dehydration

Lars Erik Øi Birendra Rai

Department of and Process, Energy and Environmental Technology, University College of Southeast Norway, Norway

lars.oi@usn.no

Abstract

Water must be removed from CO_2 prior to transport or storage to avoid corrosion and hydrate formation. Absorption into triethylene glycol (TEG) followed by desorption is the traditional gas dehydration method, and is expected to be the preferred method for large scale CO_2 dehydration. There is no agreement on the level of accepted water content after dehydration, and the specifications vary normally in the range between 5 and 500 ppm (parts per million by volume). In literature, it is claimed that use of solid adsorbents is necessary to reduce the water content to below 30 or 10 ppm. In this work, simulations in Aspen HYSYS demonstrate that it is possible to obtain below 1 ppm water using a traditional glycol dehydration process including an extra stripping column. The models Peng-Robinson (PR) and Twu-Sim-Tassone (TST) with updated parameters in Aspen HYSYS version 8.0 are used. A Drizo process using a stripping gas which is later condensed and recirculated is also simulated, and this process also achieves a water content below 1 ppm in dehydrated CO_2.

Keywords: CO_2, glycol, dehydration, Aspen HYSYS

1 Introduction

CO_2 removed from natural gas or from CO_2 capture should be dehydrated prior to transport or storage. Water may lead to problems like corrosion and hydrate formation. The need for water removal from CO_2 and possible specifications are discussed in several references (Cole et al., 2011; Uilhorn, 2013; Buit, 2011) and water specifications are normally in the range between 5 and 500 ppm (parts per million by volume). CO_2 for enhanced oil recovery normally requires the lowest water content.

There are several different gas dehydration methods available. The most used processes for dehydration are based on absorption, adsorption or membranes. The most traditional method for large scale dehydration to moderate water levels is by absorption into triethylene glycol (TEG). For very low water levels, adsorption processes are claimed to be necessary (Kohl and Nielsen, 1997; Kemper et al., 2014). There are however simulated reasonable processes for glycol dehydration of CO_2 down to water levels below 5 ppm (Øi and Fazlagic, 2014) using stripping gas and an extra stripping column. The Drizo process makes use of a condensable stripping gas which is recirculated and is able to reduce the water content down to 1 ppm (Prosernat, 2016).

A recent study (Kemper et al., 2014) has evaluated different commercial processes for CO_2 dehydration based partially on information from vendors of technology. Processes based on glycol and on solid adsorption were evaluated. It was claimed that use of solid adsorbents is necessary to reduce the water content to below 30 or 10 ppm.

The main purpose of this paper is to present updated simulations of flow-sheet models for CO_2 dehydration by absorption in triethylene glycol. The Peng-Robinson (PR) model and the Twu-Sim-Tassone (TST) model (the glycol package in Aspen HYSYS) are used. In version 8.0, the parameters in the TST model have been updated compared to version 7.2 which was used in earlier work with Aspen HYSYS (Øi and Fazlagic, 2014). Especially, it is an aim to simulate the alternative including an extra stripping column and a Drizo process achieving a water level down to 1 ppm. The simulation results in this work are mainly from a Master Thesis work (Rai, 2016).

2 Simulation Programs and Models for Glycol Dehydration

Commercial process simulation programs which have been used for glycol dehydration are Aspen Plus, Aspen HYSYS, Pro/II and ProMax. Process simulation programs are useful for simulation of absorption processes because complex vapour/liquid equilibrium models are available in the programs and because efficient stage to stage models for absorption and desorption columns are available.

Absorption and distillation columns are traditionally simulated as a sequence of equilibrium stages. The stages can also be specified with a Murphree efficiency. A Murphree efficiency can be defined as the change in mole fraction of a component (in this case water) from the stage below to a given stage, divided by the change if equilibrium was achieved on the given stage (Kohl and Nielsen).

Vapour/liquid equilibrium data in the TEG/water system has been discussed in several papers (Kohl and Nielsen, 1997; Øi and Fazlagic, 2014; Øi, 1999). The vapour/liquid equilibrium between CO_2 and water has also been evaluated (Cole et al., 2011; Austegard, 2006). This equilibrium must be included in a complete model of the TEG/water/CO_2 system. One special challenge for such a model, is to calculate the correct solubility of CO_2 in a TEG/water solution.

In Aspen HYSYS, the equilibrium models PR (Peng and Robinson, 1976) and TST (Twu et al., 2005) are available for glycol dehydration. The TST model is claimed in the Aspen HYSYS program documentation to be the most accurate. This is however based on the assumption of dehydration of natural gas, and it is uncertain whether the TST model is accurate when CO_2 is the dominating gas. The TST model parameters have been updated from earlier versions in the Aspen HYSYS version 8.0 used in this work. The PR model has only one adjustable parameter for each binary component pair while TST has 5 adjustable parameters for each binary pair. In Aspen Plus, PRO/II and ProMax there are also models available recommended for the TEG/water system (Øi and Fazlagic, 2014).

Simulations of the natural gas dehydration process in Aspen HYSYS have been performed with emphasis on glycol regeneration by Øi and Selstø (2002). A traditional TEG dehydration process was simulated using the PR equation of state. A water content of 58 ppm was specified in the dehydrated gas. Different regeneration processes were simulated, e.g. addition of stripping gas to the reboiler and adding stripping gas to an extra stripping column. Bilsbak (2009) used the simulation program Pro/II to simulate TEG dehydration of CO_2 using an equation of state.

Besides the references mentioned in this work, there is very little information found in the open literature about simulation of CO_2 dehydration processes and particularly of CO_2 dehydration based on absorption in glycol.

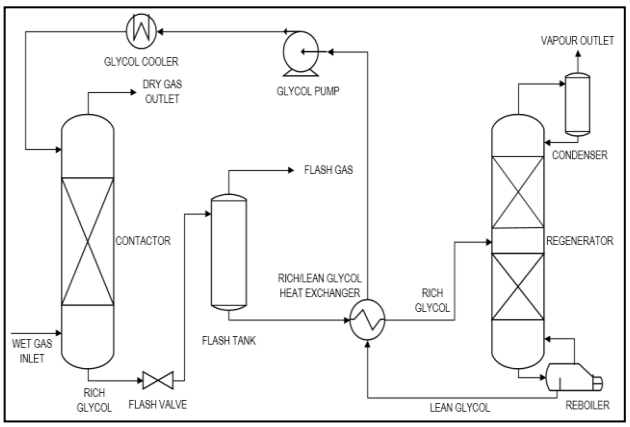

Figure 1. A traditional TEG dehydration process

3 Process Description

A traditional glycol dehydration process is shown in Figure 1. Water is absorbed from a gas into a glycol solution in an absorption column (contactor). The liquid (rich glycol) is then depressurized to a flash tank to evaporate some of the absorbed CO_2. Then the liquid is heated by regenerated glycol in a heat exchanger and sent to a desorber (regenerator). In this column, water is removed from the top and regenerated TEG is removed from the bottom. Heat is added in the reboiler. The regenerated TEG (lean glycol) is pumped through the heat exchanger and a cooler back to the absorber. More detailed process descriptions can be found in e.g. (Kohl and Nielsen, 1997; Øi and Fazlagic, 2014). It is possible to reduce the water content in the glycol by adding stripping gas to the reboiler. The reduction in water content in the glycol will make it possible to improve the dehydration of the CO_2 in the treated gas. The stripping gas can come from the flash gas or from the dehydrated gas. The water content in the glycol can be reduced further by adding an extra stripping column below the reboiler. This is shown in Figure 2.

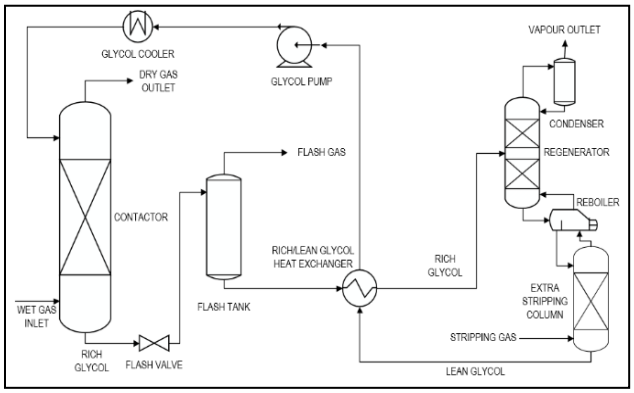

Figure 2. A TEG dehydration process with extra stripping column

There are also different special glycol dehydration processes. One example is the Drizo process (Prosernat, 2016) where the added stripping gas is a condensable component which is condensed after the stripping column and recirculated to the bottom of the stripping column. In earlier work (Øi and Fazlagic, 2014) the possible water content achievable from these processes was calculated using Aspen HYSYS. A traditional process could achieve below 200 ppm. Using stripping gas, less than 50 ppm could be achieved. Adding an extra stripping column below the reboiler could reduce the water content to below 5 ppm.

To achieve very low water content, the height of the absorption column has to be increased compared to a traditional process. The absorption column will contain plates or packing. An expected plate efficiency is order

of magnitude 50 %, and an expected packing efficiency of a packing height of 0.5 meter is also order of magnitude 50 % (Øi, 2003). An increase of the packing height from 10 to 20 stages or order of magnitude from 5 to 10 meters will increase the cost significantly. The extra stripping column will add complexity to the process. The cost for extra height in this column is however small because the diameter is very low.

4 Process Simulation, Results and Discussion

4.1 Simulation of Standard Process

A traditional TEG dehydration process as in Figure 1 has been simulated in the simulation program Aspen HYSYS version 8.0 using the PR equation of state and TST model (the glycol property package). The Aspen HYSYS flow-sheet model for the base case simulation is presented in Figure 4. The specifications for the base case process calculation are given in Table 1. These are similar to the specifications in earlier simulations (Øi and Fazlagic, 2014). The enthalpy setting in Aspen HYSYS was changed to the Cavett model instead of the default property package EOS (equation of state) to avoid unrealistic low temperatures.

Table 1. Specifications for base case simulation

Parameter	Value
Inlet gas temperature	30 °C
Inlet gas pressure	3000 kPa
Inlet gas molar flow rate	501.1 kmol/h
Water in inlet gas	0.23 mol-%
TEG to contactor temperature	35 °C
TEG to contactor pressure	3000 kPa
TEG to contactor, flow (in first iteration)	3.583 kmol/h
Water in lean TEG (in first iteration)	1.04 mass-%
Number of stages in absorber	10
Murphree efficiency in absorber stages	0.5
Pressure after depressurization valve	110 kPa
Temperature in TEG to regeneration	153 °C
Number of stages in desorber	4
Murphree efficiency in desorber stages	1.0
Reflux ratio in desorber	0.5
Reboiler temperature	200 °C
Desorber pressure	101 kPa
Pressure after TEG pump	3000 kPa

Recommendations for a traditional process can be found also in Kohl and Nielsen (1997). The absorption column was simulated with 10 stages and with Murphree efficiency 0.5 on each stage, which is assumed to be equivalent to approximately 10 actual plates or 5 meter of structured packing (Shresta, 2015).

The calculation sequence of the process in the Aspen HYSYS flow-sheet is mostly following the real flow direction. The gas feed stream to the absorber is saturated with water. The liquid feed to the absorber has to be estimated in the first iteration. Then the absorption column and the rest of the process is calculated step by step. The cold side of the main heat exchanger is calculated based on a specified temperature on the stream to the desorber.

Using the base case specifications in Table 1, the water content in dehydrated gas was calculated to 153 ppm with the PR model and 133 ppm with the glycol package using the TST model. Compared to earlier simulations, the results from the PR model were identical. The results using the TST model were lower in water content compared to the earlier results (Øi and Fazlagic, 2014). The differences are expected to be due to updated TST parameters. The deviations between calculated water content from PR and TST are lower in this work. The process was simulated also at other absorption pressures. The results are shown in Figure 3.

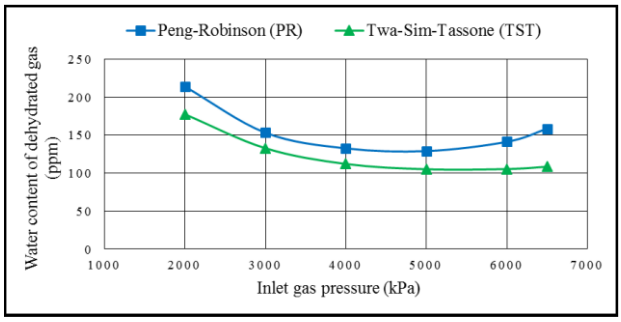

Figure 3. Water content in dehydrated gas as a function of absorption pressure

Both models gave a minimum water content and maximum dehydration efficiency at 5000 kPa. Minimum water content was 129 ppm at 5000 kPa using the PR model and 105 ppm using the TST model. In earlier work Øi and Fazlagic (2014) the TST model gave a minimum water content at 3000 kPa.

The dehydration can be improved by increasing the TEG circulating rate and by increasing the number of absorption stages in the standard process. However, these changes gave only minor improvements in achieved water content in the dehydrated gas.

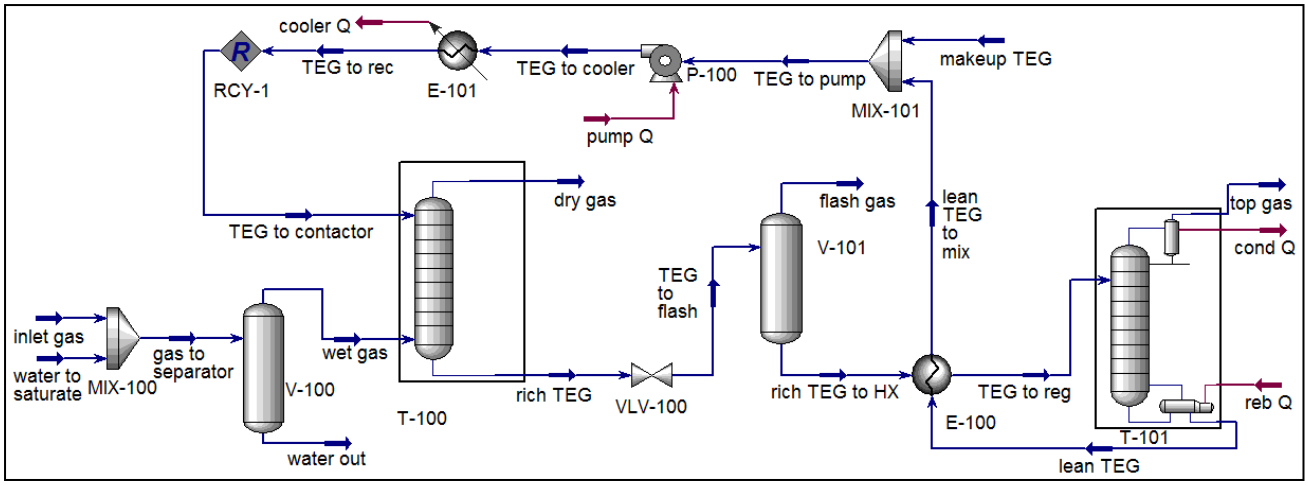

Figure 4. Aspen HYSYS flow-sheet model for traditional TEG dehydration process

4.2 Simulation of Stripping Gas to Reboiler

A process with stripping gas added to the reboiler was simulated. The stripping gas was specified with temperature 190 °C, pressure 101 kPa, 99.17 % CO_2 and 0.83 % water (Øi and Fazlagic, 2014). The composition was similar to the flash gas composition from depressurization after the absorption column in the base case calculation. Figure 5 shows the results from the Aspen HYSYS simulations using the TST model.

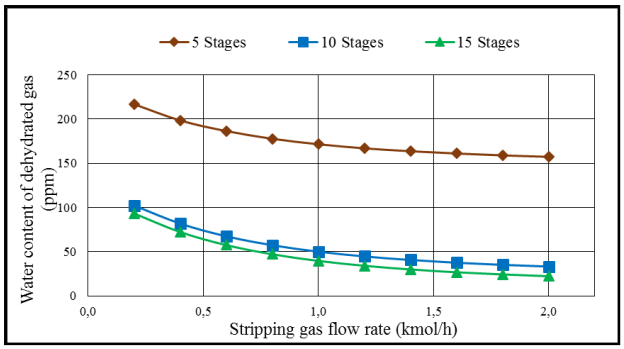

Figure 5. Water content as a function of stripping gas and number of absorber stages with stripping gas to reboiler using the TST model

Calculations comparable to the base case simulations were performed with varying the stripping gas flow and number of stages in the absorption column. Using the TST model, less than 50 ppm was achieved using 10 absorption stages and 1 kmole/h stripping gas. Using 15 stages, it was necessary to use 0.6 kmole/h to achieve less than 50 ppm in the dehydrated gas.

There is some difference in calculated flash gas amount for the two models, 0.89 kmole/h for the PR model and 0.63 kmole/h for the TST model. This indicates that the two models calculate the CO_2 solubility in the TEG/water solution differently. When using the PR model, the water amount for a given stripping gas amount is slightly higher than using the TST model. But because the PR model calculates a higher flash gas amount, the PR model also calculates about 50 ppm when the amount of stripping gas is set to the amount of available flash gas.

Increasing the number of stages and the amount of stripping gas made it possible to improve the dehydration down to about 30 ppm. This was achieved with both the PR and the TST model.

4.3 Simulation of Stripping Gas to Extra Column

A simulation of the process in Figure 2 was performed. In earlier work (Øi and Fazlagic, 2014) this process has been simulated using two strategies. The first strategy was to simulate the process with two columns. The second strategy was to simplify the flow-sheet model by simulating the desorption column and the extra stripping column as one column with heating at an intermediate stage as shown in Figure 6. Similar numerical results have been achieved using these two strategies (Øi and Fazlagic, 2014; Øi and Selstø, 2002). The strategy with only one column was chosen in this work because these simulations are easier to converge.

The extra stripping column was specified with 3 equilibrium stages. In the case of the extra stripping gas and the desorber simulated as one column, it was 3 stages between the stripping gas feed to the bottom and the reboiler heat addition. The number of stages above and below the feed in the desorber and in the extra stripping column have been varied in earlier work (Shresta, 2015). The results showed that increasing the number of stages in the sections above 3 (as specified in this work) did not improve the dehydration efficiency significantly.

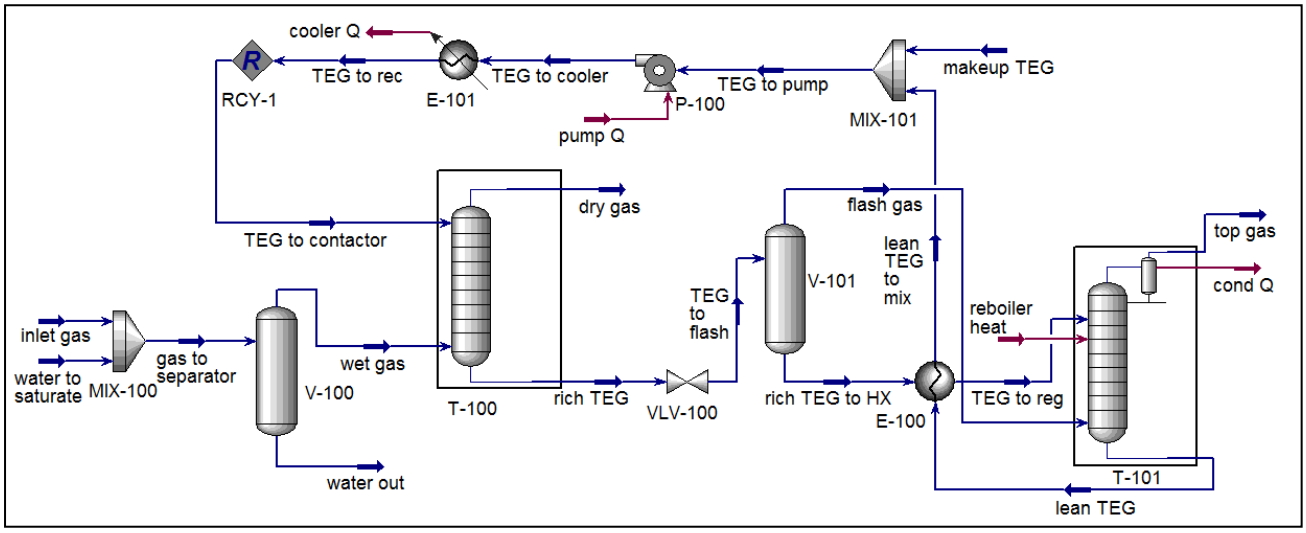

Figure 6. HYSYS flow-sheet of dehydration process with extra stripping column

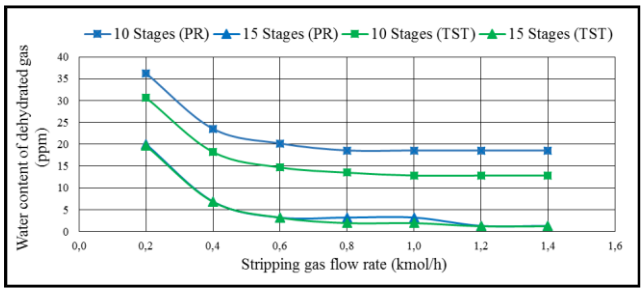

Figure 7. Water content as a function of stripping gas and number of absorber stages with extra stripping column

Figure 7 shows results from these calculations as a function of stripping gas and number of absorber stages for the process with an extra stripping column.

Using 10 absorber stages reduces the water content down to about 20 ppm using the PR model and down to about 15 ppm using the TST model. The water content is not reduced further by adding more stripping gas with 10 absorber stages. With 15 stages or more, less than 5 ppm was achieved using the available flash gas, and less than 2 ppm was achieved by adding more stripping gas. Using more than 15 absorber stages did not improve the dehydration efficiency significantly.

In earlier work (Øi and Fazlagic, 2014) similar results were obtained using 20 absorber stages for the same conditions. With more than 1.2 kmole/h, less than 5 ppm was achieved with both the PR model and the TST model.

At very low water content (below 2 to 5 ppm) the water amount in the stripping gas is a limiting factor. Less than 1 ppm water in dehydrated gas has been calculated when pure (dehydrated) CO_2 was used as stripping gas. This was calculated using 15 absorber stages and a high stripping gas amount with both the PR and the TST model.

4.4 Simulation of a Drizo process

A Drizo process with n-heptane as stripping gas was simulated. The flow-sheet is shown in Figure 8. The condensing of the stripping gas is performed in a three phase separator, and the organic phase is pumped back and evaporated in a heater before it is added to the bottom of the extra stripping column. It was checked that the amount of recirculated n-heptane was approximately equal to the n-heptane added to the desorber in the simulation.

A similar process has been simulated earlier (Øi and Selstø, 2002). An argument for not closing the loop in the simulation of the recirculation of the stripping gas, is that a small fraction of the added stripping gas will be dissolved in the solvent and lost e.g. in the flash gas. This is of minor interest for the evaluation of the process.

The results for n-heptane as a stripping gas using the TST model are presented in Figure 9. Similar results were obtained using the PR model. Similar simulations were also performed with the components benzene and toluene as stripping gas. When using benzene and toluene, more of the stripping gas was dissolved in the glycol, so that the deviation between added stripping gas and recirculated stripping gas became larger.

Similar levels of water were achieved as in the simulations with flash gas or CO_2 as stripping gas. Less than 20 ppm was obtained using 10 absorption stages in the absorber and available flash gas. Less than 5 ppm was obtained with 15 stages and stripping gas amounts similar to the available flash gas and less than 1 ppm when the amount of stripping gas was increased.

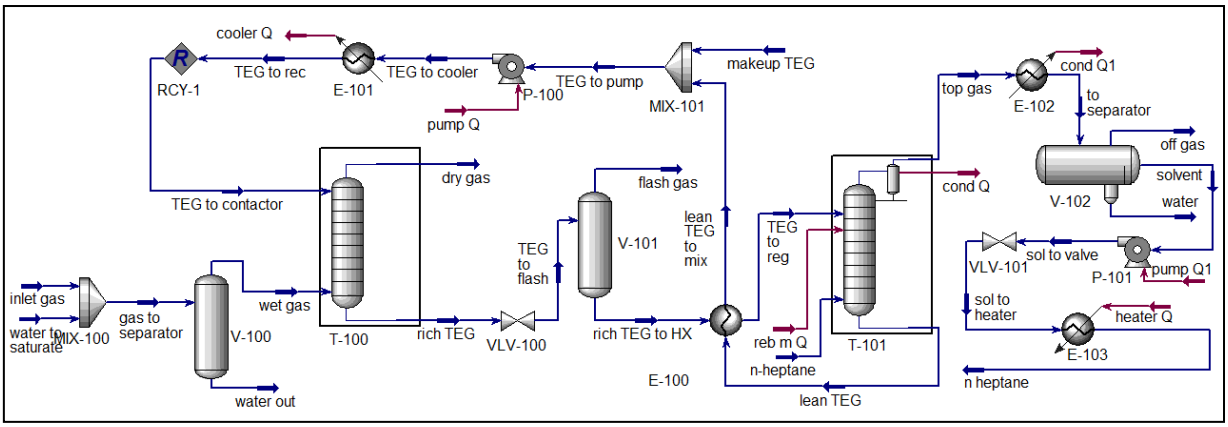

Figure 8. Aspen HYSYS flow-sheet of Drizo process using n-heptane as stripping gas

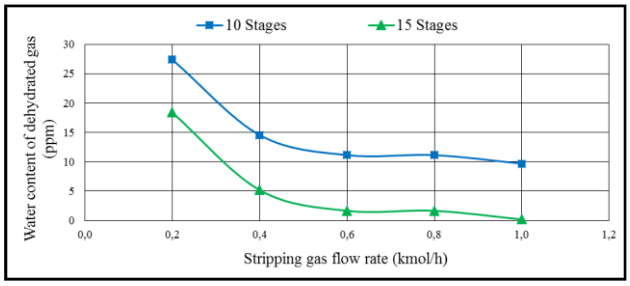

Figure 9. Water content in Drizo process with n-heptane as a function of stripping gas and number of absorber stages using the TST equilibrium model

5 Conclusions

It is demonstrated that it is possible to simulate both a traditional glycol dehydration process and more advanced CO_2 dehydration processes like the Drizo process using the process simulation program Aspen HYSYS. The PR and TST models give similar results for all the simulated alternatives. The calculated water content for different absorption pressures shows that a maximum dehydration efficiency is achieved at a pressure of about 5000 kPa.

A traditional TEG dehydration process is satisfactory to achieve a water content below 150 ppm in dehydrated CO_2. Using stripping gas, a water specification of less than 50 ppm can be achieved. In a Drizo process or a process including an extra stripping column and a high absorption column, it is possible to achieve less than 1 ppm water in dehydrated CO_2.

Abstract

Mixing of two granular phases in a rotary kiln was investigated through CFD simulations using a two-dimensional transverse plane based on the Eulerian approach and the kinetic theory of granular flows. Simulations were performed transverse with the aim to investigate mixing of two particulate solids, $CaCO_3$ and Al_2O_3, under the rolling mode. Simulation results indicated particle segregation rather than mixing during the plane rotation. Volume fractions and velocity contours of each phase were examined to understand the mixing and segregation. Particles with lower density and small particle diameter are collected in the middle section of the bed, while particles with a higher density and larger particle diameter get collected at the bottom of the rotating cylinder. Variations in densities and particle sizes of solid particles were identified as the main causes of the particle segregation. Further studies are required to examine the effect of degree of filling on mixing performance and how the use of lifters may improve the mixing efficiency.

Keywords: rotary kiln, granular flow, rolling mode, active layer, passive layer

1 Introduction

In industry, materials are needed to be processed in various ways to gain the desired quality of the product. Rotary kilns are widely accepted for the pyroprocessing of many types of materials in different industries owing to efficient mixing and heat transfer performances (Liu et al., 2016). Understanding of particles mixing inside the kiln is vital to enhance heat transfer performance within the bed that improvise material conversion rates in pyro processing.

Granular flows of a transverse plane in a rotary kiln can be categorized into six transport modes; slipping, slumping, rolling, cascading, cataracting and centrifuging. Bed motion depends on Froude number, filling degree, wall friction coefficient, ratio of particle to cylinder diameter, angle of internal friction and dynamic angles of repose (Yin et al., 2014). In industrial rotating drums, the rolling or cascading mode is often applied, and the rolling mode is considered optimum for mixing (Demagh et al., 2012; Boateng et al., 2008).

The approach of numerical analysis in multiphase granular flows facilitates understanding of the bed behavior in rotary kilns. CFD simulations can be performed to investigate motions of particles in the bed according to two mathematical models. Both Euler-Lagrange and Euler-Euler models, along with the kinetic theory of granular flow, are used to simulate the bed motion. In the Euler-Lagrange model, the gas phase is treated as a continuum while the solid particles are considered as a discrete phase (Crowe et al., 1998). Trajectories of individual solid particles are calculated to understand the behavior of the kiln bed. The Euler-Euler model considers each phase as a continuum, and continuity and momentum equations for each phase are applied (Valle, 2012).

Both two-dimensional (2D) and three-dimensional (3D) CFD simulations to investigate mixing of one granular phase in a rotary kiln have been reported in the literature. 2D-CFD simulations were done by Liu et al. (2016) to study particle motion and heat transfer in a rotary kiln. The surface particle motion in rotary cylinder was analyzed via a 2D-CFD model to analyze the dynamic characteristics and rheology of a granular viscous flow in a rotary cylinder to validate real cement rotary kiln (Demagh et al., 2012). A three-dimensional study was done by Yin et al. (2014) to understand granular motion during rolling mode in a rotary kiln. The particle residence time and angle of inclination of the rotary kiln were considered in the simulation.

This study focuses on 2D numerical simulations of mixing of two granular phases in a rotating cylinder. Particle motion in a rotating cylinder was considered similar to the bed behavior of the transverse plane in a rotary kiln. The mixing behavior was analyzed considering two granular particle types, of calcium carbonate ($CaCO_3$) and aluminum oxide (Al_2O_3), in rolling mode. A mathematical model based on the Euler-Euler approach and the kinetic theory of granular flow were used to describe the dynamics of particles in the transverse plane. The behavior of $CaCO_3$ and Al_2O_3 was first studied separately, and then mixing of $CaCO_3$ and Al_2O_3 was investigated.

CFD simulations were carried out using ANSYS FLUENT 16.2 and 2D model was developed using ANSYS DesignModeler. The model has the geometrical characteristics of a transverse plane of a rotary kiln.

2 Model Description

2.1 Particle Mixing in a Transverse Plane

The dynamics of the particle bed in a rotating cylinder under rolling mode has been observed by different techniques (Yin et al., 2014). In rolling mode, particles at the top surface of the bed move down continuously while the bottom part moves up showing a plug flow motion. The maximum particle mixing is achieved under rolling mode. Considering the characteristics of the particles movement, the bed motion can be further divided into two regions, an active layer and a passive layer (Boateng et al., 2008). Figure 1 shows a schematic diagram of a kiln operated in rolling mode.

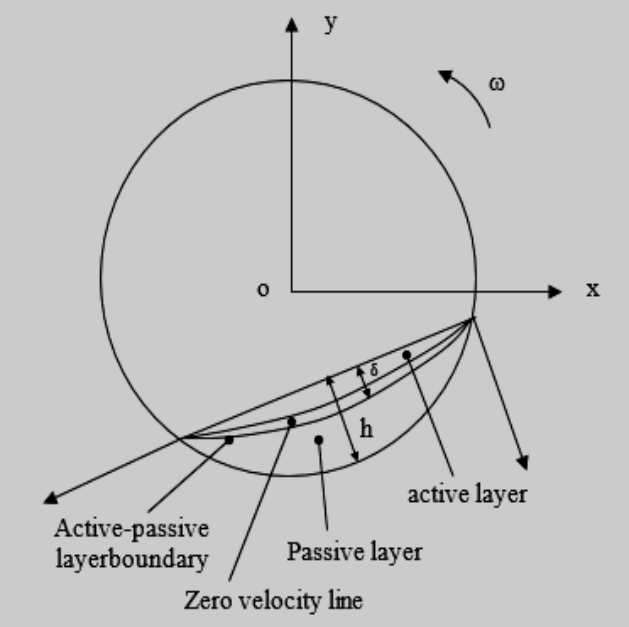

Figure 1. Schematic diagram of a kiln operated in a rolling mode

Here, most of the particle mixing takes place in the active region and mixing in the passive region is negligible. The active layer particle mixing determines the surface renewal rate, which in turn affects the bed-freeboard heat and mass transfer and chemical reactions (Ding et al., 2001). The heat transfer is, however, not included in the present work, which focuses on the particle motion.

2.2 Governing Equation of Two-Fluid Model

2.2.1 Continuity Equations

The continuity equations for the gas phase and the solid phase are as follows:

$$\frac{\partial}{\partial t}\left(\varepsilon_g \rho_g\right)+\nabla\cdot\left(\varepsilon_g \rho_g v_g\right)=0 \tag{1}$$

$$\frac{\partial}{\partial t}\left(\varepsilon_S \rho_S\right)+\nabla\cdot\left(\varepsilon_S \rho_S v_S\right)=0 \tag{2}$$

$$\varepsilon_g+\varepsilon_S=1 \tag{3}$$

Here, ρ is density, v is velocity, ε is volume fraction and t is time. S and g refer to solid phase and gas phase, respectively.

2.2.2 Momentum Equations

Momentum equations describe how the viscous, pressure and gravity forces govern the motion of the gas and the solid particles. The momentum equations for the gas phase and the solid phase are written as:

$$\frac{\partial}{\partial t}\left(\varepsilon_g \rho_g v_g\right)+\nabla\cdot\left(\varepsilon_g \rho_g v_g v_g\right)=-\varepsilon_g \nabla P_g+\varepsilon_g \rho_g g - \beta_{gs}\left(v_g-v_s\right)+\nabla\cdot\left(\varepsilon_g \tau_g\right) \tag{4}$$

$$\frac{\partial}{\partial t}\left(\varepsilon_s \rho_s v_s\right)+\nabla\cdot\left(\varepsilon_s \rho_s v_s v_s\right)=-\varepsilon_s \nabla P_g+\varepsilon_s \rho_s g - \beta_{gs}\left(v_g-v_s\right)+\nabla \tau_s \tag{5}$$

Here P_g , g , β_{gs} and τ_g are the fluid pressure, gravity, drag coefficient between the gaseous and solid phases and viscous stress tensor of the gas phase, respectively.

The viscous stress tensor for the gas phase, τ_g in Eq (4), and for the solid phase, τ_s in Eq (5), are given by the Newtonian form:

$$\tau_g=v_g\left[\nabla v_g+\left(\nabla v_g\right)^T-\frac{2}{3}\mu_g\left(\nabla\cdot v_g\right)\right]I \tag{6}$$

$$\tau_s=\left(-P_s+\zeta_s\nabla\cdot v_s\right)I+\mu_s\left\{\left[\nabla v_s+\left(\nabla v_s\right)^T\right]-\frac{2}{3}\left(\nabla\cdot v_s\right)I\right\} \tag{7}$$

Here P_s , μ_s , ζ_s and I are solid pressure, solid viscosity, solid bulk viscosity and unit tensor, respectively.

Particle-particle collisions create normal forces which are represented by the solid pressure P_s for one solid phase (Benyahia et al., 2000):

$$P_s=\varepsilon_s \rho_s \Theta+2g_0 \rho_s \varepsilon_s^2\left(1+e_p\right)\Theta \tag{8}$$

Here, Θ is the granular temperature (further explained below), g_0 is the radial distribution function and e_p is the particle-particle restitution coefficient.

The bulk viscosity of the solid, ζ_s in Eq (7), is given by (Neri and Gidaspow, 2000):

$$\zeta_s=\frac{4}{3}\varepsilon_s^2 \rho_s d_p g_0\left(1+e_p\right)\sqrt{\frac{\Theta}{\pi}} \tag{9}$$

Here, d_p is the particle diameter.

The solid shear viscosity in Eq (7) is given as (Arastoopour, 2001):

$$\mu_s = \frac{4}{5}\varepsilon_s^2 \rho_s d_p g_0 (1+e_p)\sqrt{\frac{\Theta}{\pi}} + \frac{10\rho_s d_p \sqrt{\pi\Theta}}{96(1+e_p)\varepsilon_s g_0}\left[1+\frac{4}{5}\varepsilon_s g_0 (1+e_p)\right]^2 \quad (10)$$

Wen and Ergun (Huilin and Gidaspow, 2003) proposed that the exchange coefficient β_{gs} between the gas and the solid phase given in Eq (4) and (5) could be calculated by:

$$\beta_{gs}\big|_{Wen\ \&\ Yu} = \frac{3}{4}C_D \frac{\rho_s \varepsilon_s |v_g - v_s|}{d_p}\varepsilon_g^{-2.65} \qquad \varepsilon_g > 0.8 \quad (11)$$

$$\beta_{gs}\big|_{Ergun} = 150\frac{(1-\varepsilon_g)\varepsilon_s \mu_g}{(\varepsilon_g d_p)^2} + 1.75\frac{\rho_g \varepsilon_s |v_g - v_s|}{\varepsilon_s d_p} \qquad \varepsilon_g \le 0.8 \quad (12)$$

The drag coefficient depends on the value of the Reynolds number, Re:

$$\begin{cases} C_D = \dfrac{24}{\mathrm{Re}}\left(1+0.15\,\mathrm{Re}^{0.687}\right) & \mathrm{Re} < 1000 \\ C_D = 0.44 & \mathrm{Re} \ge 1000 \end{cases} \quad (13)$$

$$\mathrm{Re} = \frac{\rho_g \varepsilon_g |v_g - v_s| d_p}{\mu_g} \quad (14)$$

2.2.3 Kinetic Theory of Granular Flow

Granular kinetic theory is extensively used in granular flow modelling to achieve a high level of accuracy of model results to be able to compare with data from the actual system. This theory considers the particle-particle collisions to predict physical properties of the particulate phase. The kinetic theory has been widely used in modelling of fluidized beds to model solid particles in a gas.

A new variable Θ, called the granular temperature, was introduced in this theory. It is a measure of the kinetic energy of the solid. Granular temperature is defined as one-third of the mean square velocity of the random motion of particles $\Theta = v_s'^2/3$, and $v_s'^2$ is the square of the fluctuating velocity of the particle. A transport equation for the granular temperature can be written as (Huilin et al., 2001):

$$\frac{3}{2}\left[\frac{\partial}{\partial t}(\varepsilon_s \rho_s \Theta) + \nabla\cdot(\varepsilon_s \rho_s \Theta) v_s\right] = (\nabla PI + \varepsilon_s \nabla \tau_s) : \nabla v_s + \nabla\cdot(k_s \nabla\Theta) - \gamma_s + \Phi_s + D_{gs} \quad (15)$$

Here, γ_s is dissipation of turbulent kinetic energy, Φ_s is energy exchange between gas and particle and D_{gs} is energy dissipation.

The turbulent kinetic energy dissipation, γ_s in Eq (15), is given as (Neri and Gidaspow, 2000):

$$\gamma_s = 3(1-e_p^2)\varepsilon_s^2 \rho_s g_0 \Theta\left(\frac{4}{d_p}\sqrt{\frac{\Theta}{\pi}} - \nabla\cdot v_s\right) \quad (16)$$

The radial distribution for one solid phase can be expressed as (Rahaman et al., 2003):

$$g_o = \left[1 - \left(\frac{\varepsilon_s}{\varepsilon_{s,\max}}\right)^{1/3}\right]^{-1} \quad (17)$$

The energy exchange between the fluid and solid phases in Eq (15) is defined as (Huilin and Gidaspow, 2003):

$$\Phi_s = -3\beta_{gs}\Theta \quad (18)$$

The rate of energy dissipation per unit volume is in the form of the following equation:

$$D_{gs} = \frac{d_p \rho_s}{4\sqrt{\pi\Theta}}\left(\frac{18\mu_g}{d_p^2 \rho_s}\right)^2 |v_g - v_s|^2 \quad (19)$$

2.3 Simulation

The simulations were performed under rolling mode as this mode is considered to give good mixing. The rotational speed of the cylinder was maintained under a Froude number of 16×10^{-4} to achieve the rolling mode. The cylinder and the particles rotate in the counterclockwise direction.

2.3.1 Physical Properties of Materials and Model Parameters

In this study, two granular phases, made of $CaCO_3$ and Al_2O_3 were used in the simulations. Table 1 shows the related physical properties of gas and solids with model parameters.

Table 1. Physical Properties of Materials and Model Parameters

Parameter	*Description*	*Value*
ρ_{CaCO_3} (kg/m^3)	Particle density	1760
$\rho_{Al_2O_3}$ (kg/m^3)		3000
d_{CaCO_3} (μm)	Particle diameter	175
$d_{Al_2O_3}$ (μm)		1000
f (%)	Degree of particle fill	15
ω (rpm)	Rotational speed	2

2.3.2 Geometry and Mesh

A circle with 0.4m diameter was created in DesignModeler to represent the transverse plane of the rotating cylinder. A mesh was refined to yield about 5500 elements. Figure 2 provides the mesh of the transverse plane.

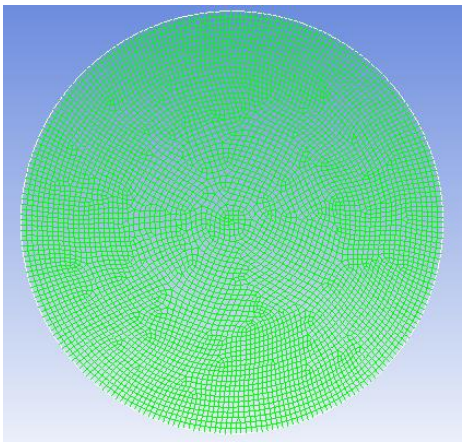

Figure 2. Mesh of the transverse plane

2.3.3 Initial and Boundary Conditions

The main boundary condition of the transverse plane in a rotating cylinder is the relative motion of the bed material and the rotating wall. There, a no-slip condition was assumed, meaning that the relative velocities of the gas and the particles at the wall are set to zero. And it was assumed that particles were subjected to wall friction and gravity.

2.3.4 Solution Strategy and Convergence Criteria

In this study, the finite volume approach was used to solve all the governing equations of the model. Since the flows could be considered incompressible, a pressure-based solver was used. The pressure-velocity coupling was done by a segregated algorithm called "SIMPLE" (Patankar and Spalding, 1972). A second order upwind scheme was used for discretization of the governing equations. The volume fraction was discretized according to the QUICK scheme (Versteeg and Malalasekera, 2007). The time step of the simulations was 10^{-3} s and residual values for the convergence were set to 10^{-3}.

3 Results and Discussion

3.1 Motion of a Single Solid Phase in a Transverse Plane

First, two simulations were performed to understand the bed behavior of $CaCO_3$ and Al_2O_3, respectively. Figures 3(a) and (b) show the volume fraction contours of $CaCO_3$ at 0s and pseudo-steady-state. Initially the top surface is flat, but with the time particles gradually move upwards, following the wall rotation. After a certain time period particles reach a maximum height and then roll down along the top layer in a continuous cyclic motion.

The results indicate that the bed material can be divided into two zones, one active and one passive region. In the active layer, particles move down with relatively high velocities compared to the passive layer.

Figure 4 illustrates the magnitude of the velocity field of $CaCO_3$. Two separated layers can be observed in that a thin upper layer moves with higher velocities than the thick lower layer. Figure 5 shows the velocity contours of $CaCO_3$ particles, which also reveal that the active layer has much higher velocity magnitudes than the passive layer, and the zero velocity region is clearly observed.

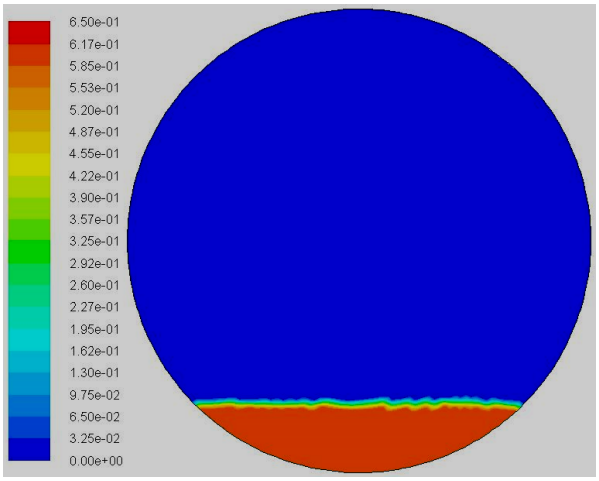

Figure 3(a). Volume fraction contours of $CaCO_3$

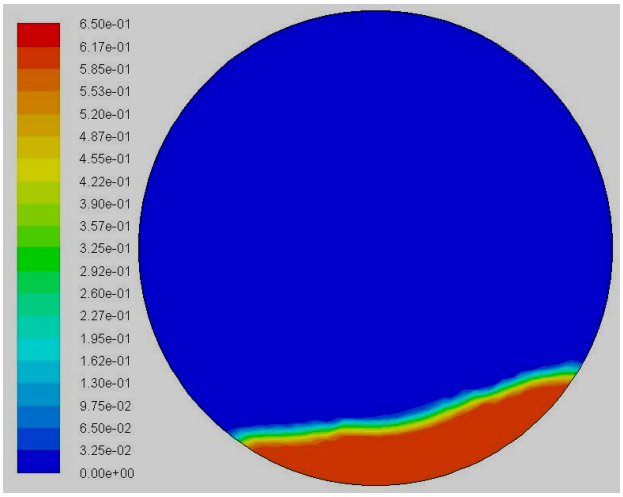

Figure 3(b). Volume fraction contours of $CaCO_3$

In general, the downwards motion in the left direction in the active layer balances the upwards motion in the right direction in the bottom layer, resulting in cyclic pseudo-steady-state flow process. This means that top layer particles exposed to heat transfer from above, as is the case in rotary kilns, would mix with particles in the bottom layer and transfer heat by conduction.

Very similar results were found for the Al_2O_3 motion, so no graphics are included for this particle type.

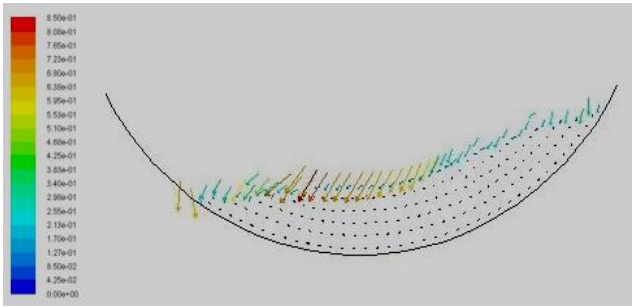

Figure 4. Velocity vector of particle at pseudo-steady-state

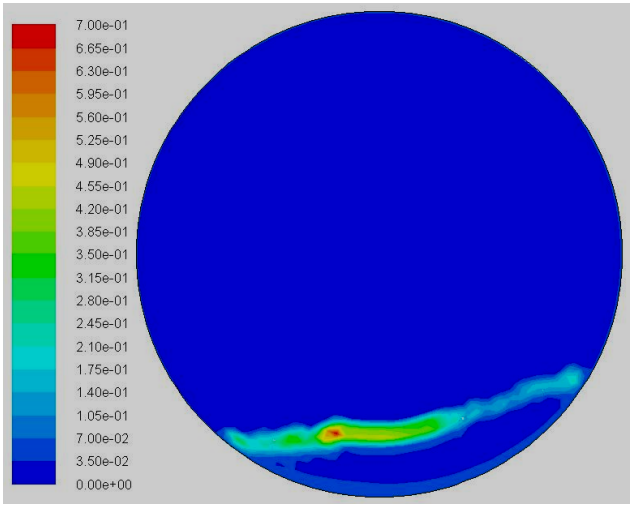

Figure 5. Velocity contours of $CaCO_3$ at pseudo-steady-state

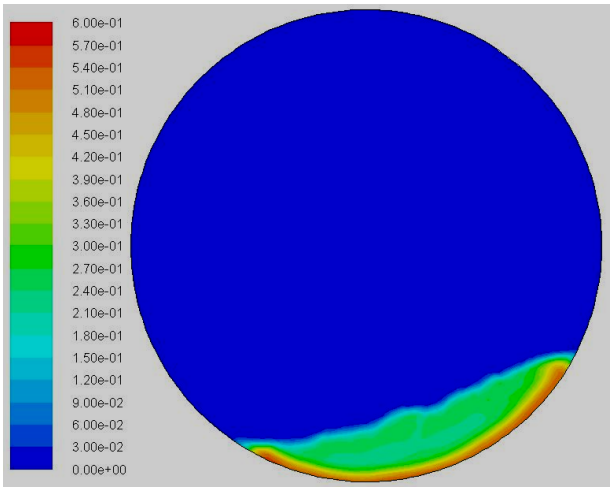

Figure 6. Volume fraction contours of Al_2O_3 in the mixture at pseudo-steady-state

3.2 Mixing of Two Solid Phases in a Transverse Plane

A mixture of $CaCO_3$ and Al_2O_3 were simulated to investigate the mixing performance when two solids with different characteristics are exposed to the rotational motion. Volume fractions of both solids were examined to understand the mixing behavior. Contour plots of volume fractions of solids are shown in Figures 6 and 7. Figure 6 shows the volume fraction variation of Al_2O_3 in the particle bed, revealing that Al_2O_3 accumulates at the bottom of the particle bed. $CaCO_3$, as seen in Figure 7, is collected in the middle of the bed. This illustrates that a mixture of two particle types will undergo segregation instead of mixing during rotation.

Variation of particle size and density are the key factors of segregation in a rotating cylinder. In the active layer of the particle mixture, both solids roll down relative to the slowly moving passive layer. Due to this particle motion, small particles have a higher probability to separate within the active layer and move into middle of the bed. Larger and denser particles move downwards by sustaining the active layer and entering into the passive region at the bottom of the particle bed, near to the wall.

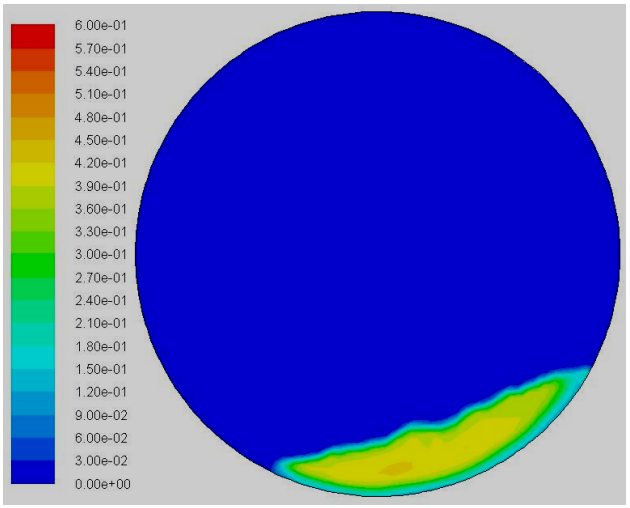

Figure 7. Volume fraction contours of $CaCO_3$ in mixture at pseudo-steady-state

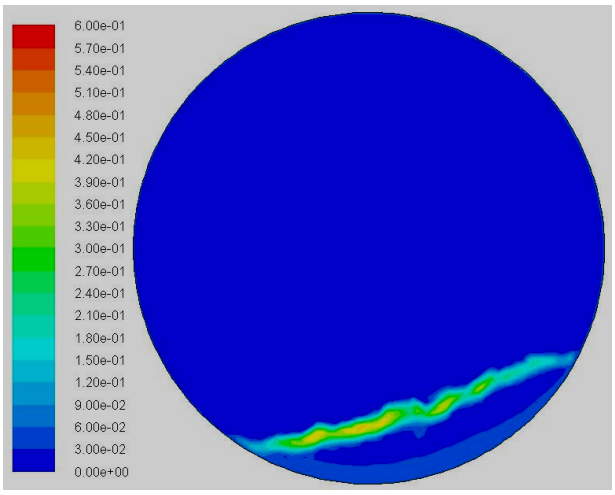

Figure 8. Velocity contours of Al_2O_3 in mixture at pseudo-steady-state

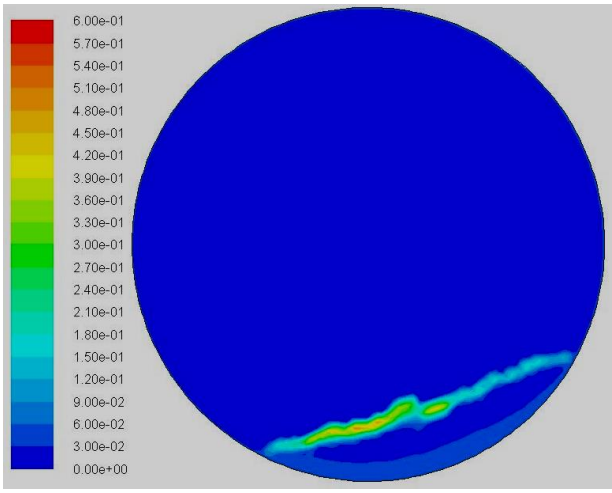

Figure 9. Velocity contours of $CaCO_3$ in mixture at pseudo-steady-state

Velocity contours of both solids are shown in Figure 8 and 9. Both materials are present in the active layer of the mixing bed. The simulation results depict that the intensity of the velocity contours decrease in $CaCO_3$ rather than in Al_2O_3 when materials move towards the lower (left) end of the active layer. This indicates that a smaller amount of $CaCO_3$ particles will remain at the active layer lower end due to segregation.

Generally, particles start to segregate when they are subjected to motion. The particle motion in the active layer facilitates segregation of particles of different size and density.

4 Conclusions

Mathematical modelling of a two-dimensional transverse plane in rotating cylinder, based on the Eulerian approach and the kinetic theory of granular flows, predict the particles mixing behavior in a rotary kiln. The rolling mode can be recommended to achieve internal mixing for a single solid phase. However, particle segregation is observed when two different granular phases are being exposed to the rotary motion under the rolling mode. Lighter and smaller particles are collected in the middle section of the bed while particles with a higher density and size get collected at the bottom of the rotating cylinder. More studies need to be done to understand the mixing mechanism for two granular particles under the rolling mode. In addition to that, further studies are required to determine the best mode for the particles motion in rotating cylinder. Some industrial applications use internal lifters to acquire a higher degree of material mixing. 2-D simulation of the transverse plane with lifters attached to the wall may be applied to investigate to what extent this will improve mixing efficiency of two granular phases.

Interactive Visual Analytics of Production Data - Predictive Manufacturing

Juhani Heilala, Paula Järvinen, Pekka Siltanen, Jari Montonen, Markku Hentula, Mikael Haag

VTT Technical Research Centre of Finland Ltd, Espoo, Finland, http://www.vttresearch.com/ {juhani.heilala, paula.jarvinen, pekka.siltanen, jari.montonen, markku.hentula, Mikael.haag}@vtt.fi

Abstract

Manufacturing creates a lot of data, and this is increasing due to digitalization of manufacturing, industrial Internet of Things (IIoT) and needs for product traceability as well as predictive maintenance. Typically data from production material flow is not analyzed and thus the improvement potential is not found. There is need for interactive analytics tools that can turn raw data from heterogeneous data sources e.g. starting from sensor data, manufacturing IT systems, (e.g. Enterprise Resource Planning, ERP, Manufacturing Execution System, MES and Supervisory Control And Data Acquisition, SCADA), into meaningful information and predictions—and presented on easy-to-use interfaces. This paper presents a feasibility study focusing on interactive visual analytics of manufacturing data set carried out at VTT Technical Research Centre of Finland Ltd.

Keywords: manufacturing industry, statistical analysis, machine learning, visual analytics, industrial internet of things

1 Introduction

The role of data in manufacturing has traditionally been understated. Manufacturing generates about a third of all data today (Simafore, 2013), and this is certainly going to increase significantly in the future. Data forms the backbone of all Digital Manufacturing technologies, which will be the centerpiece of the strategy for advancing Manufacturing in the 21st century (Simafore, 2013).

Manufacturing companies are facing global competition – they have to be better, cheaper and faster. In order to manage they need a productivity leap. Manufacturing companies collect huge amount of data of their manufacturing processes. Even though utilization of the data could potentially enable a big productivity leap, this data is poorly used. A recent survey published (MESA, 2016) find out that only 14% of respondents are using manufacturing data in analytics. This is largely because manufacturing companies lack tools and expertise needed to analyze the data. On the other hand, Industrial Internet of Things (IIoT), analytics and simulation methods, collaboration and visualization tools are mature enough to be used and worldwide interest for applying them exists.

Many of current analytic tools require data analytics expertise and are mainly used as a desktop, "island of analysis". Current analytics tools are also static, pre-programmed, focusing mainly on business issues and targeted for upper management level. Typically those tools are expensive and aimed for large organizations. The current tools also have poor synchronous collaborative analysis and decision making features. There are several useful analytics methods that are not included in the current tools.

Advanced analytics refers to the application of statistics, machine learning, data mining and other mathematical methods to manufacturing and business data in order to assess and improve practices.

Predictive analytics is about extracting information from existing data, in order to determine patterns and predicting potential trends and outcomes. Predictive analytics forecasts what might happen in the future. The goal is to go beyond descriptive statistics and reporting on what has happened to providing a best assessment on what will happen in the future. The end result is to streamline decision making and produce new insights that lead to better actions.

In manufacturing, operations managers can use advanced predictive analytics to take a deep dive into historical process data, identify patterns and relationships among discrete process steps and inputs, and then optimize the factors that prove to have the greatest effect on yield.

For networking manufacturers, the IIoT becomes a full ecosystem when software, cloud computing (or in-house servers), and analytics tools are combined to turn raw data into meaningful information or predictions—and when it's presented on easy-to-use interfaces (such as dashboards or mobile Apps) enabling users to monitor, and in some cases, automate response actions or remotely control equipment or systems (PwC, 2015).

The research question is how to convert manufacturing big data to business and manufacturing advantage? In this article we present a feasibility study of applying visual analytics to manufacturing data. For

the purpose we use VTT OpenVA visual analytics platform for measurement data (Järvinen *et al*, 2013). The objectives are twofold: getting experience and guidelines for applying visual analytics in manufacturing and analyzing the feasibility of the VTT OpenVA platform with manufacturing data.

1.1 Impact estimations

Manufacturers taking advantage of advanced analytics can reduce process flaws, saving time and money. Gains will likely show up in both labor productivity and resource productivity: The impact estimations are (MGI, 2011).

- Sensor data-driven operations analytics: -10-20% operation costs, up to +7% revenue
- "Digital Factory" for lean manufacturing: -10-50% assembly cost, + 2% revenue

For extended enterprise real-time visibility between suppliers and the production line allows key value chain participants to optimize material flow and reduce process cycle time. Furthermore, the use of predictive and prescriptive analytics using real-time data allows the enterprise to rectify future bottlenecks and eliminate high costs associated with operational downtime.

General Electric estimates that full-scale exploitation of the industrial internet potential will bring an annual one percentage point increase in global production for the next 15–20 years. One percentage point might not sound much, but calculating one percent growth over fifteen consecutive years as compounding growth we end up with a global increase of ten to fifteen trillion dollars in national product – that is to say, an increase in products and services to the tune of 10,000 or 15,000 billion dollars each and every year. If even a part of this can be realized, we will have gone some way beyond mere hype! (Ailisto 2014).

An efficient workforce with strong data analytical skills and cross-domain expertise can facilitate transition into a smart factory.

2 Visual Analytics in Manufacturing Domain

One key change in the manufacturing process will come in the form of visual analytics (Riley 2015). For many industrial companies, the Industrial Internet of Things (IIoT) is the main source of Big Data. IIoT connects data produced by different objects – such as sensors, devices, machines, humans, other assets, and products – to different applications. IIoT provides access to data generated and manipulated by e.g. intelligent equipment with an IP address, machine-to-machine (M2M) communications, mobility, cloud computing, analytics, and visualization tools.

Inside the factory, having the ability to utilize data masses from orders and machine status allows production managers to optimize operations, factory scheduling, maintenance, and workforce deployment (Noor, 2014).

2.1 Visual Analytics

Visual analytics (Thomas and Cook, 2009; Järvinen *et al*, 2009; Keim *et al*, 2010; Järvinen, 2013,) provides visual and interactive tools to support analytical reasoning and finding insight from data. It combines the human capabilities to interpret visualizations with automatic data processing. A visual analytics tool shows the information in the form of interconnected and interactive visualizations, making the analysis easy for non-experts in data analysis. Behind the visualizations are statistical, data mining and machine learning methods. Users can look for patterns, trends, anomalies, similarities and other relevant features from the visualizations. Visual analytics is an iterative process, (see Figure 1), where users launch analysis, browse and navigate in visualizations, and highlight and select important areas for further study.

The use of visual analytics is still rare in manufacturing operation management. Examples on visual analytics at plant monitoring are shown by (Aehnelt *et al*, 2013; Tack *et al*, 2014).

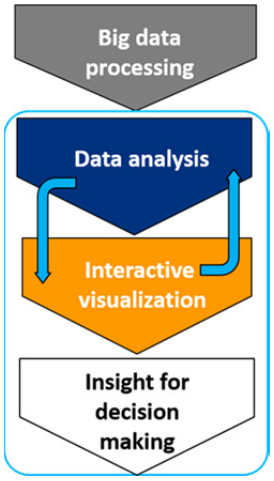

Figure 1. Steps in interactive visual analytics

2.2 Heterogeneous data sources in manufacturing domain

Heterogeneous data stems from various data sources and that comes in a multiplicity of data formats. In the domain of manufacturing, for example enterprise resource planning systems (ERP) are used to manage information about orders and personnel, while manufacturing execution systems (MES) are employed to collect and evaluate data about the production process. For an integrated analysis, different data access interfaces to the different data sources must be used (Aehnelt *et al*, 2013).

In addition to MES and ERP, there are various other systems at factory floor having useful information, such as different sensor systems, SCADA (supervisory control and data acquisition) and various automated systems log files. The most difficult data source is the human at the factory floor, how to get real-time information from him or her. ERP doesn't provide a real time feedback loop from production floor to the planning level. There is latency, delays on submitting the progress data to the ERP and potentially many human interactions are required, thus manual errors are possible. The time stamps from production phases can have inaccuracies. Typically the work phases status are entered at the end of the working shift; there could be the same time for starting and finishing the work phase or some of the work phase recordings are missing.

In case of manual reporting on paper, it requires another human action to type data to the information systems. Information on work progress status, exceptions, missing parts and quality etc. are needed for e.g. real-time control of manufacturing (Järvenpää *et al*, 2014a). Methods for analyzing this historic data are typically missing (Järvenpää *et al*, 2014b).

2.3 VTT OpenVA concept

VTT OpenVA is a visual analytics platform for measurement data by VTT Technical Research Centre Of Finland Ltd. It consists of a data base, a library of visualization and analysis methods, an interactive user interface and a visual analytics engine that delivers data and analysis requests between the different components.

The database stores the application data in a domain independent form. The data base contains data of background variables, measured variables and indicators, and it is populated with application specific metadata.

The analysis and visualization library contains a selection of analysis and visualization methods, and it is extendable. The visual analytics tool adapts itself to each application with the help of the metadata stored into the database. The data to be analyzed is loaded from external sources to the databases through a uniform data interface.

3 Feasibility Test Case – Automated Material Handling System Analysis

The feasibility of OpenVA platform for analyzing manufacturing data was tested with a small sample of industrially relevant data set. The motivation for the feasibility test was to see if the platform would help in the following goal: Advance from descriptive and diagnostic analytics towards predictive analytics – with prescriptive analytics as the next generation capabilities. This could be described as a move from traditional questions of "what happened?" and "why did it happen?" towards a questions "what will happen?" and "how can we make it happen?"

In the feasibility test case, the focus was on visual and interactive analytics, from status monitoring to predictive analytics. The problems of getting data were not studied. The data sets were structured data from a simulation study of an automated material handling system. The feasibility test data was similar to real industrial data that is typically automatically collected from automated equipment and robotics e.g. working time, disturbances, set-up and process times, utilization rate, Overall Equipment Efficiency (OEE) data etc.

In the feasibility test we were utilizing the following parameters from the automated material handling system: capacity (pieces/hour), various equipment (3 machines, 2 robots and lifter) utilization rate, operating time, and storage content (Figure 2). The monitoring of equipment data shows, that production (pieces/hour), utilization rates of robots are low while the utilization rates of the machines are high.

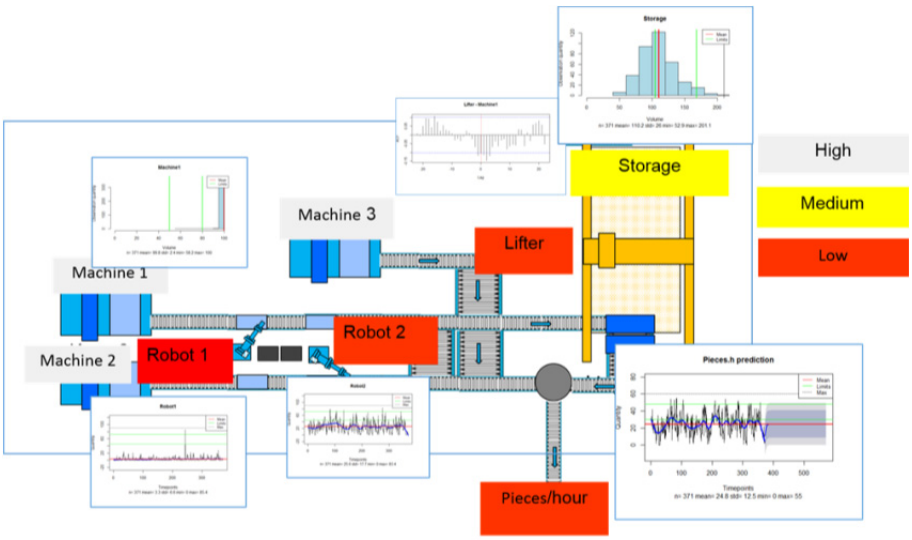

Figure 2. Automated material handling system and equipment's data visualization.

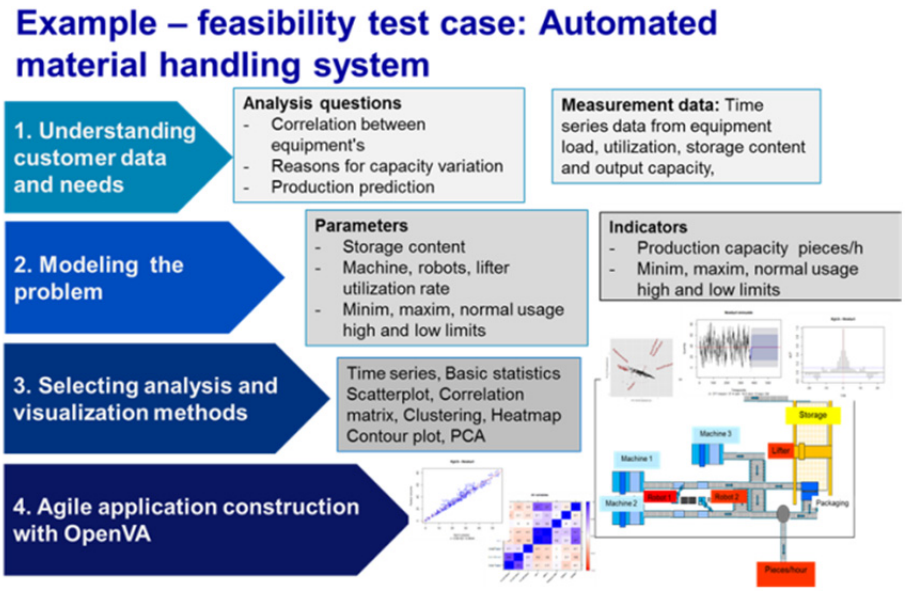

Figure 3. Setting up OpenVA test on automated material handling system

4 Methodology for Setting Up Interactive Visual Analytics

OpenVA is applied by a step-by-step configuration process (**Error! Reference source not found.**). The first step is to understand the customer business, the analysis needs and find out what data is available. Then the next step is to define the phenomena that are followed, to identify the variables that might explain the system behavior and form indicators from the variables. In the third step appropriate analysis and visualization methods are specified. A set of methods is already provided by OpenVA, but new methods can be added. In the final step the analytics application is constructed by configuring the OpenVA platform and loading the application onto the platform database.

In our feasibility study the analysis questions were to study the efficiency of the automated material handling system, to predict the production and find bottlenecks. The selected variables were the utilization rates of each production line component. The indicator chosen for the system production output was finished products/hour. The set of analysis and visualization methods included time series, histogram, contour plot, scatterplot, cross-correlation, correlation matrix, Principal component analysis (PCA), clustering and logistic regression.

The analysis with OpenVA is performed as an iterative reasoning process. First, the user is shown the current status of the performance indicators and the most important variables (Figure 2). The user can study indicators and the other variables in detail with the help of visualizations.

The user starts the analysis by formulating an analysis questions, e.g. "What explains the low production?" Next, the user selects the variables and indicators that might give answers to the questions. The tool suggests suitable analysis and visualization methods to the user based on the number and type of the selected variables. Then the user launches the analysis and gets the results in visual form.

In the analysis of the automated material handling system the most interesting result is shown by the correlation matrix (Figure 4). It shows that the lifter and the production indicator (pieces/hour) have a complete positive correlation, suggesting that the lifter might be the bottleneck of the system. The PCA and logistic regression formula confirm the result. Thereby answers to the analysis questions are: the efficiency of the production line is low, the lifter is the bottleneck of the system and the capacity of the production line is predicted by the lifter alone.

5 Discussion

Predictive analytics applies different analysis methods to predict the possible outcomes of the events that the data describes. It does not give exact measures of what will, could or did happen, just the possibilities of what may occur.

In small series production, different requirements (e.g. high mix, low volume, multiple jobs with different due dates, routing and process time requirements) need to be concurrently processed through the same production setup competing for shared resources of limited capacity. Extreme complexity is characteristic in the discrete made-to-order production, where availability of materials, machines and manpower creates dynamic or moving bottlenecks.

Data quality is a well-known problem in data mining research (Rahm and Do, 2000). The problem is partly caused by missing or erroneous measurements, as well

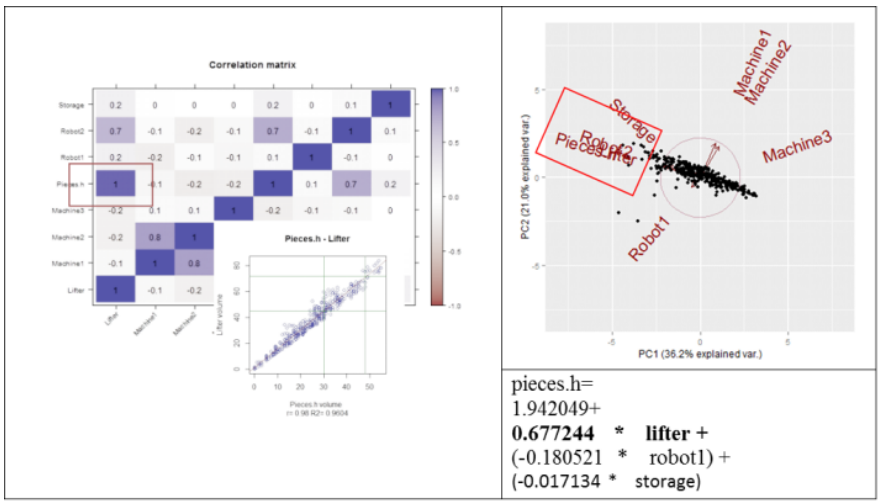

Figure 4. Correlation matrix, cross correlation, PCA and logistic regression

as disparate data formats when combing data from several sources In practical implementations, for example when comparing and estimating measurements from different data collecting applications, the data quality problem is faced immediately. The applications have their own databases, each storing the monitored data in different format. In our test case, the data resulted from a simulation study, and therefore data was cleaner than in a normal industrial case.

The production managers need easy to use tools for finding and eliminating those moving bottlenecks and doing manufacturing process improvements. The production manager needs to consider two different time frames: on the one hand development of equipment and control principles with longer planning and implementation time and on the other hand daily operative decision making. Even if amount of data is low (e.g. because of low production volumes), the predictions do give valuable insight to potential near future events.

As discussed in this paper, the visual and interactive tools can be used to support analytical reasoning and for finding insight from data. However, the visualizations should be chosen case by case so that they are focused on the task at hand, and support exactly those decisions that must be made.

6 Conclusions

In this study our focus was on interactive visual analytics. The key findings regarding the future use of analytics are:

- Instead of looking manually multiple time history plots, numerical tables and reports, one can use the power of interactive visual analytics.
- Getting information from heterogeneous sources, collected from factory floor, manufacturing ICT systems or production engineering design systems for decision making and improvement planning.
- Comparing high and low productivity days, finding correlations, patterns, exceptions, digging deeply to the facts behind events, learning, reasoning and pin pointing improvement areas.
- Visual analytics can diminish the need of multiple customer interviews or simulation studies in a development project by getting findings from existing data.
- Visual analytics can be used with simulation studies, to enhance analysis of the simulation run results in order to get deeper understanding, as done in the feasibility study.

OpenVA platform concept proved out feasible for manufacturing data analysis.

6.1 Future Research

This was a small test with promising results and gives ideas for future research. One of them is synchronous collaborative visual analytics in manufacturing. Analysis and visualization of data are traditionally made asynchronously by individual users with their local tools. Research on synchronous collaborative visual analytics is still in its infancy. Supporting synchronous, multi-party collaboration over networks is becoming increasingly important in order to increase the efficiency of data analysis. An important objective is to combine the best ideas of collaborative work with those of Visual Analytics, i.e. to support interactive collaborative visualizations in multi-party settings. This enables the decision makers to get best possible support from e.g. data scientist without geographical limitations.

For collaborative visualization, integration of data access, communication and messaging functionalities in the Visual Analytics tools are needed. This will support the exchange of opinions and information over

the problem at hand. In addition it requires support solutions for viewing and processing the design collaboratively, linking comments to the specific parts of the object (documents, drawings, 3D designs, visualizations, data sets, etc.), as well as accessing, classifying and filtering those comments at any desired way.

The other development need is reliable and real-time access to data from heterogeneous data sources, from factory floor, sensors, devices, human operators and manufacturing information systems.

For building an IIoT system, all following topics are needed: connectivity, data management, analytics, and interoperability. Reference architectures as well standardization in this domain are evolving e.g. Reference Architecture Model for Industrie 4.0 (RAMI4.0) and the Industrial Internet Reference Architecture (IIRA).

The ability to analyze large amounts of complicated, heterogeneous data with custom-written visual analytics will be key component in the future business and industrial intelligence – analytics. Data-driven decision-making in manufacturing enables productivity leap.

Predictive manufacturing analytics enables users to:

- Progress from monitoring to predictive analytics, optimization and to "how can we make it happen?"
- Near real-time warnings of potential problems, embedded dashboard to factory floor, etc.
- Analyze production characteristics and business performance.

Acknowledgment

Support from VTT Technical Research Centre of Finland Ltd (http://www.vttresearch.com/) is gratefully acknowledged. This small feasibility study was part of VTT spearhead program For Industry. The program was aimed at boosting the competitiveness of the Finnish manufacturing industry.

Cost Optimization of Absorption Capture Process

Cemil Sahin Lars Erik Øi

Department of and Process, Energy and Environmental Technology,
University College of Southeast Norway, Norway, lars.oi@usn.no

Abstract

In this work, a CO_2 absorption process using aqueous monoethanol amine (MEA) as solvent for a post combustion capture plant was simulated using Aspen HYSYS. An Aspen HYSYS spreadsheet was used for equipment dimensioning, cost estimation and cost optimization. A standard process and a vapor recompression process for 85 % CO_2 removal were simulated using the Li-Mather thermodynamic model. The energy consumptions and the total cost were calculated and compared. Cost optimum process parameters were calculated from sensitivity analysis. The vapor recompression process was shown to be both energy and cost optimum. With 20 years calculation period, the cost optimum absorber packing height was 16 meter, optimum temperature approach was 14 K and optimum recompression pressure was 130 kPa. With 10 years calculation period, the optimum values for the same parameters were 16 meter, 17 K and 140 kPa. Calculations of optimum process parameters dependent on factors like the calculation period have not been found in literature. Except from the temperature approach, the optimum values varied only slightly when the calculation period was changed.

Keywords: CO_2, amine, absorption, cost estimation, Aspen HYSYS

1 Introduction

CO_2 absorption with aqueous monoethanol amine (MEA) as solvent is well-known and mature for large scale post combustion CO_2 capture. This process has a high energy consumption. There have been suggested many modifications to reduce the heat demand for the reboiler in the desorption column. Vapor recompression is one of the simplest way to reduce the energy need (Øi et al., 2014). In this paper, the standard and vapor recompression configuration were simulated, cost estimated and optimized using the process simulation program Aspen HYSYS. The results in this work are mainly from a Master Thesis work (Sahin, 2016).

The economic performance of a CO_2 removal process plant has been evaluated in earlier work (Abu-Zahra et al., 2007). The amine concentration, lean amine loading and desorber column pressure was determined to be the main factors influencing on the cost. The capital cost and energy consumption of different configurations have been evaluated using the Unisim and ProTreat simulation programs (Karimi et al., 2011). One reference (Fernandez et al., 2012) has performed cost estimation and found optimum cost parameters using rate based Aspen Plus simulation. Another reference (Cousins et al., 2011) simulated different configurations using Aspen Plus and compared the energy consumption.

There is very limited published work on cost optimum parameters, cost evaluation and optimization of alternative configurations. At University College of Southeast Norway, different modification alternatives were simulated and cost estimated using Aspen HYSYS (Øi et al., 2014). The cost optimum absorber packing height, the minimum temperature approach in the main heat exchanger and the gas inlet temperature were calculated for the standard process using Aspen HYSYS (Øi, 2012; Kallevik, 2010).

The aim of this work is to simulate and cost estimate the standard CO_2 absorption process and the vapor recompression process. Then different parameters are varied to energy optimize and cost optimize different process parameters and the total process. A special aim in this work is to vary cost factors, and especially the calculation period between 10 and 20 years to evaluate the effect on the optimum parameters.

2 Process description

2.1 Principles of Standard Process

The standard amine based CO_2 capture process contains an absorber, a stripper with reboiler and condenser, a lean/rich heat exchanger, pumps and a lean amine cooler as shown in Figure 1.

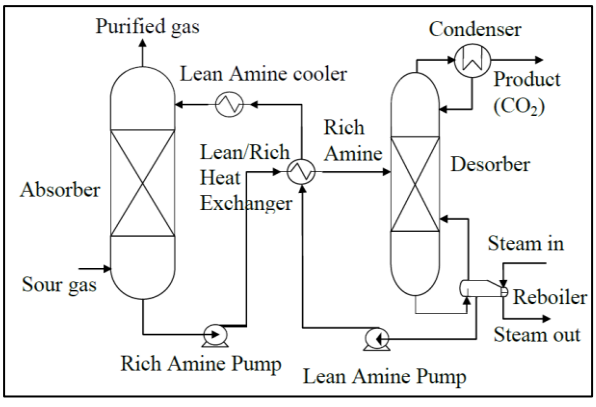

Figure 1. Principle for standard amine based CO_2 capture process (Aromada and Øi, 2015).

When the flue gas rises from the bottom to the top of the absorption column, CO_2 is absorbed by the solvent. The rich amine is pumped from the absorption column to the desorber column passing through the lean/rich heat exchanger. In the stripper, the absorbed CO_2 is removed from the solvent using thermal energy supplied to the reboiler. The lean amine from the bottom of desorber is pumped to the absorption column via the lean/rich heat exchanger and the lean amine cooler.

2.1 Principles of Vapor Recompression

The principles of vapor recompression are shown in Figure 2. The difference from the standard process is that the regenerated amine solution from the desorber is flashed using a valve and led to a two-phase separator. The liquid from the separator is returned back to the absorber. The vapor from the separator is compressed and sent back to the bottom of the desorber.

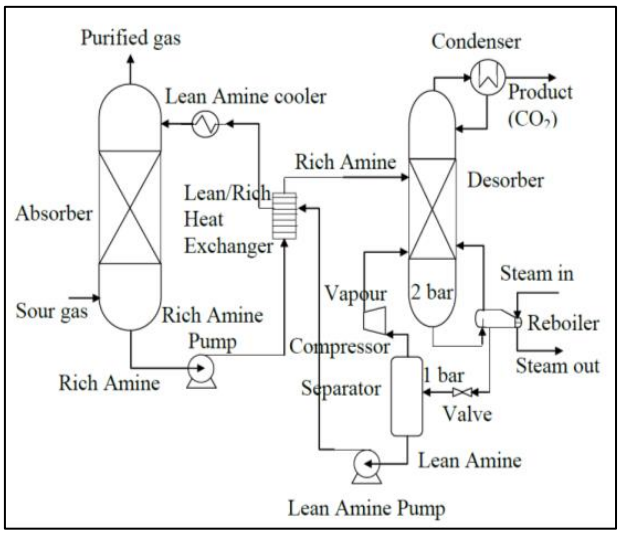

Figure 2. Principle for vapor recompression process (Aromada and Øi, 2015).

3 Models

3.1 Equilibrium Models

The Kent-Eisenberg (Kent and Eisenberg, 1976) and the Li-Mather (Li and Mather, 1996) vapor/liquid equilibrium models are available models in the Amine Property Package in Aspen HYSYS. Both models are quite complex involving several adjusted parameters. The Kent-Eisenberg model is claimed to give faster convergence while the Li-Mather model is claimed to be more robust (Øi et al., 2014). The non-ideal vapor phase model is used in the simulations in this work.

3.2 Column Models and Iteration Algorithms

Equilibrium stages are used to model the columns. A certain packing height can be modelled as an equilibrium stage. One equilibrium stage can be calculated with the assumption that there is equilibrium between the CO_2 concentration in the gas and liquid leaving the stage. A Murphree efficiency can be used to model deviation from equilibrium. It can be specified explicitly for each stage in a column in Aspen HYSYS (Øi, 2007). The Modified HYSIM Inside-Out algorithm with adaptive damping is specified for the columns. This is also done in earlier simulations (Øi, 2007).

4 Process Simulations

4.1 Specifications for Standard CO_2 Capture Process

The standard CO_2 removal process has been simulated in Aspen HYSYS with the specifications in Table 1. The Aspen HYSYS process flow diagram is shown Figure 3. The specifications are based on earlier works with amine absorption from a natural gas based power plant by Øi (2007). The amine package with the Li-Mather model was used in all the simulations in this work.

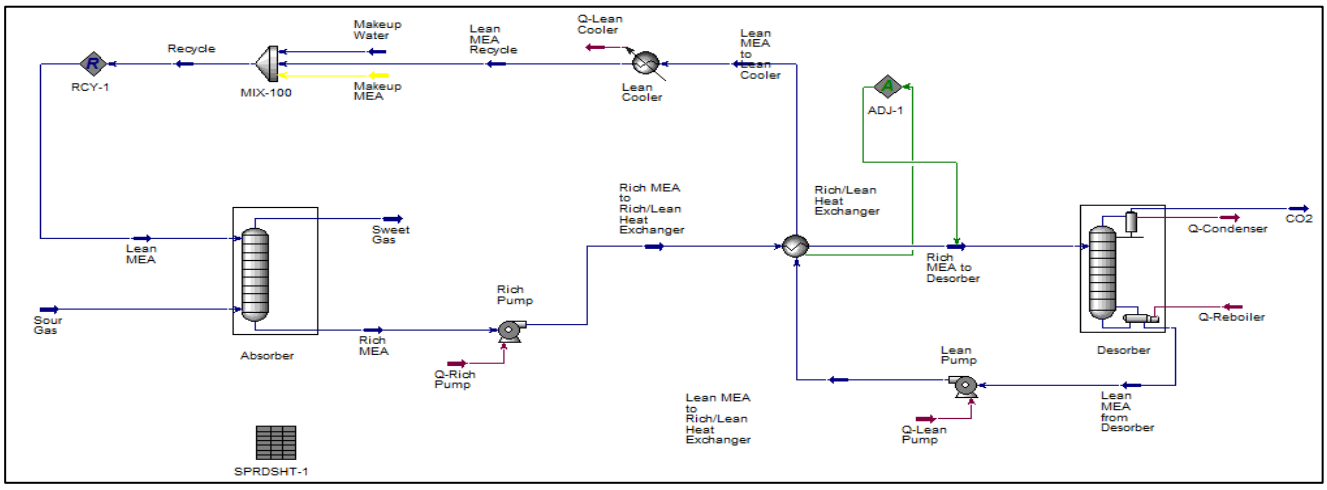

Figure 3. Aspen HYSYS flow-sheet for standard CO_2 capture process.

Table 1. Specifications for standard process.

Parameter	Unit	Value
CO_2 removal grade	mass %	85
Inlet gas temperature	℃	40
Inlet gas pressure	kPa	110
Inlet gas flow rate	kmol/h	85000
CO_2 in inlet gas	mole %	3.73
Water in inlet gas	mole %	6.71
Nitrogen in inlet gas	mole %	89.56
Lean amine temperature	℃	40
Lean amine pressure	kPa	101
Lean amine rate	kmol/h	128000
MEA content in lean amine	mass %	29
CO_2 content in lean amine	mass %	5.5
Number of stages in absorber	-	16
Murphree efficiency in absorber	-	0.15
Rich amine pump pressure	kPa	200
Rich amine temperature to desorber	℃	104.5
Number of stages in desorber	-	8 (2+6)
Murphree efficiency in desorber	-	1
Reflux ratio in stripper	-	0.3
Reboiler temperature	℃	120
Minimum ΔT in Rich/Lean HX	℃	10

The heat consumption in the reboiler was calculated to 3.72 MJ/kg CO_2 which is slightly higher than in some references (Karimi et al., 2011; Fernandez et al., 2012; Øi, 2007) but lower than in some other references (Cousins et al., 2011; Øi and Vozniuk, 2010). The range in these references are from 3.56 to 3.80 MJ/kg.

4.2 Simulation of Vapor Recompression

A simulation of the vapor recompression process was performed. The Aspen HYSYS flow diagram is in Figure 4. The flash pressure was specified to 120 kPa and the efficiency of the compressor was defined to 75 %. To achieve 85 % CO_2 removal efficiency, the lean amine flow rate was adjusted to 111000 kmol/h and the resulting lean amine CO_2 concentration was 5.12 mass %. The rich amine temperature to the desorber was adjusted to 95.8℃ to achieve the minimum temperature approach as 10℃ in the heat exchangers.

With the vapor recompression modification the reboiler heat consumption was reduced from 3.72 MJ/kg to 3.02 MJ/kg. In literature the calculated reboiler heat consumption was 3.03 and 3.04 MJ/kg (Fernandez et al., 2012; Cousins et al., 2011).

The equivalent heat consumption was calculated to 3.28 MJ/kg using a conversion efficiency from reboiler heat (low pressure steam) to electricity as 25 %. The equivalent heat consumption was calculated in literature to 3.30 MJ/kg (Fernandez et al., 2012).

4.3 Dimensioning and Cost Estimation

The absorption and desorption column diameters were calculated based on gas velocities of 2 m/s and 1 m/s respectively. The packing height was determined with the assumption of 1 meter structured packing for each stage. The column height in addition to packing was 24 m for the absorber and 20 m for the desorber. The pressure drop for each stage in the absorber was 900 Pa.

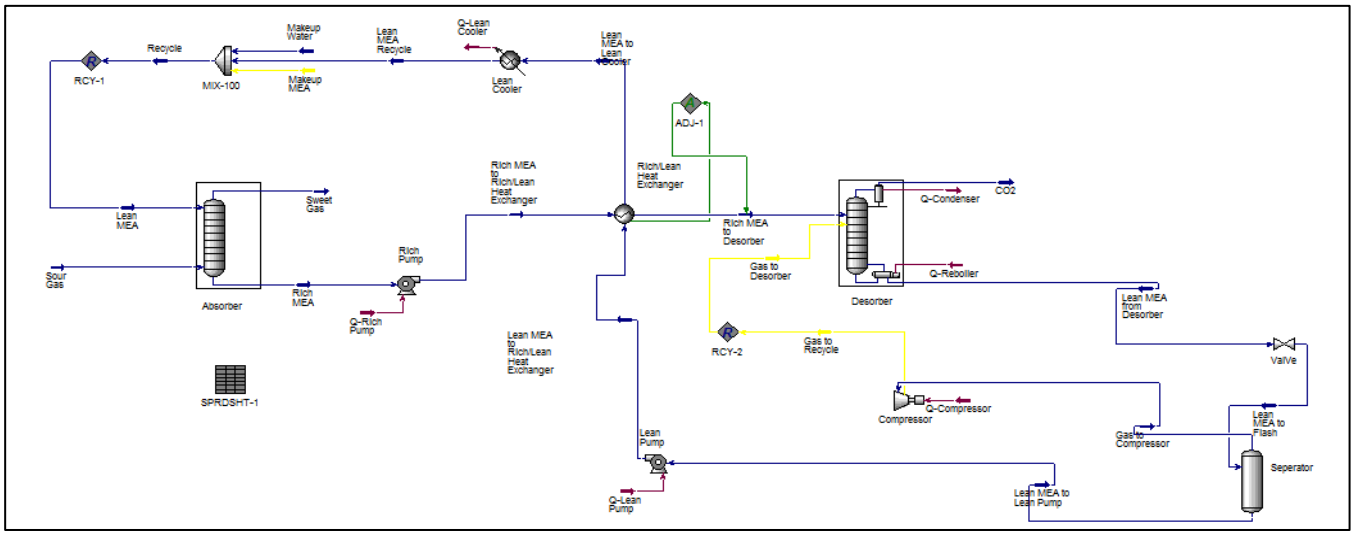

Figure 4. Aspen HYSYS flow-sheet for vapor recompression process.

The heat exchangers were specified as plate heat exchanger. The overall heat transfer coefficients were calculated for the lean/rich heat exchanger and lean amine cooler and estimated to 2500 W/m^{2}K for the reboiler and the condenser. Pumps and compressors were specified with 75 % adiabatic efficiency.

The operating cost was mainly estimated from the energy cost. The maintenance cost was specified as 5 % of the capital cost. The rate of currency was 1 USD to 8.6 NOK. The electricity cost and the steam cost was specified to 0.62 and 0.155 NOK/kWh based on a conversion efficiency from low pressure steam to electricity of 25 %. Operating time per year was defined to 8000 hours. The calculation period was 20 years and the rate of interest was 7 %.

Open source internet cost estimation calculators, one is based on data from Peters and Timmerhaus, were used to calculate the equipment cost (Milligan and Milligan, 2014; Peters et al., 2002). Outside the range of equipment size, power law exponents of 0.57, 1.0, 0.55, 0.28 and 0.95 were used for column vessels, packing, heat exchangers, pumps and compressors. The Chemical Engineering Plant Cost Index was used to convert to USD (2015). After finding the equipment cost, the installed equipment cost was calculated using the detailed factor method using factors for engineering cost, administration cost and contingency.

The net present value using the operating and total installed cost was calculated to 3810 MNOK for the standard process and 3540 MNOK for the vapor recompression process.

5 Cost Optimization

After concluding that the vapor recompression process was more cost optimum than the standard process, the net present value was calculated with varying conditions to find the optimum parameters for the vapor recompression process.

5.1 Cost Optimization of Minimum Temperature Approach

The trade-off was performed with varying minimum approach temperature in the lean/rich heat exchanger. The heat exchanger area and the steam consumption in the reboiler were the main affected variables. The energy consumption and cost optimum as a function of minimum approach temperature is shown in Figure 5.

The calculated optimum value was 14°C with the net present value of 3490 MNOK. As the minimum approach temperature increased, the operational cost increased and the investment cost decreased continuously. Similar calculations were performed for a reduced calculation period of 10 years. The cost optimum temperature approach is shown in Figure 6. The optimum value was 17°C with a net present value of 2710 MNOK. The reason for the higher value is that the investment cost dominates more than the operational cost as the calculation period decrease.

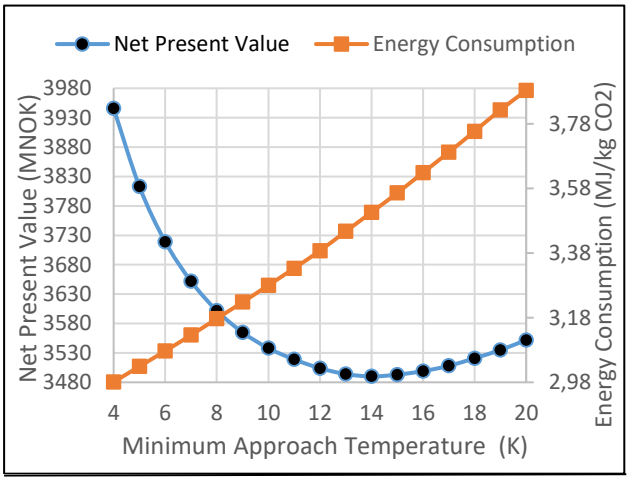

Figure 5. Net present value and energy consumption as a function of minimum temperature approach in heat exchanger for 20 years calculation period.

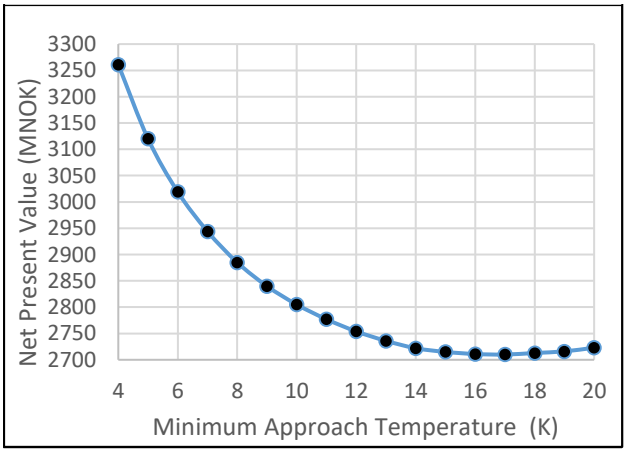

Figure 6. Net present value and energy consumption as a function of minimum temperature approach in heat exchanger for 10 years calculation period.

The cost optimum temperature approach is comparable to values found in literature. Comparisons of optimum temperature approach for different calculation periods have however not been found in literature. The optimum was calculated to 12°C for the calculation period of 15 years and the discount rate of 10.5 % (Øi et al., 2014) and to 19°C for the calculation period of 10 years and an interest rate of 7 % (Øi, 2012).

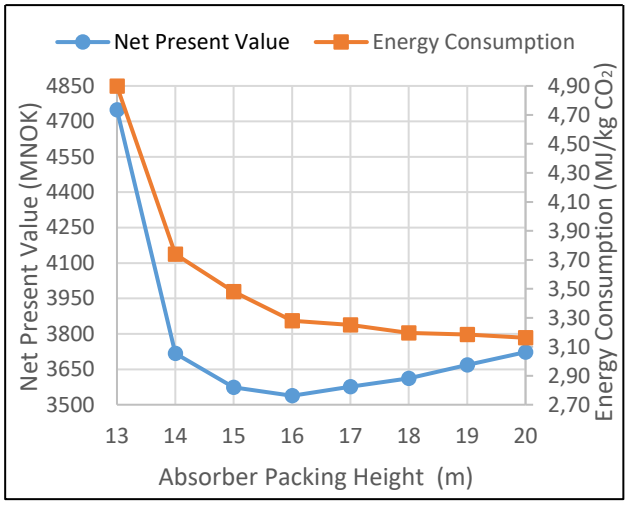

Figure 7. Net present value and energy consumption as a function of absorber packing height for 20 years.

5.2 Cost Optimisation of Absorber Packing Height

The number of absorber stages equivalent to 1 meter was varied between 13 and 20. The cost optimum value of 3540 MNOK was achieved with 16 stages as shown in Figure 7. As the number of stages increased, the necessary amine flow rate to keep the 85 % CO_2 removal efficiency decreased. The equivalent heat consumption decreased from 4.9 MJ/kg CO_2 at 13 stages to 3.16 MJ/kg CO_2 at 20 stages. The investment of the absorber column, the amine heat exchanger, the compressor, the electric consumption due to fan and compressor and steam consumption in the reboiler were the major changes. For 10 years calculation period, the cost optimum value was also achieved with 16 stages as shown in Figure 8.

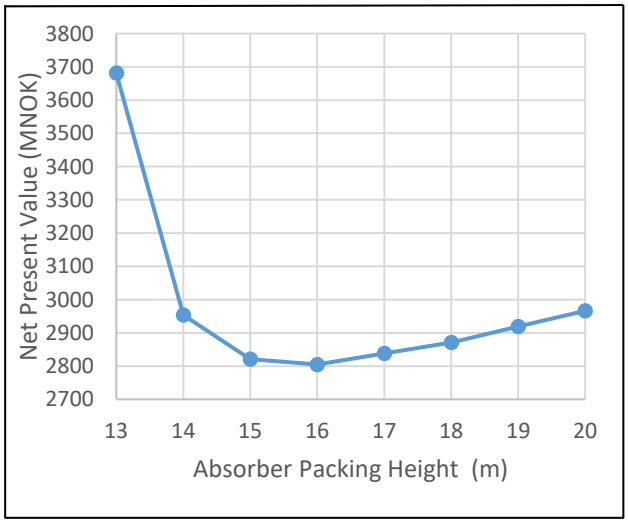

Figure 8. Net present value and energy consumption as a function of absorber packing height for 20 years.

Similar values are found in literature. For the calculation period of 15 years, 16 stages in the absorption column was calculated as the cost optimum value (Øi et al, 2014). In another optimization calculation, the optimum value was also 16 stages for a calculation period of 10 years (Øi, 2012). Evaluations of the influence of the calculation period on the optimum packing height have not been found in literature.

5.3 Cost Optimization of Flash Pressure

The flash pressure (pressure before recompression) can be varied. The cost of the lean/rich heat exchanger, the compressor, the reboiler and the energy consumption in the compressor and the reboiler changed when the flash pressure was varied. The equivalent heat consumption was reduced to 3.27 MJ/kg CO_2 at 1.1 bar. The cost optimum pressure was calculated to be 1.3 bar with a net present value of 3530 MNOK. The result of the cost optimum flash pressure is given in Figure 9. The cost optimum flash pressure is slightly different from the energy optimum value. The reason is that the energy saving is dominated by the investment cost of the compressor until 1.3 bar.

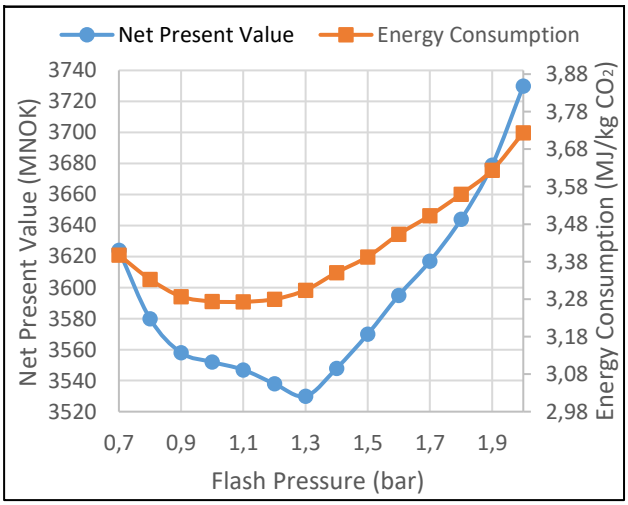

Figure 9. Net present value and energy consumption as a function of flash pressure for 20 years.

For a calculation period of 10 years, the cost optimum flash pressure was calculated to be 1.4 bar as shown in Figure 10. The dependency of the optimum flash pressure on the calculation period is not obvious. It is however reasonable that as the calculation period increases, the optimum value will intend to decrease because the operational cost becomes more dominant.

In literature, energy optimum flash pressures have been calculated to 1.12 and 1.17 bar (Karimi et al., 2011). In Fernandez et al. (2012), the cost optimum flash pressure was calculated to 1.2 bar. The cost optimum

pressure is slightly higher than the energy optimum because the change in compressor cost is significant. Calculations of optimum flash pressure dependent on factors like the calculation period have not been found in literature.

5.4 Evaluation of Uncertainty

The calculations of the equilibriums, the material balances and the energy consumptions in the process simulations are regarded to be reasonable accurate. As a result of this, the deviation in calculated energy consumptions compared to values found in literature is quite low.

The uncertainties in cost estimation of the equipment are much larger. First, there are uncertainties in the dimensioning of the process equipment. Then there is a high uncertainty in the cost of especially heat exchangers and the absorption columns. And the installation cost of all types of equipment also have high uncertainty. The chosen calculation period and chosen discount rate will also influence on the total cost estimate.

The main aim in this paper was to find cost optimum process parameters. It is of interest to find out whether these optimums are dependent on the choice of different cost factors. When comparing optimum parameters calculated in this work compared to values found in literature, the deviation is rather low.

In this paper, optimum parameters have been calculated for a calculation period of 10 and 20 years. The differences in calculated optimums are very small. The only deviation was in the optimum temperature difference approach in the main heat exchanger that changed slightly from 14 to 17 °C.

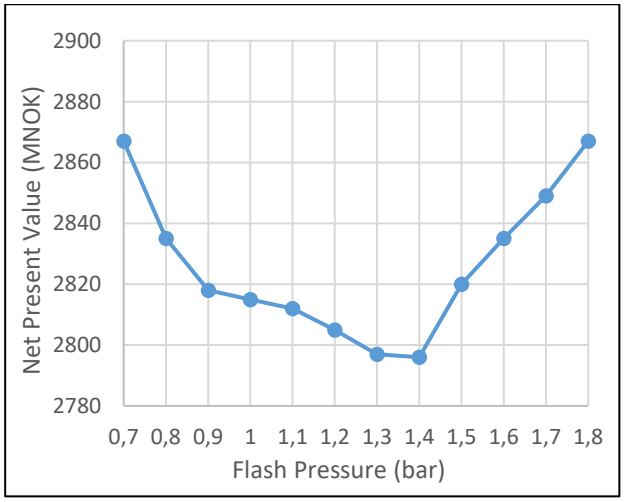

Figure 10. Net present value as a function of flash pressure for 10 years.

6 Conclusions

Simulations and optimizations of an amine-based CO_2 removal process were performed in the search for a cost optimum process. The process configurations examined were a standard process and a vapor recompression process. The energy consumptions and the total cost were calculated and compared.

The vapor recompression modification gave lower total cost compared to a standard process. Optimizations of parameters like minimum temperature approach, height of absorber packing and flash pressure were performed. Cost optimum process parameters were calculated from sensitivity analysis.

Calculations of optimum process parameters dependent on factors like the calculation period have not been found in literature. With 20 years calculation period, the cost optimum absorber height was 16 meter, optimum temperature approach was 14 K and optimum recompression pressure was 130 kPa. With 10 years calculation period, the optimum values for the same parameters were 16 meter, 17 K and 140 kPa. Except for the minimum temperature approach, it seems like when varying different cost factors like the calculation period, the cost optimum values vary only slightly.

Abstract

The paper is focused on practical aspects of advanced nonlinear identification method applied to a real industrial process. Fuzzy identification is used to model the air preparation stage within a system for reducing nitrogen oxides (NOx) emissions in exhaust air from the dryers and ovens in a factory of automotive catalytic converters. The system for NOx emissions reduction operates efficiently in predetermined temperature and air flow ranges of the exhaust air only. Due to those conditions, exhaust air from the dryers and ovens must be prepared in advance by controlling the ventilator speed and fresh air and exhaust air dampers positions. At the same time operating conditions of dryers and ovens have to be maintained within defined ranges. Currently used control system of the exhaust air preparation shows some deficiencies, so a feasibility study of possible improvements has been carried out. Modelling presented in this paper has been used to evaluate and compare control solutions. The results show such an improvement is feasible. The proposed control system can be ready for implementation in the real process with minor changes of the controller parameters and supervisory logic settings.

Keywords: fuzzy logic, Takagi-Sugeno model, catalytic converter, emission reduction, process control

1 Introduction

Emissions of pollutants are a challenging problem in many contemporary industrial processes. In particular, emissions of atmospheric pollutants in exhaust air have direct influence on quality of the living conditions in the neigbouring areas of industrial plants, as well as other important environmental impacts, e.g. climate change.

The nitrogen oxides (NOx) emissions in the exhaust air can be effectively reduced by catalytic converters, which are based on the same operation principles as used in internal combustion engine exhaust system in traffic vehicles. Industrial catalytic converters typically work on selective catalytic reduction (SCR) principle, although also selective non-catalytic reduction (SNCR) based systems have been used, e.g. in waste incineration plants. With SCR, a gaseous reductant is added to the stream of exhaust air, typically anhydrous ammonia, aqueous ammonia or urea, which reacts with gas mixture in the exhaust air and the catalyst to form molecular nitrogen, water and carbon dioxide.

To achieve the (near) optimal operation of the catalytic converter unit, the incoming production process exhaust air must be properly conditioned. This involves control of flow, pressure and the temperature.

The currently used control system of the exhaust air preparation stage in the process under investigation shows some deficiencies, so a feasibility study of possible improvements has been carried out. A substantial part of the feasibility study was development of a mathematical model, which is presented in this paper. The model was necessary in order to be able to experiment with control system. The presentation focuses on practical aspects of deriving a model by fuzzy identification based on actual production data.

2 Air preparation process

The system considered in the paper is a part of the catalytic converters production plant. The produced catalytic converters are used to reduce NOx emissions from internal combustion engine driven vehicles.

Due to the used production technology, the NOx emissions are present in the production process itself so an emissions reduction unit is installed. The operating conditions are varying substantially with the changing production. Therefore an air preparation stage is installed in between the production process and the catalytic converter (Fig. 1). This way a stable operating regime of the NOx emissions reduction unit is achieved.

The process contains a pipe system delivering exhaust air from ovens and dryers, equipped with controllable dampers and ventilators; a set of pressure/differential pressure and temperature sensors, and damper position sensors is installed. Low pressure is maintained to transport the air out of the process and the air flow is calculated from differential pressure reading within the catalyst converter unit, taking into account air pressure and air temperature. According to specifications the control relevant signals are: air flow, pressure before ventilator, differential pressure over the ventilator, ovens exhaust pressure and dryers exhaust pressure.

The currently operating system involves automatic control of the exhaust air preparation system, but the control system is not operating in a closed-loop manner. The con-

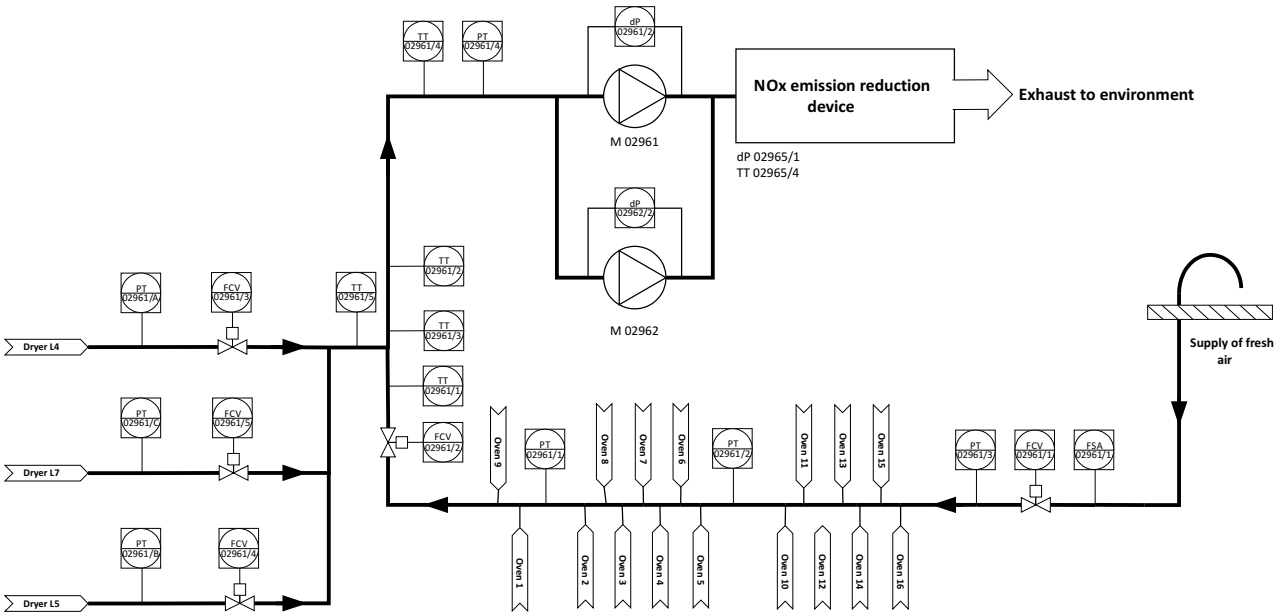

Figure 1. Air preparation process.

trol logic is programmed in accordance with a set of predefined rules based on operator expertise. The manipulated signals of dampers and ventilators are changed stepwise, with large intermediate intervals to allow the process to settle in the changed operating point. This induces substantial delays before the process adapts to any changes in the exhaust air conditions. Therefore a feasibility study was carried out to show potential improvements in reduction of emissions employing closed-loop control in the air preparation stage.

The study is based on simulation so a mathematical process model was needed. Experimentation on the actual system was not possible due to potential environmental hazard. In fact, the system involves several safety measures to prevent this and experimentation with the air preparations stage potentially induces the production shutdown, which is not acceptable.

3 Fuzzy identification

Due to nonlinear nature of the process dynamics, fuzzy logic (Zadeh, 1965) was chosen as a modelling framework and Takagi-Sugeno (TS) type model was developed. The model parameters were identified by actual production data, a separate dataset was used for model validation. The intended use of the model is to simulate a closed loop control system with some typical operation scenarios.

3.1 Takagi-Sugeno fuzzy model

With TS fuzzy model an arbitrary nonlinear system can be approximated by smooth interpolation of affine local models (Takagi and Sugeno, 1985). Every local model contributes to global model in the frame of fuzzy clusters in the space described by membership functions.

If the input data is denoted as $X = [x_1, x_2, \ldots, x_n]^T$ and the output data as $Y = [y_1, y_2, \ldots, y_n]^T$, then the model in TS form (Takagi and Sugeno, 1985) is written as a set of rules:

$$R_i : \text{if } x_k \text{ is } A_i \text{ then } \hat{y}_k = \phi_i(x_k) \quad i = 1, \ldots, c \tag{1}$$

Vector x_k represents the input data in premise while $\hat{y}_k$ is the output of the fuzzy model at time instant k. Premise vector x_k relates to fuzzy sets $(A_1, \ldots, A_c)$, where every fuzzy set A_i $(i = 1, \ldots, c)$ is characterized by a real valued membership function $\mu_{A_i}(x_k)$ or $\mu_{ik} : R \to [0,1]$ representing the membership degree of x_k with respect to fuzzy set A_i. Functions $\phi_i(.)$ are in general arbitrary smooth functions, while mostly linear or affine functions are used.

The model output in (1) can be expressed as:

$$\hat{y}_k = \frac{\sum_{i=1}^{c} \mu_{ik} \phi_i(x_k)}{\sum_{i=1}^{c} \mu_{ik}} \tag{2}$$

Equation (2) can be simplified by introducing $\beta_i(x_k)$ defined as:

$$\beta_i(x_k) = \frac{\mu_{ik}}{\sum_{i=1}^{c} \mu_{ik}}, \; i = 1, \ldots, c \tag{3}$$

In this way the degree of fulfillment of a fuzzy rule is given in a normalized form. $\sum_{i=1}^{c} \beta_i(x_k) = 1$ independently of x_k, as long as $\beta_i(x_k)$ is not zero (which can be easily assured by extending membership functions over the whole range of x_k).

Joining (2) and (3) results in:

$$\hat{y}_k = \sum_{i=1}^{c} \beta_i(x_k) \phi_i(x_k), \; k = 1, \ldots, n \tag{4}$$

The output is often defined as a linear combination of the consequence states:

$$\phi_i(x_k) = x_k \theta_i, \; i = 1, \ldots, c, \; \theta_i^T = \left[\theta_{i1}, \ldots, \theta_{i(p)}\right] \tag{5}$$

The vector of fuzzified input variables at time instant k is written as:

$$\psi_k = [\beta_1(x_k)x_k, \ldots, \beta_c(x_k)x_k], \; k = 1, \ldots, n$$

which implies fuzzified data matrix:

$$\Psi^T = \left[\psi_1^T, \psi_2^T, \ldots, \psi_n^T\right] \tag{6}$$

If the coefficient matrix for the overall set of rules is written as $\Theta^T = \left[\theta_1^T, ..., \theta_c^T\right]$, (4) can be modified to:

$$\hat{y}_k = \psi_k \Theta \tag{7}$$

and in compact form, which describes the overall data set relations:

$$\hat{Y} = \Psi\Theta \tag{8}$$

where $\hat{Y}$ is a vector of model outputs $\hat{y}_k$ and $k = 1, \ldots, n$ ($\hat{Y} = [\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_n]^T$).

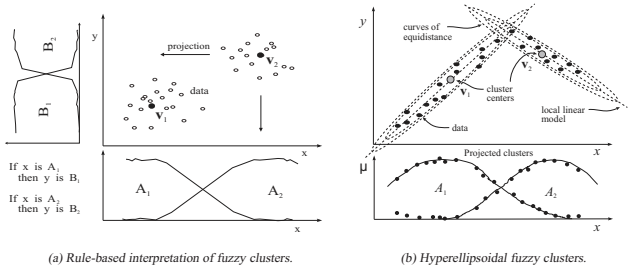
The fuzzy model (7) is often denoted as affine Takagi-Sugeno model and can be used to approximate any real valued continuous function with arbitrary precision (Kosko, 1994; Wang and Mendel, 1992; Ying and Chen, 1997). This can be proved by Stone-Weierstrass theorem. Any real valued continuous function can be approximated with a fuzzy model (Lin, 1997).

3.2 Fuzzy clustering

The TS model can be derived from available process data by identifying the structure and the parameters of the local models (Takagi and Sugeno, 1985). Structure identification includes an estimation of the cluster centers (antecedent parameters), which is usually done by fuzzy clustering. Then for each cluster the sub-model's parameters are estimated, which is usually done with a least-squares method (Chiu, 1994). Clustering can be performed in the input space only or in the product space of the input and output. The later is more general and is commonly termed shortly as clustering in the product space

The basic principle of fuzzy clustering is depicted in Fig. 2(a). Here the data is clustered into two groups with prototypes v_1 and v_2, using the Euclidean distance measure (Babuška, 1998).

If-then rules of the fuzzy model are extracted by clusters projection onto the axes. The clusters can be ellipsoids with adaptively determined shape (Gustafson and Kessel, 1979), see Fig. 2(b). From such clusters, the antecedent membership functions and the consequent parameters of the TS model can be identified (Babuška, 1998). Each obtained cluster is represented by a rule in the TS model. The principle of system identification employing fuzzy clustering consists of a series of steps depicted in Fig. 3.



(a) Rule-based interpretation of fuzzy clusters. (b) Hyperellipsoidal fuzzy clusters.

Figure 2. Identification by fuzzy clustering (Babuška, 1998).

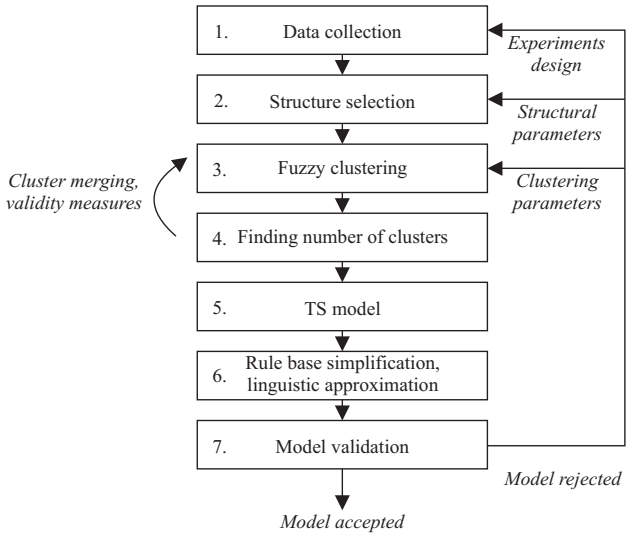


Figure 3. Identification approach based on fuzzy clustering (Babuška, 1998).

The procedure is supported by dedicated software tools, such as Fuzzy Modelling and Identification Toolbox for Matlab (FMID), which was used in the presented work. Implementation of some of the steps of Fig. 3 will be discussed in the following sections.

4 Data collection

Data collection is a key step that largely determines the quality of the modelling result. Proper identification experiments have to be designed and this is a very problematic step in several industrial processes, in particular when a process is already in operation. In some cases the process shutdown is impossible for the reason of cost or safety; in others the standalone experimentation is not possible. Because of process interconnections, it is often required that several process stages operate in line with the process under observation.

When experimentation is performed during operation, typically a number of operating restrictions have to be observed, which severely limits the experimentation possibilities.

In the presented case the air preparation process cannot run independently of main production process which delivers the polluted exhaust air. At the same time nominal operating regime has to be maintained within the main process to avoid product scrap or even automatic process shutdown, and furthermore, the emissions should stay within allowed ranges.

The first identification attempt was done with signals acquired during the control commissioning. Signals ac-

quired while the operation of control logic was tested were used as input-output data. The modelling results were not useful, because it turned out that the testing has not covered adequately large portion of the input-output space. Only manipulated values could be directly changed during testing while several other signals depend on process operating conditions that were not directly controlled. Large number of situations was simply not covered by the testing procedures, which is quite common in complex processes.

The second attempt was based on data acquired during a longer process operation testing period. The problem in this case was the built-in data compression within the data acquisition system, which writes the data only on sufficient changes. The problem was solved by interpolating available sensor measurements and by stepwise holding the manipulated values. The results were resampled by 1 *s* interval.

5 Structure selection

According to (Babuška, 1998) the structure selection in fuzzy modelling involves a set of tasks, such as: a choice of input and output variables, representation of the systems' dynamics, and a choice of the fuzzy models granularity.

5.1 Input and output variables

The control relevant output signals were specified by the customer, the same were chosen as model outputs. The inputs were chosen in accordance with the known physical background of the process. Also an expertise of the process operators was considered.

Additionally, the possibilities of data analysis with regard to determination of influential variables were tested (Glavan et al., 2013). The analysis has not brought any new insights into the input output dependencies. This indicates that for well-known processes data analysis methods are not superior to human expertise. Inputs of some of the submodels depend on the outputs of other submodels. Fig. 4 shows the initial structure of the overall process model.

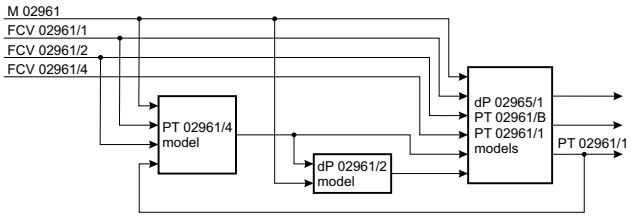

Figure 4. Initial model structure.

While individual models show good matching with the process data, the overall model of Fig. 4 exhibits large modelling error. The reason is in the error accumulation in PT 02961/1, PT 02961/4 and dP 02961/2 models (signals are labelled in accordance with process scheme in Fig. 1). Therefore, another model structure was chosen, which consists of separate models for all quantities of interest, which directly build on measured data. E.g., the model for air pressure in the ovens outlet is shown in Fig. 5.

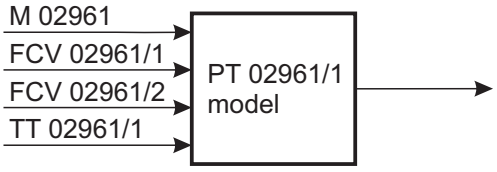

Figure 5. Fuzzy model of air pressure in the ovens outlet.

5.2 Representation of the systems' dynamics

The main design issue here was to choose the number of delayed input and output samples used as model regressors. The choice was determined by an iterative procedure, during which we started the identification with one sample delay on input and output, and then repeated the identification with increasing number of delayed outputs up to four. The effect of adding additional delayed input was also tested as well as changes of sampling interval to 2 and 3 *s*.

The quality of derived models was compared by variance accounted for (VAF) performance index (Babuška, 1998)

$$VAF = 100\% \left[1 - \frac{var(y_1 - y_2)}{var(y_1)} \right] \tag{9}$$

Among others, the above procedure led us to adjust the sampling period of the acquired data; for the further experimentation a 3 *s* sampling interval was chosen. This allowed us to use a low number of delayed signals as model regressors (2 to 3), which prevents overfitting and improves model generalization capability.

5.3 Fuzzy models granularity

When fuzzy clustering is applied to generate fuzzy models from data, the main parameter that must be chosen with regard to granularity is the number of clusters. The applied strategy here was to start with a moderate number of clusters (e.g. 5) and then experiment in a similar manner as above, gradually increasing the number of clusters up to 8, and taking VAF index as performance measure.

6 Fuzzy clustering and model validation

All models for the control relevant variables defined in Sect. II were built in a similar manner by using FMID tool and experimenting with main parameters.

Fig. 6 shows the performance of the best model for air pressure in the ovens outlet with respect to the identification signal and the validation signal.

The VAF value is 67.4 % for the identification signal and 28.9 % for the validation signal. The result of validation is rather low but the reason is in the nature of the process operation. The observed pressure largely depends

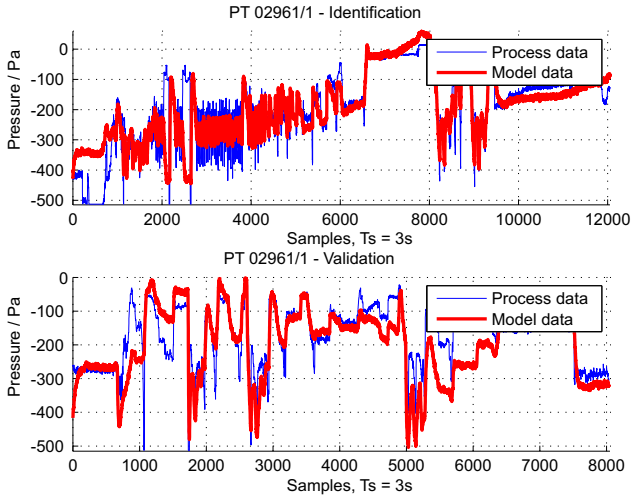

Figure 6. Performance of the fuzzy model of air pressure in the ovens outlet.

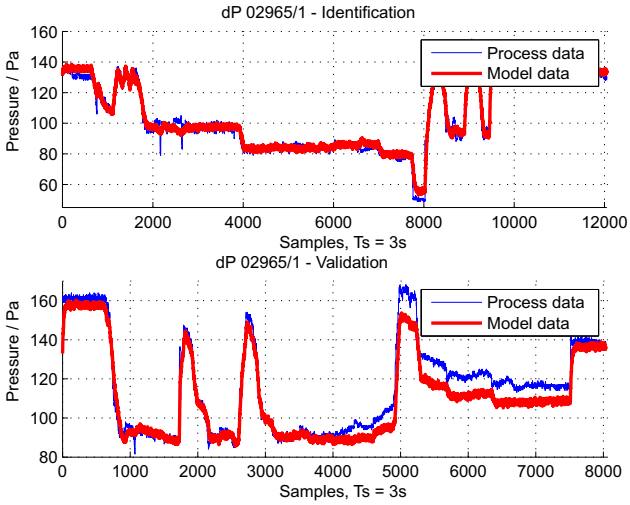

Figure 7. Performance of the fuzzy model of differential pressure in the catalyst converter unit.

on the number of the operating ovens. This parameter was not available in the process database so it could not be included as an input. It is assumed that occasional large deviations from the measured validation signals are due to change of this condition.

Fig. 7 shows a similar graph for the model of differential pressure, which is the basis for the air-flow calculation.

The VAF value is 97.8 % for the identification signal and 95.0 % for the validation signal, which is much better than in the previous case. This indicates that chosen modelling method can be very effective when proper input-output data is provided.

6.1 Comments on resulting model performance

We estimate that derived fuzzy models are of sufficient quality to test and compare various control solutions. There are noticeable deviations in responses of the PT 02961/1 model and the real system, but these are presumably mainly caused by varying conditions in the quantity of supplied exhaust air due to variable number of operating stages in the main manufacturing process.

The most relevant control variable is the air flow FIA 02965/2 (Φ_{air}) through the NOx emission reduction device, which is calculated based on dP 02965/1 ($\Delta p\ [Pa]$) and TT 02965/4 ($T\ [^oC]$) readings as follows:

$$\Phi_{air} = 3600 \cdot A \cdot v_{air} \quad [m^3/h] \tag{10}$$

$$v_{air} = \sqrt{\frac{2\Delta p}{R \cdot \rho}} \quad [m/s] \tag{11}$$

$$\rho = 1.293 \frac{273}{T + 273} \quad [kg/m^3] \tag{12}$$

where $R = 4.6285$ and $A = 2.1316\ m^2$.

As presented above, the VAF index obtained during validation shows good quality of dP 02965/1 model, which indicates the obtained model is of sufficient quality for testing air flow control strategies.

By stepwise changes of the manipulated variables the model behavior was also qualitatively evaluated, and all the signals change in accordance with experience on the real process.

Additional temperature measurements were considered as model inputs during the identification. When testing control strategy these signals are not available, therefore a set of disturbance generating models were additionally identified. Major disturbances were generated, in particular the air temperatures in different parts of the system.

These models are not very precise but enable generation of disturbances during simulated experiments with control system. Control robustness is tested this way.

7 Control experiments

As the signals observed in the real process are noisy and disturbed by additional influential variables, these aspects are added to the model used for control experiments. Noise amplitude and frequency bandwidth of the noise filter were chosen in accordance to observed process signals in the manual mode.

7.1 PID control

After model was validated and brought close to the actual process behavior by addition of noise, it was used to test various control strategies. As the focus here in this paper is not on control design, only a sample simulated scenario of the air flow is shown in Fig. 8. Note that simple PI controller was used that was tuned in a chosen operating point without noise in the model. After tuning, the control robustness was checked in the presence of noise and disturbances. Among others, additional noise cancelling measures were implemented, such as deadband on manipulated value and error filtering.

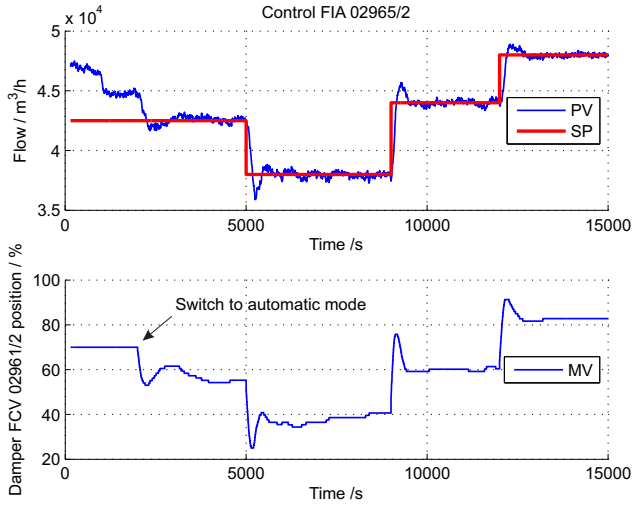

Figure 8. Illustration of the control system performance - air flow.

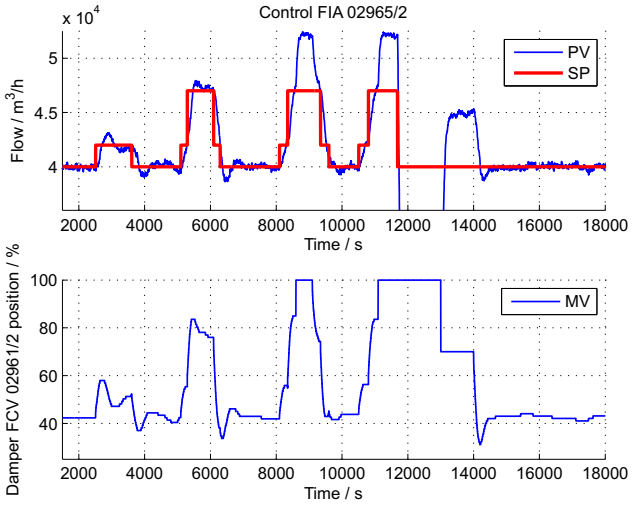

Figure 9. Illustration of the control system performance in the presence of process exceptions.

7.2 Supervisory logic

The advantage of the conventional (currently used) open-loop control system is the simple accommodation for the process exceptions. These are treated by addition of related rules in the control logic.

The main process exceptions are related to:

- start-up of the air preparation system
- exceptional process values
- invalid pressure set points.

In the following we briefly illustrate how exceptional process values are treated. The observed values are:

- high temperature in the ovens output airflow
- high temperature before the main ventilator
- high emissions concentration on the input
- high differential pressure on the main ventilator.

The desired action in all these exception is to increase the air flow through the system. In the conventional logic this is achieved by simply opening the corresponding damper for a predefined proportion.

In the proposed new control system this is accommodated by additional supervisory logic, which increases setpoint value for airflow at the predefined warning levels. With the low warning level the setpoint is increased for 2000 m^3/h, at the high warning level the setpoint is increased for 5000 m^3/h.

When lower alarm level is reached the system switches to manual mode with fully open dampers and predefined ventilator speed. At higher alarm level the system is shut down with dampers fully open.

The sample simulated operation scenario is shown in Fig. 9, where setpoint changes and related changes in the damper position can be observed, and normal system operation reestablishment can be seen when operation conditions are brought back to normal.

The results show that treatment of the exceptional conditions can be accomodated by adjustments of the setpoint values by supervisory logic.

8 Conclusions

The feasibility study shows the control of the air preparation stage could be improved with a moderate investment in the control equipment and related application software. The currently used control system is implemented in the ControlLogix 5570 family of Programmable Logic Controllers (PLCs) with PID control support within the corresponding PLC programming software. The application software could be adjusted by replacing open-loop control logic with PID controllers. Minor parameter adjustments are foreseen mainly due to different scaling of the control signals compared to simulation study.

The chosen modelling approach showed its value in relatively simple identification of the submodels when the proper model structure was determined. Nevertheless, the determination of the structure was a challenging task that was solved by using a-priori knowledge of the system behaviour in combination with experimental adjustments of the main structural parameters. Inferring this automatically from a given data set remains a difficult task, in particular in real industrial processes where possibilities of the experimentation with the input signals are limited, due to technological and safety restrictions.

The focus of the presented model development was in obtaining a model that is representative enough to enable simulated control experiments. We estimate the goal was achieved and results of the simulation experiments are satisfactory. Addition of data related to operating parameters in the main process, in particular the number of operating ovens, would open a way to improve the model and perform a feasibility study involving more advanced con-

trol strategies. Nevertheless, the potential implementation of such strategies in the industrial process under study is limited with existing control equipment.

Abstract

Optimal utilization of complex processes involves real-time operational optimization and scheduling, especially in cases where the production line consists of both continuous and batch operated unit processes. This kind of real-time optimization requires process models which can be computed significantly faster than real-time. Iterative balance calculation is typically far too slow for these cases. This paper presents a method for converting an iterative balance model to a directly calculating model suitable for on-line process optimization. The approach is demonstrated with the first unit process in the copper smelting line, the flash smelting furnace (FSF). The method consisted of formulating an equation group based on the constrained FSF HSC-Sim model and solving the unknown parameters and static states with use of a symbolic calculation software. The solution was implemented as a function whose calculation time fulfilled the requirements for scheduling use.

Keywords: real-time model, static, mass balance, equation group, symbolic computation, metallurgy, copper smelting, scheduling

1 Introduction

The general digitalization of society has brought on a pronounced digitalization wave in process industry. The benefits of digitalization are not fully utilized in some conventional industrial processes and there new advantages are available which can improve their efficiency and ability to stay competitive in increasing global competition. Often the design of these industrial processes is based on long term empirical and theoretical knowledge which has been incorporated into thoroughly built mathematical models. These models often include iterative balance calculations to fulfill empirical and physical process constrains. These models are well suited for steady state process design and often used when offering, planning and constructing new process lines.

Optimal utilization of processes typically involves real-time operational optimization and scheduling, especially in cases where the production line consists of both continuous and batch operated unit processes. This kind of real-time optimization requires process models which can be computed significantly faster than real-time. Iterative balance calculation is often far too slow for these cases. The high demand on execution time can often be compensated by lowering demands on model precision for the real-time operation optimization. Examples of demanding real-time optimization utilized in process design can be found in (Harjunkoski et al., 2016; Touretzky et al., 2016; Pelusi 2012a; Pelusi 2012b).

Good examples of thoroughly built steady state models can be found in metallurgy. Most metallurgical processes are old and have large societal impact which has allowed extensive development work to model process behavior over many decades. These processes comprise complex physical and chemical reactions and modelling has been both theoretical and empirical. To fulfill the basic requirement of mass and energy conservation and empirical observations iterative calculation is often employed.

The incentive for this study is the need for operational optimization of a copper smelting line. Optimal operation of a copper smelting line is challenging for the operators as the operation is divided into many complex individual sub processes. Plant wide operation is required to maximize production and resource efficiency. Additionally, more challenging ores have to be used to retain economic competitiveness worldwide which increases the need for process optimization. Improved operation of copper smelting can provide improved utilization of different input materials and recyclants. Copper smelters present a challenging optimization problem where the harsh environment can prevent obtaining mineral and operational information, data is highly uncertain or measurements may be severely delayed. A full scale optimization of the complete process line will include a considerable amount of variables and require the consideration of large time horizons. Further, many of the underlying models are nonlinear. Thus, sub processes and the related models should be relatively lightweight in terms of their computational requirements. In principle, the development of optimization for a copper smelting line

operation consists of modelling of unit processes and designing of optimization / scheduling for the combined unit process models.

Static input output process models can be derived with use of mass and energy balances supplemented with sometimes uncertain process reaction knowledge completed with empirical knowledge. In principle this empirical knowledge can be written as constraints in equation form. These equations can be completed with mass and energy balances to form a complete equation group determining process reactions. By solving the equation group, the unknown parameters and thereby the static process state can be solved under the given constraints. In practice this approach is challenging as the equations are often complex and manual solutions may be error prone and exceptionally time consuming. Development of aids for this challenge started in the beginning of the 1970s under the scientific area of symbolic computation. Software programs for manual computation are called computer algebra systems (CAS) and are at present highly developed and even implemented in hand held calculators. These systems include Mathematica (Wolfram) and Maple (Maplesoft), the latter has been implemented in Matlab (Mathworks) as the Symbolic Math Toolbox. In later Matlab versions, the toolbox is based on the MuPAD symbolic engine originally developed at the University of Paderborn. Matlab offers a convenient way of shifting from symbolic calculus to numeric powerful computation.

Utilization of symbolic computation for solving unknown variables of restricted mass balance equations seems to be a rare approach or rarely reported. A similar method was used in (Korpela et al., 2014) in the same research group but the authors have not found similar work by others. Symbolic computation is, however, commonly utilized when forming first principle models (Belkhir et al., 2015; Lin et al., 2009; Yakhno et al., 2016). Its use is especially convenient for model design with e.g. Lagrangian mechanics (Moosavian et al., 2004).

For optimization of the operation of the copper smelting line computationally lightweight models of all unit processes are required. This paper presents a method for converting an iterative balance model to a directly calculated model suitable for process operation optimization. The method is demonstrated with the first unit process in the copper smelting line, the flash smelting furnace (FSF).

2 Copper Production Line

Copper smelting begins from the mixing of a suitable concentrate mix with a copper content of 20-30 % which, after drying, is fed to the FSF. The mix reacts with the oxygen-enriched air feed and separates to matte (~62-70 % Cu) and slag. These are removed intermittently from the FSF, matte is moved to the converters, and slag is processed further in the slag treatment plant. After treatment, both FSF and converter slag can be recycled back to the FSF. The matte copper content can be viewed as one of the main decision variables in smelting as the higher copper content in matte is, the higher the copper content in the slag. Additionally, it is often used as a variable in separation of other valuable metals to both matte and slag. Silica flux is added to the FSF feed and to converters during operation to achieve suitable conditions for separation of matte and slag. One of the main bottlenecks for operation is the capacity of the gas treatment plant which produces sulphuric acid from the off gasses of both the FSF and converters.

Pierce-Smith converters use a submerged feed of oxygen enriched air. Converters are operated in batches where first, in multiple slag-making stages, FSF matte is added between air blows. Here, most of the iron compounds will react and move to slag. Second, in one longer copper-making stage the remaining sulphur is removed from copper compounds. Temperature is controlled with the addition of recycled material, e.g. scrap metal. Finally, the ensuing blister copper (~99 % Cu) is moved to anode furnaces where oxygen is removed from the matte and copper is cast to anodes for transportation to electrolysis. Figure 1 shows a full copper production line including both smelting and refining. A detailed description of the smelting process can be found for example in (Schlesinger et al., 2011).

3 Model Conversion

The method for converting an iterative balance model to a directly calculating model is here demonstrated with a model of the flash smelting furnace, modelled in HSC-Sim (Outotec). HSC-Sim is a calculation module of HSC Chemistry software developed by Outotec. The name refers to the automatically utilized thermochemical database which contains enthalpy (H), entropy (S) and heat capacity (Cp) data for an extensive amount of chemical compounds. The HSC-Sim module enables application of HSC Chemistry to a whole process made up of process units and streams. The HSC-Sim module consists of a graphical flowsheet and spreadsheet type process unit models. The custom-made variable list enables creation of different types of process models in chemistry, metallurgy, mineralogy, economics, etc. Each process unit is actually one Excel file. In the Distribution units the compounds are divided into elements and calculation is done with element distribution coefficients. Based on process knowledge some coefficients are defined as fixed. Coefficients for assisting elements in compound formation are calculated based on molar need and supply and called float. Surplus elements are divided with coefficients called rest. Units can be used together or separately and the calculations can be Excel- or DLL-based.

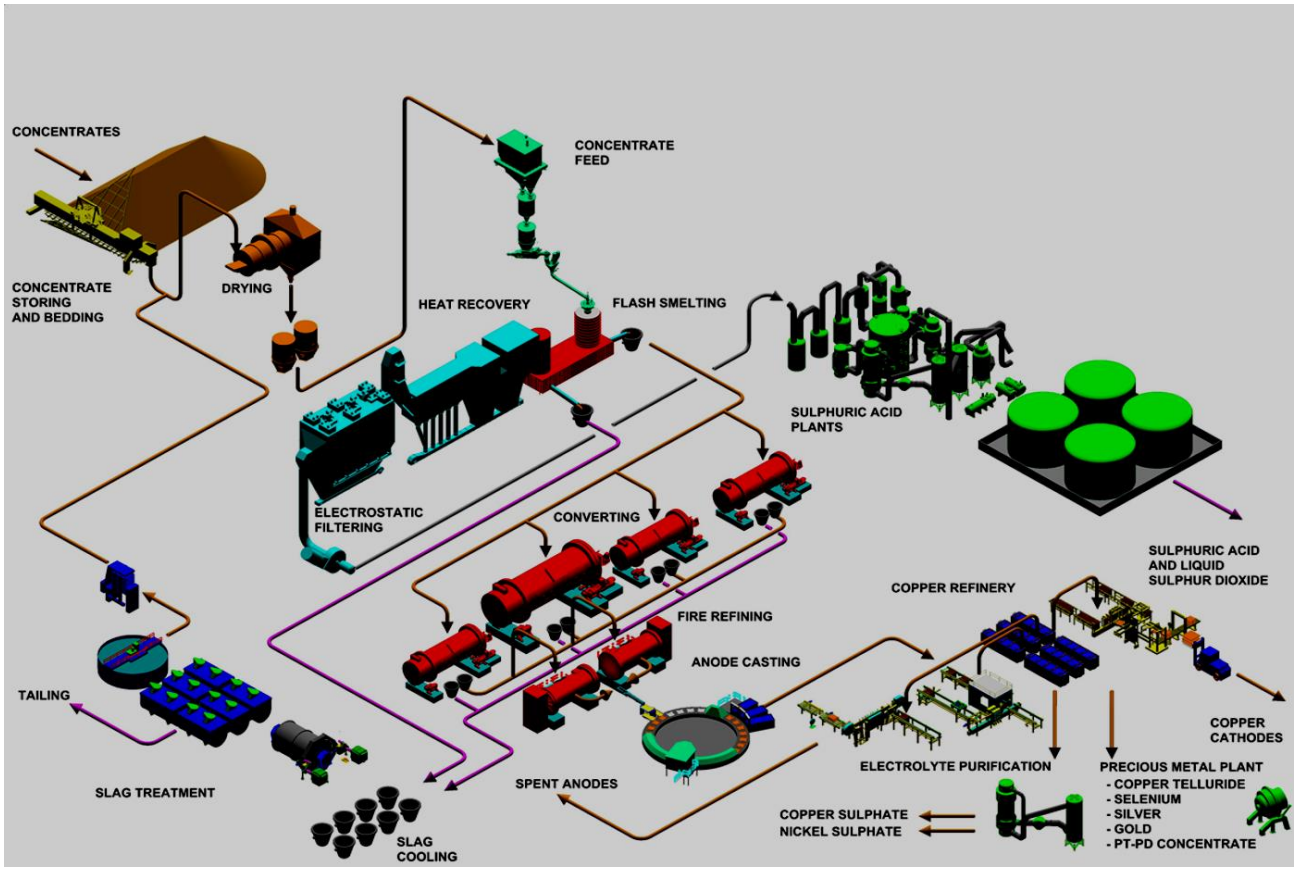

Figure 1. Flow sheet of copper process at Boliden Harjavalta (Boliden).

HSC Sim pyro models are mathematical process models based on mass- and energy balances and empirical knowledge controlling the equilibrium state. These models are successfully used in strategic planning of metal processing. The drawback of these models is the iterative calculation needed for reaching the equilibrium state. This iterative calculation is too slow for use in on-line process optimization.

3.1 Legacy model

The flash smelting furnace process has been modelled in HSC-Sim as a static division process with empirical knowledge controlling parts of the division coefficients. The implementation is a spreadsheet-like division calculation with iterative calculation to fulfill constraints derived from empirical and physical knowledge.

The model consists of three main spreadsheets; Input, Distributions and Output, each containing 146-424 rows and 68 columns. The Input sheet is sparsely filled with element mass flows and describes how input compounds in different streams are broken up to elements according to chemical molar consistency. The Distributions sheet is sparsely filled with distribution coefficients dividing element mass flow into compounds for different output streams partly according to chemical reactions. The Output sheet is filled with corresponding element mass flows that build up the output compounds in different output streams. Additionally, to the three main spread sheets, a Controls sheet includes 27 empirical process observations that must be fulfilled in the stationary state.

In principle, the distribution from input compounds to output compound is built up around how the main elements copper (Cu) and iron (Fe) is distributed between compounds in the output streams. The chemical reactions requre assisting element as oxygen (O) and silicon (Si) which are brought in as floating elements. Sulphur (S) is partly handled as a main element and partly as an assisting element. As a result the model consists of some fixed distribution coefficients, many coefficients which are iteratively adjusted to fulfill the empirical observations and numerous coefficients calculated as float according to corresponding chemical reactions or as rest for surplus elements. The model is thus a system of four spread-sheets with a large number of interconnected cells. An iterative routine is used to solve the distribution coefficients and thereby the element and compound streams in the stationary state.

The calculation is very useful for off-line strategic planning of metal processing. The calculation is, however, too slow for real-time process optimization.

3.2 Method for derivation of fast calculating model

In general, the objective for the study was to find a method for converting iterative output controlled balance models to directly calculating models suitable for process scheduling. The basic idea was to form a symbolic equation group based on the flash smelting furnace HSC-Sim model and to solve this group analytically with symbolic computation to achieve causal outputs as direct functions of inputs. The solution is possible due to empirical knowledge included in the Controls sheet of the FSF HSC-Sim model.

Thus, the task was to write a fully parametrized equation group based on the FSF HSC-Sim model where the equations are based on the equations of empirical knowledge in the Controls sheet. The model is in this analytic approach simplified. The input elements include only the main elements; copper (Cu), iron (Fe), nitrogen (N), oxygen (O), sulphur (S), silicon (Si) and other content (Ot). The distribution of the elements between the output streams, which are settler gas, settler fume, settler dust, slag and matte, is fully in line with the FSF HSC-Sim model. The eight equations determining empirical knowledge regarding the main elements was chosen as base for the equations. To enable an analytic solution with the symbolic software the equation group has to be exactly determined.

The equation group formulation starts with defining all basic variables as symbolic variables. This example included 7 element mass flows, 23 distribution coefficients for element distribution to output streams and 41 distribution coefficients for element distribution into compounds in the different output streams. The main formulation work is to define the relationship between these variables with emphasis on the formulation of the float and rest variables. Here, this part required about 75 definitions. After these definitions, the output compounds can be formulated. Afterwards, the final equations based on the empirical knowledge in the Controls sheets can be written. To ease the derivation of the analytic solution of the software the nonlinearities in the empirical knowledge were linearized. The same variables as the manipulated variables in the iterative solution of HSC-Sim model were chosen as variables for the calculation to solve. They were; distribution coefficient for Fe to matte, distribution coefficient for Fe in slag to FeS, distribution coefficient for Cu to slag, distribution coefficient for Fe in matte to Fe_3O_4, Ot to matte, Si input stream, O input stream and distribution coefficient for Fe in slag to Fe_3O_4.

This study utilizes the Symbolic Math Toolbox in the Matlab software. With the relationships concerning use of oxygen still undefined, the solver managed to achieve a fully symbolical solution in around five minutes with a laptop. When oxygen is taken into account, the solver has been forced to settle for a numeric approximation, which still includes all the variables in an appropriate manner. The length of the analytic solutions is over 25 000 characters. The solutions are at this stage provided with the values of the fixed variables. The last task of the program is to produce usable functions of the long analytic solutions.

4 Model Validation and Discussion

Model validation is performed to ensure usability of the model in real-time process optimization and scheduling. As copper content in matte is a good measure of the process state, the validation is performed at varying matte copper percentage.

4.1 Similarity to legacy model

Figure 2 shows a comparison between the analytical direct solution results, with the blue line, and iteratively calculated HSC-Sim results, red line, as function of matte copper percentage.

The cause for the differences is the fact that the analytically solved model is a simplified model of the process including only the main elements. E.g. both silicon and oxygen is consumed by other minor compounds which are not included in the model. The difference is mainly a shift of magnitude which can easily be compensated by a term proportional to the total concentrate flow. With this compensation the analytically solved model is adequate for the on-line utilization.

4.2 Calculation time

As the optimization and scheduling algorithm calls the model hundreds of times per second the calculation time has to be short. A test function call from Matlab showed that the execution time is only some milliseconds for calls of two to eight variables, which is sufficient for the on-line utilization. The calculation time for the iterative solution of the HSC-Sim model is tens of seconds.

5 Model Utilization

The directly calculating model of the flash smelting furnace process will be utilized in scheduling of a copper production line to optimize production and costs. When solving the equation group the solvable variables can be freely chosen. There are two evident ways of model formulation that can be utilized.

5.1 Direct input output

A natural solution would be to form a direct input output model to mimic the real smelting process. Figure 3 represents a scheduling structure that utilizes the input output model. As scheduling is a high level task whose interests are in production rate and oxidation level in first stage smelting, a lower level control structure has to deal with the unit control of the flash smelting furnace. This is shown as feedback control of the open

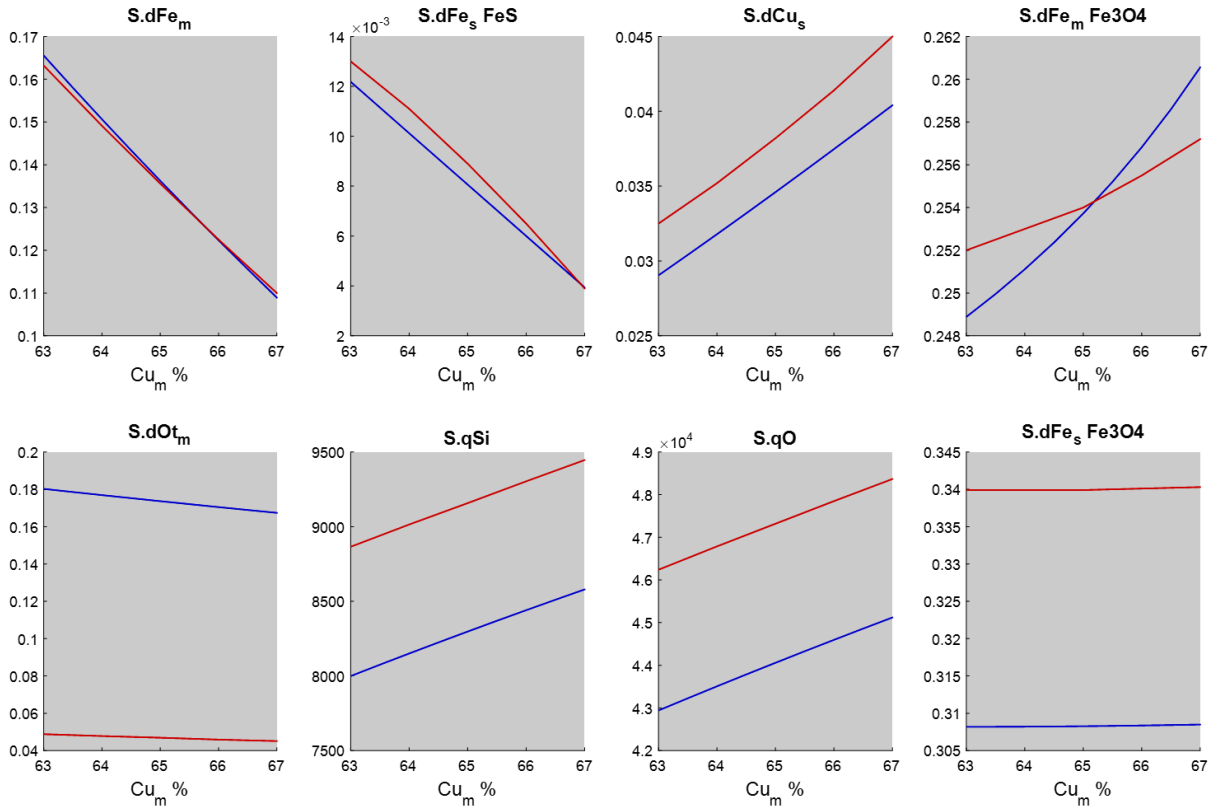

Figure 2. A comparison between analytical solution results with blue line and iteratively calculated HSC-Sim results with red line.

loop model. In practice, this could be a sub optimization task for the scheduling routine.

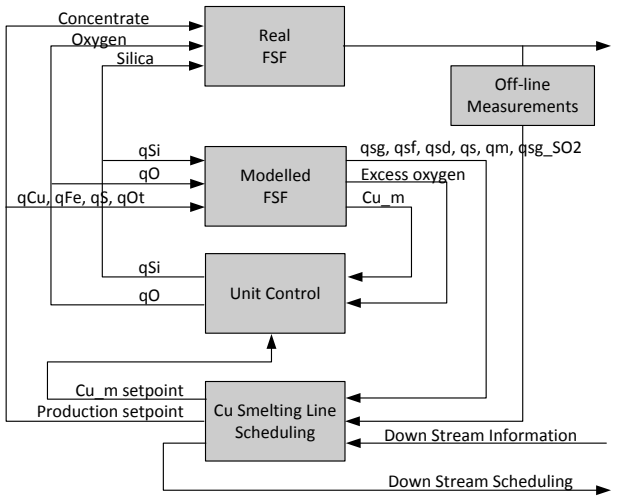

Figure 3. Direct input output model utilized in scheduling.

5.2 Closed analytic solution

To enhance the direct scheduling interests, the required control variables can directly be chosen as solvable variables in the equation group. The static model allows us to utilize a closed analytic solution whose scheduling structure is clear and shown in Figure 4. This direct solution will not need the sub optimization. Feedback from the off-line measurements compensates for model inaccuracy.

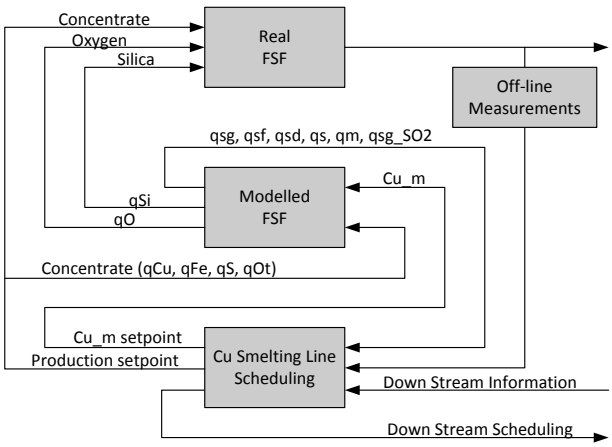

Figure 4. Closed analytic solution utilized in scheduling.

6 Conclusions

The objective of this study was to develop a method for converting iterative output controlled balance models to directly calculating models for process optimization and

scheduling. This method was used in the case of a flash smelting furnace, previously modelled in HSC-Sim. The fast calculating model is to be used in optimization of the total production line operation.

The method consisted of formulating an equation group based on the constrained FSF HSC-Sim model and solving the unknown parameters and static states with use of a symbolic calculation software. The study was successful even if it requires careful formulation work and the solution matched the solution of the original model. The equation group should be fully determined to enable a solution. The solution was implemented as a direct calculation function whose calculation time fulfilled the requirements for scheduling use.

The advantage with the approach is that even though the length of the generated functions disables model maintenance in function form, functions can easily be recalculated after updates in the HSC-Sim model are done. The modelling method has shown to be a powerful general way of converting complex iteratively solvable models to fast directly calculating models for utilization in process optimization and different operator advisory systems.

The presented demonstration model did not include an energy balance and thereby the amount of nitrogen (N) feed is kept constant even if the nitrogen feed is in practice the means to affect process temperature. The legacy model is built on the assumption that temperature is on normal level which enables a mass balance without temperature dependency. The energy balance will be included in future work.

Abstract

Carbon dioxide absorption by mixtures of propylene oxide / polypropylene carbonate at 60^0C was monitored by Raman spectroscopy at 20, 40 and 60 bar in a 2 L autoclave reactor. Multivariate preprocessing techniques were used to process raw Raman spectra and Principal Component Analysis was performed. Simulation data from the Peng- Robinson equation of state were used to model the absorbed CO_2 amount and spectroscopic signals. Results showed that Principal Component Analysis can be used to explore the dynamics of the system at different pressure levels and to track the CO_2 absorption. A similar analysis was carried out to monitor CO_2 absorption by four different amines at room temperature and pressure in a batch reactors. The CO_2 content was determined from titration and was used to model the spectroscopic data. Principal Component Analysis proved to be able to identify CO_2 absorption capacity in the amines. This feasibility study confirms that Raman spectroscopy together with multivariate analysis can effectively report chemical information and dynamics in these CO_2 absorption systems and hence can be used for developing regression models for online monitoring and control.

Keywords: principal component analysis, CO_2 absorption, propylene oxide, amines

1 Introduction

Carbon dioxide (CO_2) is known to be the primary greenhouse gas contributing more than 60% of global warming. Capturing CO_2 from power plants and industrial sources and utilization them to produce usable products is of paramount importance from a standpoint of "waste to money". Absorption of CO_2 by amines is one of the most popular technologies for CO_2 capture. Amines are categorized as primary, secondary or tertiary amine based on their chemical structure. The reaction between amines and CO_2 is complex (McCann *et al*, 2009). However, when considering the CO_2 mass balance, it can be seen that once absorbed by a primary amine, CO_2 will remain in the form of carbonate, bicarbonate, carbamate or molecular CO_2 as given in (1). When it is a tertiary amine, there is no carbamate formation (2).

Synthesis of polypropylene carbonate (PPC) by reaction of CO_2 and propylene oxide (PO) in the presence of a catalyst has become a fascinating research area as a CO_2 utilization technique to produce a polymer out of a waste greenhouse gas (Jiang *et al*, 2014). In the presence of a catalyst, the chemical reaction of PPC synthesis takes place as given in (3).

CO_2 absorption capacity by an amine or by in the liquid phase PO is a key performance criteria in industrial scale CO_2 capture and polymerization processes. However, the measurement of CO_2 absorption in these mixtures are challenging and require proper understanding of the chemistry behind reaction (1), (2) and (3). Several offline analytical instruments and chemical methods are available such as titration, Nuclear Magnetic Resonance spectroscopy and gas chromatography to determine the CO_2 absorption in both applications above. Most of these methods are time consuming. A fast, online method to detect CO_2 absorption is important in process monitoring and control. Considering the in-situ performance, Raman spectroscopy can be suggested as a competitive approach for this purpose. It gives chemical information of a sample as a function of Raman wavenumber and scattered light intensity. When converting the information given by a Raman spectroscopy, multivariate calibration is required to transform the spectroscopic measurement into informative output. Raman spectra contain several wavenumbers or group of wavenumbers which are chemically important and needed to be included in the multivariate regression models. However, it is often misleading to use

traditional multilinear methods such as ordinary least square for calibration, when a single wavenumber (X variable) is not sufficient to predict the useful quantity (y variable); when X variables are highly correlated or when there is no adequate information to understand which X variables are correlated to the y variable. In such instances, multivariate analysis gives the advantage of overcoming the collinearity problems while preserving useful information hidden in collinear data. In this study, Principal Component Analysis (PCA) which is a fundamental multivariate analysis tool, has been used as a data compression and exploratory method to investigate the feasibility of Raman spectroscopy as a viable analytical technology to quantify CO_2 absorption by amines and propylene oxide. Eight experimental cases have been used in this analysis. Four of them are related to CO_2 absorption by PO and a mixture of PO and PPC. These experiments were meant to compare CO_2 absorption in the CO_2-PO system with respect to the CO_2-PO-PPC system at some selected process conditions. The other 4 experiments were used to identify CO_2 uptake by four liquid amine solvents. These solvents are currently in research interest to capture CO_2 from flue gas in power plants and industries (Leung *et al*, 2014).

2 Methods

Experimental description of 8 test cases are presented in Table 1. Six organic chemicals were used in the experiments and they are given in Table 2. Case 1-4 were carried out in a closed 2L steam jacketed autoclave reactor equipped with a stirrer while the pressure was increased gradually by adding CO_2 to the reactor. Case

Table 1: Description of test cases.

Case Number	CO_2 loaded solution	Description
1	PO in non-stirred condition	Each case has one sample in a 2L reactor at 60^0C. Tested pressure levels :20, 40 and 60 bar Stirrer speed = 400 rpm
2	PO in stirred condition	
3	PO+PPC in non-stirred condition	
4	PO+ PPC in stirred condition	
5	MEA 37 samples	Each sample in 10 mL glass reactor. Reaction between CO_2 and amine took place at room temperature and pressure
6	3AP 42 samples	
7	3DMA1P 41 samples	
8	MDEA 41 samples	

1 and 2 were PO-CO_2 binary mixtures while Case 3 and 4 were PO-PPC-CO_2 ternary mixtures. A Raman immersion probe was connected through the bottom of the reactor and signals were acquired continuously with time. In case 5-8, CO_2 absorption on liquid amines was observed under equilibrium condition at room temperature and pressure. Raman signals were recorded by immersing the Raman probe into sample reactors after allowing each sample to reach equilibrium.

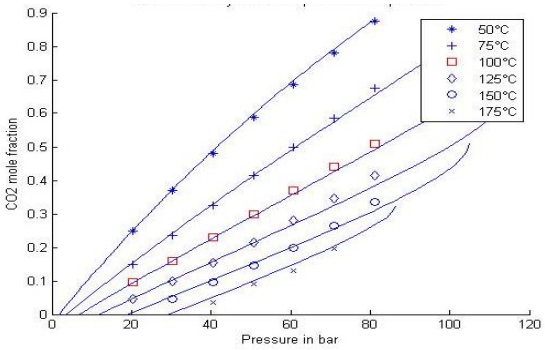

Figure 1. CO_2 mole fraction of PO-CO_2 system at different pressures and temperatures (Peng-Robinson model with binary interaction parameter equal to 0.281).

Table 2. Description of materials.

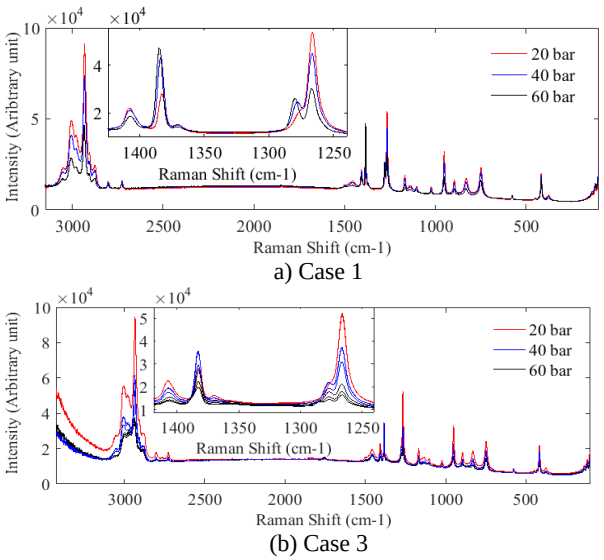
Name	Abbreviation	Chemical structure	Chemical category
Propylene oxide	PO		epoxide
Polypropylene carbonate	PPC		a copolymer of CO2 and PO
2- Aminoethanol	MEA		Primary amine
3-Amino-1-propanol	3-AP	$H_2NCH_2CH_2CH_2OH$	Primary amine
3-dimethylamino-1-propanol	3DMA1P		Tertiary amine
Methyl diethanolamine	MDEA		tertiary amine

2.1 CO_2 in polymer solutions – from thermodynamic models

In this study, Raman signals (X variables), were calibrated with the absorbed CO_2 content (y variable). Reliable measurement of y variable in Case 1-4 using an analytical method is challenging as CO_2 quickly desorbs if a sample is taken out from the reactor for analysis. Therefore, the CO_2 content data at required pressure and temperature were calculated from the vapour-liquid equilibrium (VLE) data of CO_2-PO system generated using the Peng-Robinson equation of state. The Peng-Robinson model was fitted using experimental data reported in (Chen *et al*, 1994; Shakhova *et al*, 1973). Figure 1 shows predictions of the CO_2 mole fraction in PO-CO_2 system using Peng-Robinson model simulated in Aspen Plus V7.2 software which shows that the absorption of CO_2 at a constant temperature gives a linear behavior with pressure. This linear relationship was taken to model the CO_2 mole fraction at 60^0C at which the experimental cases of 1-4 were carried out.

2.2 CO_2 in amine solutions – from titrations

In experiments from case 5-8, each sample contained 30 % of solvent (solvent weight/total weight of water and solvent) but different amounts of CO_2 added. They were prepared in 10 mL glass reactors and after reaching equilibrium a titration method was carried out to measure its true CO_2 content in units of moles CO_2 per mole solvent.



a) Case 1

(b) Case 3

Figure 2. Raman signals of CO_2 loaded polymer samples.

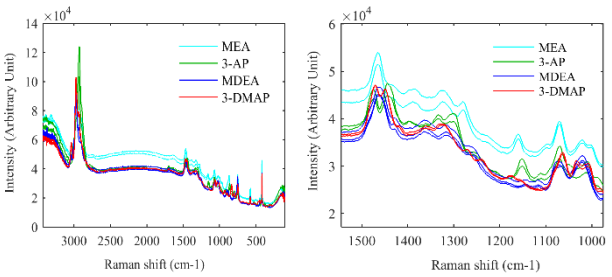
2.3 Raman Spectroscopy

Raman spectroscopy used in this study was Kaiser RXN2 Analyser of 785 nm laser wavelength, 400 mW laser power and 100-3425 cm^{-1} spectral range. An immersion optic probe which is connected to the RXN2 Analyser via a fibre optic cable, carries the laser light to the sample and in-elastically scattered Raman light is conveyed back to the instrument. The instrument output is a plot of intensity of scattered light versus energy difference (given by wavenumber in cm-1) which is called a Raman spectrum. Peaks and their intensity in a Raman spectrum carry information about the chemicals and their composition respectively.

2.4 Data Processing

For a set of n objects (eg: different samples or signals with time), a Raman spectroscopy measurement generates a data matrix of n x p where p is 3326 Raman wavenumbers. This data matrix contains useful information about the chemical fingerprint of objects as well as noise. They are also called residuals which can be due to the interference of other chemical components, laser input variations or instrument noise. Unless any data conditioning method is applied to remove this unwanted structure from the data matrix, calibration of spectroscopic signals will not be reliable and do not really generate a model which really represent the variation of analyte of interest.

Three data pre-processing techniques were applied for raw Raman data. These were baseline-whittaker filter, standard normal variate (SNV) and mean centering. The baseline-whittaker filter available in PLS toolbox in Matlab is an extended version of (Eilers, 2003) where a weighted least square method is applied to remove background noise and baseline variations. A detailed description of the algorithm can be found in the original work (Eilers, 2003) and (Atzberger *et al*, 2010). Some



(a) 100-3325 cm^{-1} (b) 950-1550 cm^{-1}

Figure 3. Raw spectra of CO_2 loaded samples (Case 5-8).

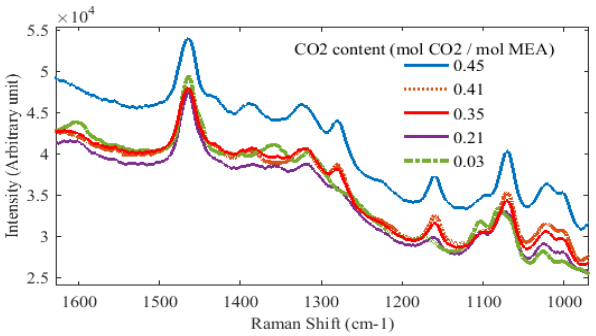


Figure 4. Raw spectra of CO2 loaded MEA samples (Case 5).

spectra which should be otherwise identical, become different due to baseline and pathlength changes. SNV was applied to remove these scatter effects in the spectra which were specially observed in case 1-4. The algorithm is similar to autoscaling row wise and hence corrects each spectrum individually (Barnes *et al*, 1989). By mean centering of data, each column in the data matrix is centered by subtracting the mean. It is reported that by mean centering, rank of the model is reduced, data fitting accuracy is increased and offset is removed (Bro *et al*, 2013).

2.5 Principal Component Analysis (PCA)

Principal component analysis is one of the most important data analysis methods providing a platform for advanced chemometrics methods. As stated in (S. Wold *et al*, 1987) PCA can have many goals; simplification, data reduction, modelling, outlier detection, variable selection, classification, prediction and unmixing. It can be used to understand general characteristics of data set and guide further investigation through more refined techniques (Wentzell *et al*, 2012). PCA reduces the dimension of data by calculating principal components (PCs) which reflect the structure of data corresponding to maximum variance. These PCs can then be plotted to visualize the relationship between samples and variables through the use of scores and loading plots. A tutorial review on PCA can be found in (Bro *et al*, 2014). Decomposing a data matrix X into a structure part which consists of a score matrix (T) and a

loading matrix (P) and noise part or residual matrix (E), is shown in (4) and (5).

$$X = TP^T + E \quad (4)$$

$$X = t_1 P_1{}^T + t_2 P_2{}^T + t_3 P_3{}^T + \cdots + t_A P_A{}^T + E \quad (5)$$

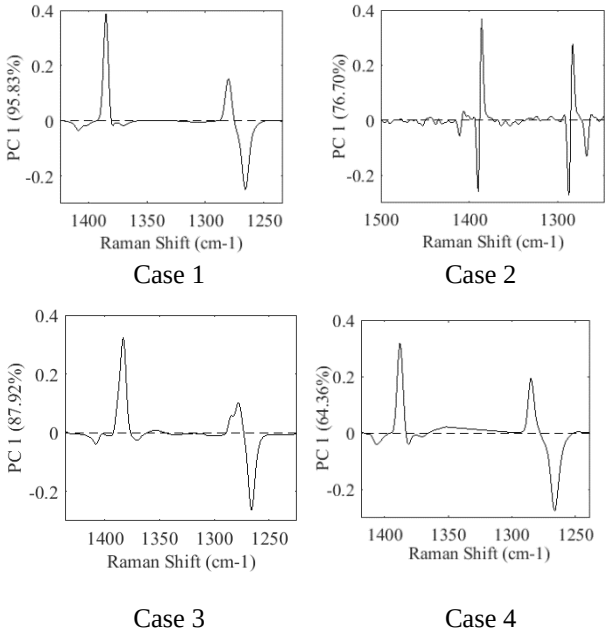

Figure 5. Loading plots of the first principal component for case 1-4 (Region : 1225 – 1450 cm-1).

t_A and P_A are score vector and loading vector for PCA respectively. PC1 is the first principal component which relates to the maximum variance of the data, and PC2 is the second principal component which corresponds to the second largest variance etc. Score values provide information about sample variations while loading value explains the relationship between variables. Residuals provides information as to what spectral variations have not been explained. There are different ways to decompose a matrix to score and loading vectors. NIPALS (*Non-linear Iterative Partial Least Squares*) algorithm (H. Wold, 1966) uses iterative sequence of ordinary least square regression to calculate PCs and was used in this study.

2.6 Important variables related to CO_2 absorption

CO_2 absorbed PO, PPC and amine mixtures exhibit several sharp overlapping peaks in the region of 300 to 1500 cm-1 and 2700 to 3250 cm-1. The focal point in this study is to investigate CO_2 absorption and hence only the peaks related to absorbed CO_2 are considered in the model development. In case 3-4, the monomer PO and the polymer PPC were added into the autoclave reactor and the CO_2 was absorbed into this mixture. Therefore, CO2 bands related to dissolved CO_2 in the PO or PO/PPC mixture were followed in this study.

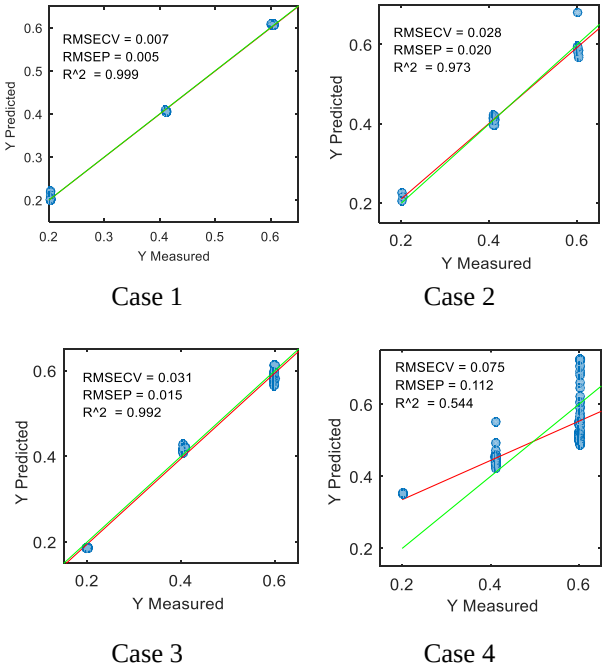

Figure 6. Development of linear regression model using PC1 score values and thermodynamic model data.

(Y measured = CO_2 mole fraction predicted by VLE data; Y predicted = CO_2 mole fraction predicted by PC1 scores; red line= best fitted line based on calibration points; green line=1:1 target line; RMSE (CV/P)= root mean square error of (cross validation/prediction)

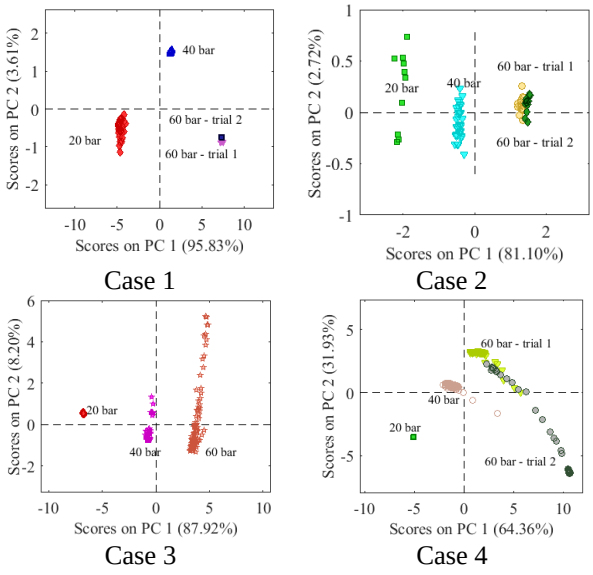

Figure 7. Score plots – PC1 vs PC2 for case 1-4.

Literature reports such Raman wavenumbers of 1264, 1284, 1369, 1387, 1408 cm-1 (Hanf *et al*, 2014). In case 5-8, peaks related to carbonate, bicarbonate, carbamate and dissolved CO_2 fall in the region of 1000-1500 cm-1 ((Vogt *et al*, 2011), (Wong *et al*, 2015)). Therefore, for development of PCA models, the region between 1000-1500 cm-1 and 1225-1450 cm^{-1} were selected for case 1-4 and case 5-8 respectively.

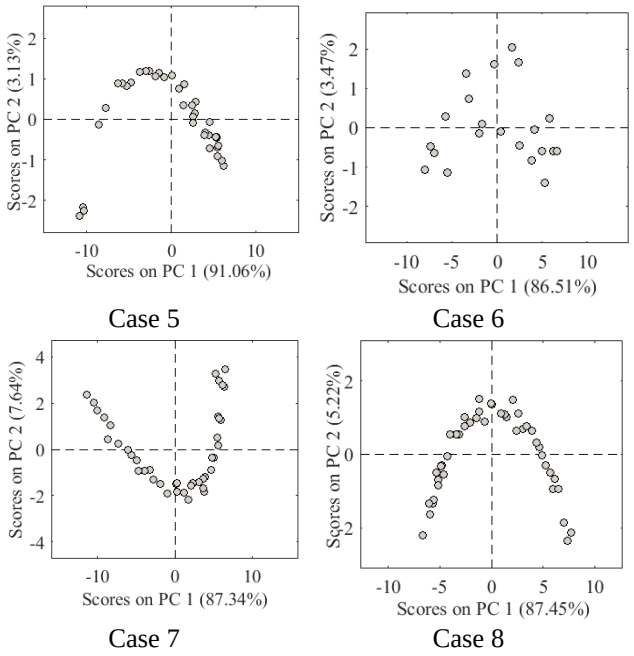

Figure 8. Score plots for case 5-8.

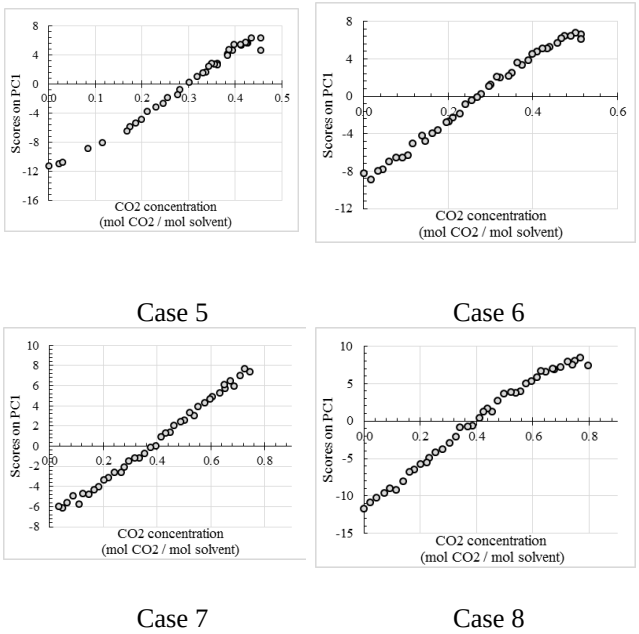

Figure 10. Development of linear regression model using PC1 score values and CO_2 content given by titration data.

3 Results and Discussion

Figure 2 (a) and (b) show raw spectra for case 1 and 3 respectively highlighting spectral variation with increasing pressure in the region of 1225 to 1450 cm^{-1}. CO_2 peaks at 1264, 1284, 1369, 1387, 1408 cm-1 can be identified in this figure. A similar spectral behavior was observed for case 2 and 4 in the same region. Figure 3 gives raw Raman signals observed for CO_2 loaded 4 different amine solvents. Only two spectra from each solvent are shown. Figure 4 shows how the intensity of Raman bands varies with the CO_2 content for MEA samples (Case 5). Both Figure 3and Figure 4 claim that spectral evolution in the region between 1000 to 1500 cm-1, for case 5-8 with respect to case 1-4 is complex due to curved baseline, baseline offsets and overlapping bands. The reason is that the chemical products when CO_2 is reacted with the solvent appear with overlapping peaks in this region. Therefore, when quantifying the total amount of CO_2 absorbed in solvent, all these peaks are needed.

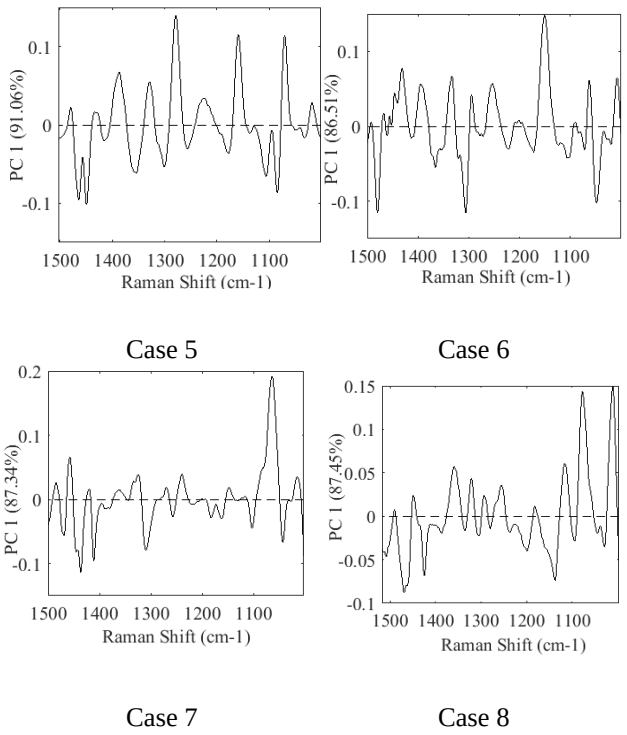

Figure 9. Loading plots of the first principal component for case 5-8.

All the Raman signals under each case were first smoothed using baseline-whittaker smoother, then SNV and finally mean centered. PCA was performed for processed data. First principal component was identified as the dimension explaining the largest variance of data in each case. Finally, score values of PC1, were compared with the mole fraction of CO_2 predicted by thermodynamic models for case 1-4 and CO_2 amount determined from titration for case 5-8. Loading plot, score plot and comparison of PC1 score value with CO_2 content under each case were used to explain characteristics in each system.

3.1 Case 1-4

With reference to Figure 5 loading plots of case 1, 3 and 4 almost give similar information about important variables (Raman shifts) while case 2 is different. This is caused by exposing the Raman sensor to both gas and liquid phases as a result of high stirrer speed and

development of vortex in case 2. There is also low viscosity in the medium at low pressures, which creates high turbulence. Score plots of PC1 vs. PC2 as given in Figure 7, show clear distinguish of recorded signals between the three pressure values of 20, 40 and 60 bar. PC2 direction explains only a small variation of data for case 1-3. Experiments for 60 bar, were conducted in replicates and their overlap in score values could be observed in case 1 and 2.

Figure 6 shows how closely PC1 score values are related to VLE data. Plots in this figure were derived by linear regression between PC1 score values as X variables and predicted CO_2 content from VLE data as y variables. From VLE data, CO_2 mole fractions at 20, 40 and 40 bar are 0.202, 0.411 and 0.601 respectively. These values are represented as 'Y measured' in Figure 6. PC1 score values at 3 pressure conditions follow the linear trend given by the mole fraction of CO_2 predicted by thermodynamic models at case 1 and 2. In the presence of PPC (case 3-4), even though pressure and temperature were maintained constant, a significant time was needed to achieve equilibrium condition of CO_2 absorption by the solvent especially at higher pressure region. For example, at 40 bar and 60 bar, PC1 score value of the initial spectra is less than the final recorded spectra at that condition. Therefore, although the reactor is maintained at the required pressure, the score plot gives the hint whether the equilibrium condition has been achieved or not. The significance of the above fact can be clearly understood when examining the score plot for case 4 (Figure 7). In this trial, we see that only 20 bar condition shows a compressed data swarm while at 40 bar, PC1 score values increases with time and this variation is more significant for 60 bar. This is further assured by Figure 6 (case 4) where the thermodynamic model satisfies the trend of final recorded data for 60 bar condition, but highly deviate from the initial recorded data at this condition. PC1 score values positively correlate with the amount of absorbed CO_2 by PO-CO_2 and PO-PPC-CO_2 systems.

3.2 Case 5-8

Absorption of CO_2 by amines (case 5-8), features several important variables in the region 1000-1500 cm-1 as given by loading plots in Figure 9 and this is the result of several parallel equilibrium reactions happening in each system. Each sample carries different information which mean different amount of CO_2 absorption and hence the concentration of chemical species produced during these reactions are different. Therefore, a data spread in score plot of PC1 vs PC2 can be observed in the score plots in each case as presented in Figure 8. However, similar to polymer-CO2 system, PC1 explains the largest variation of data structure and therefore PC1 score values were compared with total CO_2 absorbed by the system. Results are shown in Figure 10. With the increasing amount of CO_2, there is a gradual increase of PC1 score value highlighting that PC1 score value is an indication of the level of CO_2 absorbed by the sample.

4 Conclusions

Monitoring CO_2 in liquid phase of PO-CO_2 system or PO-PPC-CO_2 system by analytical techniques is challenging as the CO_2 quickly desorbs if the pressure is lowered in sample taking. Therefore, online analysis such as spectroscopy is more favorable For CO_2-amine systems, an in situ characterization of CO_2 absorption gives credits to process monitoring and control ability. Based on this study, combination of Raman spectroscopy and PCA claims that PC1 score value explains variation of data structure corresponded to absorbed CO_2 amount. PCA plots give an indication of CO_2 composition, process dynamics and equilibrium conditions in these two chemical systems and hence can be used as an efficient tool to analyse collinear process data. Further investigation of PCA model development under different process parameters is recommended to validate the findings from this feasibility study. Experiments to develop advanced chemometrics tools such as partial least square regression can now be recommended for both polymer-CO_2 system and amine-CO_2 system.

Abstract

Operation in an open-pit mining is a complex task with stochastic nature. Usually, this kind of system is analyzed by means of DES (Discrete Event System) simulation. This work considers optimizing the investment in new projects in such a way to reach maximum production of an open-pit mine. When a DES model is associated with an optimization problem, the time taken to run such model is a crucial aspect. In order to analyze the project impacts in a reasonable time, this work presents a DES markovian model which represents a load-haulage cycle. The results obtained were compared with the results acquired from validated simulation models which represent the same system. In the optimization context, the complexity is exponential. Therefore, this work proposes a formulation that considers the inter-relationship between projects, which aims to help decision makers. Instead of trying all the possible projects combinations, the proposed method searches for identifying the set of projects that produce good feasible solutions based on performance measure from designed DES model.

Keywords: Markov chain, closed queuing network, project portfolio, open-pit mining.

1 Introduction

Typically, Project Portfolio Optimization decisions are strategic decisions that are made on a yearly basis. For open-pit mine, investments in its operations are needed to reduce the production cost, enhance production, eliminate bottlenecks and to improve the use of system resources. Thus, in a Brazilian mining, several projects are proposed annually in order to improve the company competitiveness. The Project Portfolio consists of many actions, including road improvements, truck or crane acquisition, hire operator, etc. Each project impacts in a specific indicator of the open-pit mine. A preliminary goal is to identify how these projects influence the company competitiveness. A fundamental goal of any mining project is maximizing the total mine ore production in a specific time horizon. Nevertheless, to improve some indicator cannot result in an effective contribution for this goal.

The open-pit-mine is a complex and stochastic system, in which interactions between several agents impact heavily on the total mine ore production. Usually, this kind of system is analyzed by means of DES simulation. According to (Banks, 2000), simulation is the imitation of the operation of a real-word process or system over time, involving the generation of an artificial history of the system. In order to analyze the real impact of each project, a DES simulation model can be used. Therefore, it is possible to estimate and make better decisions.

When DES simulation model is associated with a discrete decision problem, we can associate the control variables to a discrete optimization problem. Discrete optimization with simulation is a methodology known in the literature as *discrete optimization via simulation*. According to (Nelson, 2010), this methodology addresses solving problems with a countable number of feasible solutions, when the system is complex enough that its expected value is estimated by running simulation.

Most commercial DES simulation software are associated with some optimization software. However, these softwares use meta-heuristics or heuristics that, although efficient in many cases and modeled to be generic and applicable in various contexts, it does not exploit the problem features and hence tend to be less efficient. Fu (Fu, 2002) summarizes the optimization packages used by most popular commercial DES simulation softwares and the search strategy used as well. According to (Fu, 2002), algorithms that apply a very general way often have a slow convergence in practice.

In a portfolio optimization, the goal is to determine a set of projects that maximizes some indicator, such as *total mine production* index. Each portfolio is formed at least by one project and correct projects combinations can maximize the expected return. From the optimization point of view, the number of combinations has an exponential growth. Thus, usually it is not possible analyze all the possibilities, especially when each evaluation is obtained using DES simulation, since this methodology can be very burden.

According to (Bolch et al., 1998), the main drawback of DES simulation models is the time taken to run such models for large and realistic systems particularly when results with high accuracy are desired. Thereby, combining DES simulation with optimization is a major challenge.

Taken into account the difficulties inherent to discrete optimization via simulation, two approaches to research can be explored. The first consist in reducing the computational time used in the function evaluation. When we consider a DES simulation model as an objective function of an optimization problem, the time taken to run such model is a crucial aspect. The second approach consist in developing a specific optimization method to the problem that explores peculiarities of the modeled system.

1.1 First step - DES model

The first step aims to create a modeling of stochastic DES through markovian approximation. This strategy was motivated by successful application in the field of the performance evaluation of computational system. According to (Bolch et al., 1998), a cost-effective alternative to DES simulation consists of analytic models, which can provide relatively quick answers and more insight to the system being studied. Before the creation of nowadays computational technology, problems with stochastic nature were generally solved analytically. Marie (Marie, 2011) claims that scientific ambition was limited by computing power, i.e., it was necessary to use the imagination to look for approximations in order to reduce a state space to a few hundred states. Recently, (Marie, 2011) observed that huge amounts of available computing resources increase the trend to solve models through simulation and did not encouraged researchers to look for tractable analytical solutions.

It is important to point out that simulation is enshrined as a good methodology to treat DES model. However, in the optimization context, the number of evaluations depends on the time taken by run the designed model. Reference (Ekren et al., 2013) presents an analytical model for an autonomous vehicle storage and retrieval system. The authors model a material-handling system as a semi-open queuing network to be used instead of DES simulation. According to (Ekren et al., 2013), the analytical model is useful in estimating key performance measures of alternate configurations of the system quickly and accurately.

Marie (Marie, 2011) explain that some mathematical/probabilistic properties can be used to analyze problems of stochastic nature without simulation. Therefore, the first step of this study consist to explore and to apply this properties. A load-haulage cycle of a realistic Brazilian open-pit mine is considered. This cycle is modeled as a closed queuing network where all queues (also known as nodes) are connected. The idea is to measure the *mean response time* of each node, and consequently, the *mean cycle time* and the *total mine production* index. Therefore, these performance measures are used in the optimization context to find a good and fast answer.

In this study we consider the cdf (Cumulative Distribution Function) approximation using exponential distribution. We assume that the service time of each node is exponentially distributed while this is not true in the real model. It is important to point out that this kind of approximation cannot provide a reasonable accuracy. Therefore, the results obtained by this approach are compared with the results acquired using validated simulation models presented in (Ribeiro, 2015). These models consider pdf (Probability Density Function) approximation using general distribution. A Petri net model and a SIMAN model representing the same load-haulage cycle are considered. The assumption is to verify whether there are significant difference among the designed analytical approximation model and the mentioned methodologies of DES simulation.

1.2 Second Step - Portfolio optimization

The second step of this study consist in determining the set of projects which maximizes the *total mine production* index respecting the established budget. One approach is to formulate this decision as a knapsack problem which is a classical combinatorial optimization problem (Pisinger, 1994). Figuratively, we can describe this problem as filling a backpack without exceeding a certain volume limit. The decision consists to place in the backpack products that maximize (maximization problem) a specified value, respecting its capacity. In this study, the products are the projects at the portfolio and the capacity is the available budget.

In order to analyze the real impact of witch project, the DES model is used. Hence, it is possible to estimate how much each one increases the *total mine production* index. Here, we named this estimative as 'gain'. A linear solution can be found maximizing the sum of individual gain. However, we cannot consider each project individually. Due to the open-pit mine features, there are interrelationships among projects. It means that a combination of two or more projects must result in different gain compared with the linear solution. Since it may unfeasible evaluate all projects combinations, the optimization strategy aims to create a formulation where the decision variables set is formed by all individuals projects in the portfolio and all 'relevant combinations'. In this study, a 'relevant combination' is a set with at least two projects with a strong inter-relationship among them. A major challenge is to find how intense this inter-relationship is.

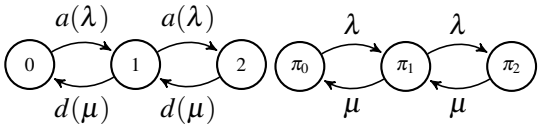
In the load-haulage cycle, the *total mine production* index depends on the *mean response time* taken in each node of the cycle. Some projects aims to reduce the service time in a specific node. A disadvantage of applying these projects is the possibility of increasing the *mean response time* of others nodes. Consequently, neither total cycle time nor *total mine production* index will be changed. The central core of the optimization method is to use the *mean response time* of each node to find 'relevant combinations'. The major idea is that this performance measure

indicates the plant bottlenecks, which must be fixed by the new projects. Section 5 describes the philosophy behind of the strategy.

2 Stochastic DES model through markovian properties

A general way to represent a stochastic DES model is through stochastic timed automata. According to (Cassandras, 2008), any timed model for DES requires the specification of a clock structure. This structure is a set of distribution functions, one for each event, characterizing the corresponding lifetimes. Beside that, it determines the dynamic of the system. When all clock sequences are iid (Independent and Identically Distributed) and the interevent times are exponentially distributed, a stochastic DES can be modeled as a Markov Chain (Cassandras, 2008).

Figure 1a shows a stochastic timed automata where a and d are events with occurrence times rates of λ and μ, respectively. Considering the markovian properties presented in (Cassandras, 2008), this automata generates a Markov chain illustrated in Figure 1b.



(a) Stoch. timed automata **(b)** Markov chain

Figure 1. Stochastic timed automata as Markov Chain

In Figure 1b, π_0, π_1 and π_2 denotes the stationary probability of the states 0, 1 and 2, respectively. According to (Cassandras, 2008), a system modeled as a Markov chain is allowed to operate for a sufficiently long period of time so that the state probabilities can reach some fixed values which no longer vary with time. The main objective of using a Markov chain is to compute these probabilities. According to (Bolch et al., 1998), long run dynamics of Markov chains can be studied using a system of linear equations with one equation for each state. Thus, solution of these equations results in stationary probabilities of the Markov chain, consequently, desired performance measures such as *mean response time* can be easily obtained.

It is known that a DES simulation model can be seen as a parallel composition of many stochastic timed automata. The set of clock structures describes how the DES model evolves as a result of event occurrences over time. Considering that all clock structure of this DES model conforms to the markovian properties, the full DES model can be simplified to a Markov chain (In a parallel composition model, the stationary probabilities are denoted by the M-tuple $\pi(n_0,\ldots,n_M)$ where M represents the number of individual automata). Accordingly, a system of linear equations to compute the stationary probabilities must still be valid. The problem of this representation is the fact that the cardinality of the state space can grow drastically in a Markov chain of a complex system. Therefore, computing the stationary probabilities of the states became a hard (even impossible) task.

Fortunately, for a class of Markov Chain, which can be expressed as a of queuing network, very fast numerical solution methods have been developed to derive important performance measures without resorting to the underlying state space (Bolch et al., 1998). One of these methods is known as convolution algorithm. This method is a sufficient analytical technique to obtain the interest measures of this study. This algorithm aims to evaluate an important performance measure without having to compute explicitly the stationary probabilities.

2.1 Product-Form Networks - Convolution algorithm

Once we approximate the stochastic automata by a Markov Chain and then by a queuing network, to compute the stationary probability it is necessary to consider the theorem proposed by (Jackson, 1957). The Jackson's theorem (also known as product-form) says the steady-state probability of the network can be expressed as the product of the state probabilities of the individual nodes. Based in the Jackson's theorem, (Gordon and Newell, 1967) present a general formulation to compute the stationary probabilities in a closed queuing network. This formulation follows the Eq. 1:

$$\pi(n_1,\ldots,n_M) = \frac{1}{G(N)} \prod_{m=1}^{M} \beta_m(n_m), \tag{1}$$

where $G(N)$ denotes the normalization constant. In this equation, $\beta_m(n_m)$ denotes a step function which depends on the number of customer n_m in each node m. Let μ_m be the service rate of the node m, and let ν_m be the relative arrival rate of the same node, the value of $\beta_m(n_m)$ is obtained using Eq. 2.

$$\beta_m(n_m) = \begin{cases} 1, & \text{if } n_m = 0 \\ \dfrac{\left(\frac{\nu_m}{\mu_m}\right)^{n_m}}{\prod_{k=1}^{n_m} b_m(k)}, & \text{else} \end{cases} \tag{2}$$

Usually, in a closed queuing network μ_m is known, while ν_m should be compute. Thus, the balance equations Eq. 3 can be used to compute ν_m, where the parameter p_{im} denotes the transition probability that a customer departs from node i and arrives at the node m.

$$\nu_m = \sum_{i=1}^{M} \nu_j p_{im} \quad \forall\, m = 1,\ldots,M. \tag{3}$$

The step function Eq. 2 depends on the queuing discipline of the node as well. In this study we consider the disciplines: FIFO (First In First Out) and IS (Infinity Server). Thus, $b_m(k)$ denotes a step function which depends on the

queuing discipline and the number of service q_m, as we can see in Eq. 4.

$$b_m(k) = \begin{cases} 0, & \text{if } k = 0 \\ \min(k, q_m), & \text{if } 0 < k \leq N \ \ \& \ \ \text{FIFO} \\ k, & \text{if } 0 < k \leq N \ \ \& \ \ \text{IS} \end{cases} \quad (4)$$

According to Buzen algorithm (Buzen, 1973), the normalization constant $G(N)$ can be computed following Eq. 5.

$$g(n,m) = \begin{cases} 1, & \text{if } n = 0, \ \forall \ m \\ \beta_m(n), & \text{if } m = 1, \ \forall \ n \\ \sum_{k=0}^{n} \beta_m(k) g(n-k, m-1), & \text{else} \end{cases} \quad (5)$$

In the Eq. 5, $g(n,m)$ denotes the normalization constant of all possible sub closed queuing network where n ($0 \leq n \leq N$) and m ($1 \leq m \leq M$) indicate, respectively, the amount of clients and nodes. Therefore, $g(N,M)$ represents $G(N)$.

2.2 Marginal probability

In order to compute the *mean response time*, it is necessary to evaluate the marginal probability. This performance measure $\pi_m(n)$ represents the probability of having n clients in the node m, accordingly with Eq. 6.

$$\pi_m(n) = \sum_{\substack{\pi_{n_1} \ldots \pi_{n_M} \\ \& \ n_m = n}} \pi(n_1, \ldots, n_M) \quad (6)$$

As mentioned, the number of states in a Markov chain of a complex system can become very huge. Therefore, it cannot be possible to compute all $\pi(n_1, \ldots, n_M)$. However, the convolution algorithm described in (Bolch et al., 1998) is sufficient to obtain the marginal probability directly. In general terms, this technique consist of to substitute Eq. 1 in Eq. 6, which results in Eq. 7.

$$\pi_m(n) = \frac{\beta_m(n)}{G(N)} G_M^{(m)}(N-n) \quad (7)$$

The constant $G_M^{(m)}(N-n)$ must be interpreted as normalization constant of a closed queuing network without the node m and with n clients less. The value of $G_M^{(m)}(N-n)$ can be computed recursively (Bolch et al., 1998), following Eq. 8.

$$G_M^{(m)}(k) = \begin{cases} 1, & \text{if } k = 0 \\ G(N) - \sum_{k=1}^{N} \beta_m(n) G_M^{(m)}(N-k), & \text{else} \end{cases} \quad (8)$$

2.3 Mean response time

As mentioned in section 1, the idea is to measure the *mean response time* of each node. Following the Little's law, this performance measure is obtained using Eq. 9:

$$\bar{T}_m = \frac{\bar{N}_m}{\psi_m}, \quad (9)$$

where $\bar{N}_m$ and ψ_m are the *mean number of clients* and the *throughput* of the node m, respectively. Moreover, these performance measures must be computed by Eq. 10 and Eq. 11, where q_m denotes the number of services in the node m.

$$\bar{N}_m = \sum_{n=1}^{\infty} n \pi_m(n) \ \ \forall \ 1 \leq m \leq M \quad (10)$$

$$\psi_m = \sum_{n=1}^{\infty} \pi_m(n) \min(n, q_m) \mu_m \quad (11)$$

In this section, we show an efficient technique to compute the *mean response time*. This performance measure can be obtained analytically in a quiet fast. In the following section we introduce concepts about the load-haulage cycle and demonstrates how to use the *mean response time* to compute the *total mine production* index.

3 Load-haulage cycle

In (Torkamani and Askari-Nasab, 2012), a DES simulation model was implemented in SIMAN language (Pegden, 1983) in order to simulate the load-haulage system in an open-pit mine. Each simulation scenario used a distinct combination of the number of trucks and shovels. The goal was maximizing the mine production index at lowest possible operating cost. As the use of simulation requires high computational effort, sometimes it is not possible to try all feasible scenarios. Thus, the strategy taken by (Torkamani and Askari-Nasab, 2012) considers proper indicators to choose the scenarios to be evaluated.

In (Ercelebi and Bascetin, 2009), another strategy for allocation of trucks in open-pit mine was proposed. The authors applied closed queuing theory to obtain some measures of interest such as the *total mine production* index. According to (Ercelebi and Bascetin, 2009), in a load-haulage system, the *total mine production* index P over a given time period of interest can be estimated by Eq. 12:

$$P = N \cdot C \cdot \frac{T_{horizon}}{\bar{T}_{cycle}}, \quad (12)$$

where C denotes the truck's capacity, N the number of trucks and $T_{horizon}$ the period of interest. The measure $\bar{T}_{Cycle}$ represents the *mean cycle time*.

In a load-haulage system, basically, each truck goes to load site and waits until the loading process is completed. Following, the trucks go to the dump site and dump the ore into a crusher. However, each truck can be diverted to other process during the transport, such as maintenance, supply, etc. Known as operational stops, these processes must be included in the load-haulage cycle with a transient probability associated p_m. The Eq. 13 represents a general expression to compute the *mean cycle time* considering the operational stops:

$$\bar{T}_{cycle} = \sum_{m=1}^{M'} \bar{T}_m + \sum_{m=M'+1}^{M} p_m \bar{T}_m, \quad (13)$$

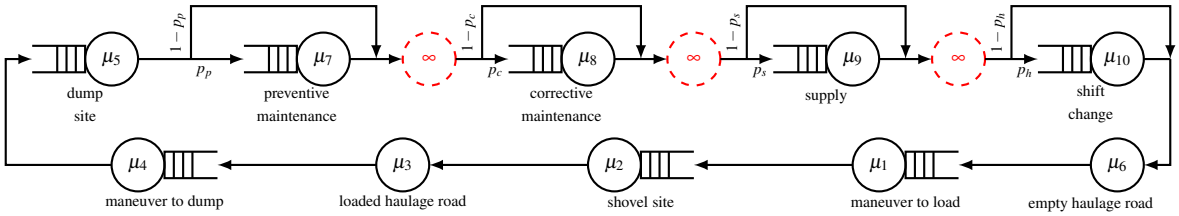


Figure 2. Closed queuing network representing the Load-haulage system

where the label m, from 1 to M' denotes the basic process of the load-haulage system, while m from 1 to M' indicates process which are operational stops.

4 DES model: Load-haulage system

In order to compute the *total mine production* index, the analytical technique presented in this paper was tested in a load-haulage system depicting a mining front of a brazilian open-pit mine. As mentioned in section 1, in this study we consider the cdf approximation using exponential distribution. The assumption is verifying whether there are significant difference among the results obtained and the results presented in (Ribeiro, 2015). Table 1 presents the process of the load-haulage system. The pdf, the first moment approximation and discipline are showed as well.

Table 1. First moment approximation

Process	Dist.	$E[x]$	μ_m	Dis
Maneuver to load	Triangular	2.266	$\frac{1}{2.266}$	FIFO
Shovel site	Tria (comp.)	3.227	$\frac{1}{3.227}$	FIFO
Loaded Haulage road	Inv. Gaussian	8.333	$\frac{1}{8.333}$	IS
Maneuver to Dump	Triangular.	1.100	$\frac{1}{1.100}$	FIFO
Dump site	Triangular	2.133	$\frac{1}{2.133}$	FIFO
Empty Haulage road	Inv. Gaussian	6.944	$\frac{1}{6.944}$	IS
Preventive maintenance	Triangular	150	$\frac{1}{150}$	FIFO
Corrective maintenance	Triangular	1120	$\frac{1}{1120}$	FIFO
Supply	Gaussian	150	$\frac{1}{150}$	FIFO
Shift Change	Gaussian	16	$\frac{1}{16}$	FIFO

The load-haulage system depicting a mining front was modeled as a queuing network. Thus, each process presented in Table 1 is seen as a node and each truck is a client. Figure 2 shows the full model. As we can see, there are four operational stops in this model. The transient probabilities to these nodes are: p_p, p_c, p_s and p_h. In addiction, it was added to the model three fictitious nodes (dashed nodes) to establish transient decisions between operational stop nodes. Taken to account that these nodes have infinity rate, they do not change the final result.

The transient probabilities were computed using the occurrence period of each operational stop of the open-pit mining front. Therefore, the estimated values are: $p_p = 0.0015$, $p_c = 0.0127$, $p_s = 0.0255$ and $p_h = 0.1232$.

Considering the transient probabilities values, the service rates and the queuing discipline showed in Table 1 the *mean response time* of each node is obtained using the technique presented in section 2. Consequently, using Eq. 13 we have the Eq. 14.

$$T_{cycle} = \sum_{m=1}^{6} \bar{T}_m + p_p\bar{T}_7 + p_c\bar{T}_8 + p_a\bar{T}_9 + p_t\bar{T}_{10} \qquad (14)$$

As mentioned before, the aim is to compute the *total mine production* index. However, it necessary to estimate the parameter C (truck's capacity). In this study, it was considered a caterpillar 793F truck with nominal payload capacity of 226.8 tonnes. Finally, specifying a time period of interest, the mine production index must be evaluated by Eq. 12.

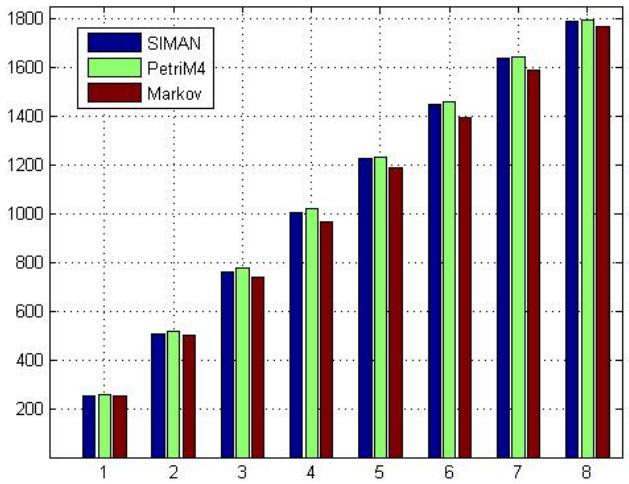

Figure 3. N^o of trucks vs Mine production index -tonnes(mil)

For a time period of interest of one month, the closed queuing network was evaluated changing the number of trucks N (clients), from 1 to 8. Figure 3 shows the comparison among the results obtained and the results presented in reference (Ribeiro, 2015).

From Figure 3 it is possible to observe there is no significant difference among the analytical approximation model designed and the methodologies of DES simulation, neither SIMAN nor Petri Nets. The maximum difference between the analytical approximation model and the

SIMAN model was 4%, while the maximum difference when compared with the Petri net model was 5.16%.

It is important to emphasize that the analytical approximation model runs hundreds times faster than DES simulation models. In conclusion, the DES through markovian properties consist of a reasonable way to represent the load-haulage system in study.

5 Project portfolio formulation

Let P_0 be the *total mine production* index of the load-haulage system shown in Figure 2, with 8 caterpillar 793F trucks and without any project application. Using Eq. 12 we have $P_0 = 1767.29$ tonnes. Let P_k be the *total mine production* index of the same system with the application of the project k, and let $E[g_k]$ be the expected gain provided by the application of this project, that is $E[g_k] = P_k - P_0$.

Knapsack problem is a typical formulation for portfolio optimization. In this study, the goal consists of maximize the sum of the gains, respecting the established budget. However, it is necessary to consider the inter-relationship between two or more projects. Since it may be unfeasible to evaluated all project combinations, the *mean response time* of each node is useful to define those who deserve to be evaluated. The major idea is that this performance measure indicates the plant bottlenecks, which must be fixed by the new projects.

Initially, consider that two or more projects have a small expected gain. Using conventional optimization methods they would hardly be included in the final optimal portfolio. However, the combination of them can generate good expected gain when evaluated jointly. Considering these circumstances, the analysis of the problem is necessary to find which combinations are relevant.

For example, a project that produces a time reduction in the dumping process and increases *mean response time* in the shovel site can produce a significant gain whether combined with another projects that provides an improvement in the second node.

A relevant combination could be composed by more than two projects. In this methodology each combination just can be obtained by pairs. However, combinations found and evaluated are converted in new decision variables (new projects). Then, in the next iteration, the strategy can combine this new project with another one.

The Eq. 15 presents a formulation where the set of decision depends of the number of projects combination $\mathbf{S} = \{X_0, \ldots, X_k, \ldots, X_K\}$. Since X_k denotes the *k-th* combination evaluated, x_k is a decision variable that represents it in the optimization function.

Considering that in equation 15 the optimal solution can be composed by more than one project combination, it is necessary to prevent that a isolated project appear redundantly in the same solution. For example, suppose we have the combinations: $X_1 = \{p_1, p_2\}$ and $X_2 = \{p_2, p_3\}$. In this circumstances, it is necessary to append at the formulation (Eq. 15) the constraint $x_1 + x_2 \leq 1$. In another case, assume that we have two other project combination previously evaluated: $X_3 = \{p_3, p_4\}$ and $X_4 = \{p_1, p_2, p_3, p_4\}$. Consequently, it is necessary to add the constraint $x_1 + x_3 \leq 1$ because a combination between this two set is equal to X_4. Based in this rules, the formulation must account the preposition 1:

Table 2. Project portfolio

Proj	Description	c (pu)	Impact	Where?
p_1	Bilateral charging	0.5	-15%	node 1
p_2	Roads improvement	1.5	-20%	nodes 3,6
p_3	Dead load reduction	1	5%	par. C
p_4	Excavation	2	-18%	node 2
p_5	1 Truck acquisition	5	$N+1$	par. N
p_6	2 Truck acquisition	10	$N+2$	par. N
p_7	Rolling A-Frame	1	-17%	node 8
p_8	Forklif acquisition	0.7	-15%	node 8
p_9	Preventive kits	0.65	-14%	node 8
p_{10}	Supply improvement	2	-35%	node 9
p_{11}	Dump site improvement	2	-25%	node 4
p_{12}	Shift change improvement	1.5	-25%	node 10
p_{13}	Backlog's reduction	5	-30%	node 7
p_{14}	DMT reduction	2.5	-24%	node 5
p_{15}	Load site improvement	3	-25%	node 1

Preposition 1 If $X_u \cap X_v \neq \emptyset$ or $X_u \cup X_v = X_k \mid k \in \mathbf{S}$ Then $x_u + x_v \leq 1$.

In this case, X_k, X_u and X_v are the combinations sets associated with the variables x_k, x_u and x_v, respectively.

Let w_k be the cost of the combination project k, the first constraint limits the sum of cost to the budget available R. Moreover, the last constraint indicates that the decision variables must be binary.

$$\begin{aligned} \text{Maximize} \quad & \sum_{k=1}^{K} E[g_k] x_k \\ \text{Subject to} \quad & \sum_{k=1}^{q} w_k x_k \leq R \\ & x_u + x_v \leq 1 (\textit{ preposition } 1) \\ & x_k, x_u, x_v \in \{0,1\} \end{aligned} \tag{15}$$

For this study, it was available from the mine company a project portfolio with 15 candidate projects and a budget R of 15pu (per unit). Table 2 presents the projects to be

considered with the projects costs (c). Moreover, Table 2 shows the impacts of the projects and the process (or parameter) affected.

This problem was formulated according to Eq. 15 with a limit of 200 'relevant combinations'. The 'Gurobi Optimizer' software was used and the best project portfolio solution was found. Lastly, the optimal solution was converted in a set of isolate project (such as Table 2) and the expected gain of this solution was obtained using the queuing network model presented in this paper. As a result, the best portfolio was $\{1,0,0,0,0,1,1,1,1,0,1,0,0,0,0\}$, which provides a production increase of 1049.09 tonnes.

6 Conclusions

In the context of projects portfolio, there is no simple way to select the best portfolio when considering the interrelationship between projects. Thus, this paper showed a strategy based on the characteristics of the load-haulage cycle of an open-pit mine, that limits cohesively the interrelationships to be evaluated, based on an adaptation of the knapsack problem. Given that the computational time is a limited resource, an analytical approximation model was designed. The results showed that there is not significant difference between this model and DES simulation models which represents the same load-haulage cycle.

Simulating the Effect of a Class of Sensor Fuzed Munitions for Artillery on a Multiple Target Element System

Henri Kumpulainen Bernt M. Åkesson

Information Technology Division, Finnish Defence Research Agency, Finland, bernt.akesson@mil.fi

Abstract

This paper presents a method for analyzing the effect of a class of artillery-launched sensor fuzed munitions on a target, which is a system consisting of several target elements and a fault logic. The target elements are armored vehicles and the munitions are designed specifically to attack single vehicles. We consider munitions which may contain one or two submunitions. We want to address the following questions: what is the probability of disabling the system given the number of ammunition, and similarly, how much ammunition is needed for disabling the system with a given confidence level. The proposed method is based on Markov chains rather than Monte Carlo simulation.

Keywords: Markov processes, probability, set theory, operations research, mathematical model, algorithms, weapons

1 Introduction

The term sensor fuzed munition is here used to denote munitions with target recognition capability and the ability to autonomously search for, detect, recognize and attack single target elements with specific signatures. Sensor fuzed munitions are generally intended for use against armored vehicles. Sensor fuzed munitions engage their targets from above from a distance using explosively formed projectiles (Dullum, 2008).

In this paper we consider sensor fuzed submunitions that are delivered by an artillery projectile. The projectile travels on a ballistic trajectory and ejects one or two sensor fuzed submunitions over a desired release point using a time fuze. The submunitions operate independently of each other, and after stabilizing and retarding their descent, scan the area beneath them for suitable target elements. Figure 1 illustrates the operation of the munitions.

A target consists of a number of target elements in a formation. Defeat of the target is defined by the damaging of specific combinations of target elements.

We propose an approach based on Markov chains. This approach has the benefit that once the effect of a single projectile has been calculated, the effects of further projectiles can be calculated by simple matrix operations.

Analytical models for different types of sensor fuzed munitions have been derived by (Halsør and Kvifte, 2003). This paper extends that work.

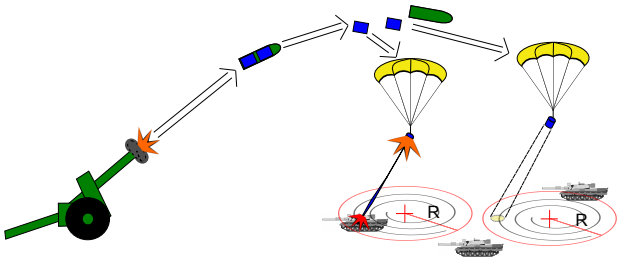

Figure 1. Schematic of the firing of an artillery projectile containing two sensor fuzed anti-tank submunitions.

A corresponding method as in this paper has been previously applied to fragmenting munitions by (Pettersson et al., 2011). The main difference is that a single fragmenting munition can damage all target elements in the area, whereas a sensor fuzed submunition can only damage a single target element.

An alternative approach that has been used before for this type of problems is to apply Monte Carlo methods, as outlined in e.g. (Halsør and Kvifte, 2003) and (NATO Standardization Office, 2012). Monte Carlo methods are known to be computationally expensive when we need accurate estimates of the kill probabilities, since their error is proportionate to $1/\sqrt{n}$ where n is the number of replications.

The paper is outlined as follows. First, an overview of the method is given. After this, a method for computing the probabilities of encountering different target element subsets is presented. Then the probabilities in the cases with one and two submunitions are derived. Finally, the failure probability of a system of target elements is considered.

2 Overview of the Method

An illustration of the method is provided in Figure 2. The computations are performed in three steps. First, the probabilities of a submunition encountering each subset of target elements are computed. After this, a state transition matrix is constructed and finally, the effect of a given number of munitions is computed. The state vector can be used together with fault logics to determine the probability of the target being broken.

The following assumptions are made:

1. The position of each target element is known

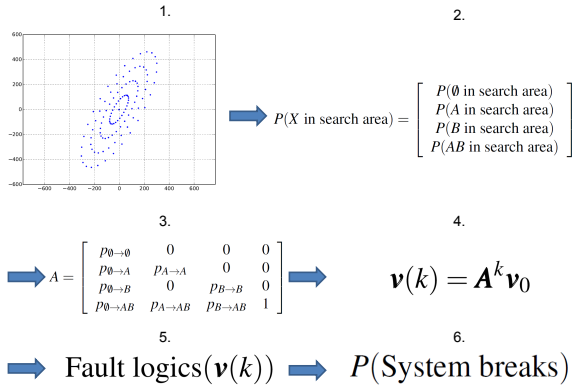

Figure 2. Illustration of the method.

2. The target elements are identical
3. A single submunition can only kill one target element
4. A target element has two states, functional and broken
5. Broken target elements are never attacked
6. The sensor is scanning, seeing only part of the search area at a time, and the munition will attack the first target it detects that fits given criteria. See Figure 1.
7. The search area, also known as the sensor footprint, is circular in shape
8. The target elements are stationary

The second assumption can be generalized by having different probabilities for detection, hit and kill for different target element types. The seventh assumption can be easily relaxed to other footprint shapes.

The carrier projectile is assumed to follow a ballistic trajectory, which can be computed using, e.g., a modified point-mass model. In this paper, the release point is for simplicity assumed to follow a bivariate normal distribution on the ground plane. The mean and standard deviations are assumed to be known.

A sensor fuzed submunition is characterized by the following parameters:

- Radius R of the search area
- Reliability p_{f}
- Detection probability p_{d}
- Hit probability p_{h}
- Kill probability $p_{\mathrm{k|h}}$, i.e., the probability of the target element breaking when hit

The probability of detection and the probability of kill may depend of the target element type together with weather and terrain conditions. The probability of detection may also depend on the distance from the center of the search area. In this paper the scanning method of the submunition is not specified, and thus all target elements inside the search area have equal probability of being detected first.

Some parameter values for existing sensor fuzed munitions can be found in open sources. For example, for a certain munition, (Dullum, 2008) reports a search area radius $R = 100$ m, and (Kosola and Solante, 2013) report a hit probability of $p_{\mathrm{h}} = 0.8$ and a kill probability of $p_{\mathrm{k|h}} = 0.95$.

3 Computing the Encounter Probabilities

We consider n identical target elements in the target area. Let us denote the set of target elements by $T = \{T_1, T_2, T_3, \ldots, T_n\}$, and the probability that the set of broken target elements after k artillery rounds is exactly X by $P_k(X)$.

Given a position (x,y) on the ground plane, there is a probability $p(x,y)$ of a sensor fuzed submunition starting its search in that point. The probability is directly the probability density function of the bivariate normal distribution. We look at a circular area with radius R around (x,y) and select all target elements within it. This corresponds to subset $X_i \subseteq T$. The integrand function returns a vector with $\dim(\boldsymbol{v}) = 2^n$, whose ith element has value $p(x,y)$.

Let $\boldsymbol{P}(\text{set in search area})$ be a vector of length 2^n containing the probabilities that a single round encounters a given subset of the target elements within its search area,

$$\boldsymbol{P}(\text{set in search area}) = \begin{bmatrix} P(\emptyset \text{ in search area}) \\ P(\{T_1\} \text{ in search area}) \\ P(\{T_2\} \text{ in search area}) \\ P(\{T_1, T_2\} \text{ in search area}) \\ \vdots \\ P(\{T_1, T_2, \ldots, T_n\} \text{ in search area}) \end{bmatrix}. \tag{1}$$

One approach, proposed in (Halsør and Kvifte, 2003), is to integrate over an area to obtain the probabilities of encountering each target element combination,

$$\boldsymbol{P}(\text{set in search area}) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \boldsymbol{f}(x,y)\,\mathrm{d}x\mathrm{d}y \tag{2}$$

where the integrand $\boldsymbol{f}(x,y)$ is a vector-valued function, such that for $i = 1, \ldots, 2^n$

$$f_i(x,y) = \begin{cases} p(x,y), & \text{if subset } X_i \text{ is within distance } R \\ & \text{from point } (x,y) \\ 0, & \text{otherwise} \end{cases} \tag{3}$$

Table 1. Encounter probabilities corresponding to the situation in Figure 3

Set X	*P(X in search area)*
$\emptyset$	0.0138
$\{A\}$	0.0018
$\{B\}$	0.0781
$\{A,B\}$	0.1427
$\{C\}$	0.1834
$\{A,C\}$	0.1521
$\{B,C\}$	0.0426
$\{A,B,C\}$	0.3853

where $p(x,y)$ is the value of the probability density function at point (x,y).

3.1 Example

The integral in (2) can be performed for an elliptical area centered on the aimpoint. Figure 3 illustrates the situation. The dispersion pattern is shown as ellipses. Three example functioning points are shown. At functioning point P_1 only target element B can be detected, at point P_2 A and C can be detected and at point P_3 all three target elements can be detected. When integrating over the area using (2) we obtain the encounter probabilities listed in Table 1.

4 State Transition Matrix

Let $P_k(X)$ be the probability that the set of target elements X is broken at time step k. Let $\boldsymbol{v}(k)$ be a vector that contains the values of $P_k(X)$ for every subset $X \subseteq T$ in bit order, i.e., $\boldsymbol{v}(k) = [P_k(\emptyset), P_k(\{T_1\}), P_k(\{T_2\}), P_k(\{T_1,T_2\}), \ldots]^T$, at time step k.

We can interpret the system as a state machine where a state is characterized by the set of broken target elements and during each time step exactly one round of the weapon system is fired. The vector $\boldsymbol{v}(k)$ contains the state probabilities. Initially, all target elements are functional, thus $\boldsymbol{v}(0) = [1,0,\ldots,0]^T$.

We can compute a state transition matrix $\boldsymbol{A}$ so that, for all k,

$$\boldsymbol{v}(k+1) = \boldsymbol{A}\boldsymbol{v}(k). \tag{4}$$

After firing k rounds the end state is given by

$$\boldsymbol{v}(k) = \boldsymbol{A}^k \boldsymbol{v}(0). \tag{5}$$

The state transition matrix $\boldsymbol{A}$ is defined as

$$\boldsymbol{A} = [P(X_j \to X_i)]_{1 \le i,j \le 2^n} \tag{6}$$

where $P(X_j \to X_i)$ is the probability of moving from state $X_j \subseteq T$ to state $X_i \subseteq T$.

Matrix $\boldsymbol{A}$ is rather large and has dimensions $2^n \times 2^n$. However, $\boldsymbol{A}$ is rather sparse, which means that all matrix operations will be faster when implemented using sparse matrices.

During an artillery firing an individual target element can either remain functional or break but broken target elements can never return back to functional. This means that $P(X_j \to X_i) = 0$ if $X_j \not\subseteq X_i$, and thus $P(X_j \to X_i)$ can only be nonzero if $X_j \subseteq X_i$. In (Pettersson et al., 2011) it was shown that when a single round is capable of killing all target elements the number of nonzero elements in $\boldsymbol{A}$ is at most 3^n.

If, on the other hand, at most n_K target elements can be killed by a single round, then $P(X_j \to X_i)$ can only be nonzero if $|X_i \setminus X_j| \le n_K$ and $X_j \cap X_i = X_j$. The number of nonzero elements matrix $\boldsymbol{A}$ is then

$$N(\text{nonzero elements in } \boldsymbol{A}) = \sum_{j=1}^{2^n} N(\text{nonzero elements in column } j \text{ of } \boldsymbol{A}) \le \sum_{i=0}^{n} \binom{n}{i} \sum_{m=0}^{n_K} \binom{n-i}{m}. \tag{7}$$

If one target element can be killed we have at most $(n+2)2^{n-1}$ nonzero elements and if two target elements can be killed the number of nonzero elements is at most $(n^2+3n+8)2^{n-3}$.

4.1 Projectile with a Single Sensor Fuzed Submunition

If the encountered set of target elements is X_k and the initial state is X_j, the set of killed target elements in the encountered set is $X_j \cap X_k$. The set of functional target elements in the encountered set is $X_k \setminus X_j$.

Since the target elements are assumed identical, for any target element $X \in X_k$ we have that

$$P(X \text{ killed} \mid X_k \text{ in search area and } X_j \cap X_k \text{ killed}) = P(1/|X_k \setminus X_j| \text{ killed}). \tag{8}$$

The probability of killing exactly one target element out of m is

$$P(1/m \text{ killed}) = (1-(1-p_\mathrm{d})^m)\, p_\mathrm{h} p_{\mathrm{k|h}} p_\mathrm{f}/m. \tag{9}$$

When only one target element can be killed each time step, the exact probability of moving from state $X_j \subseteq T$ to state $X_i \subseteq T$ in one time step is

$$P(X_j \to X_i) = P(X_j \to (X_j \cup \{T_i\})) = \sum_{\substack{X_k \subseteq T, \\ \text{s.t. } T_i \in X_k}} P(X_k \text{ in search area}) P(1/|X_k \setminus X_j| \text{ killed}). \tag{10}$$

Next we present an algorithm for calculating the state transition matrix more efficiently than the brute force approach of applying (10) for each nonzero element in the matrix.

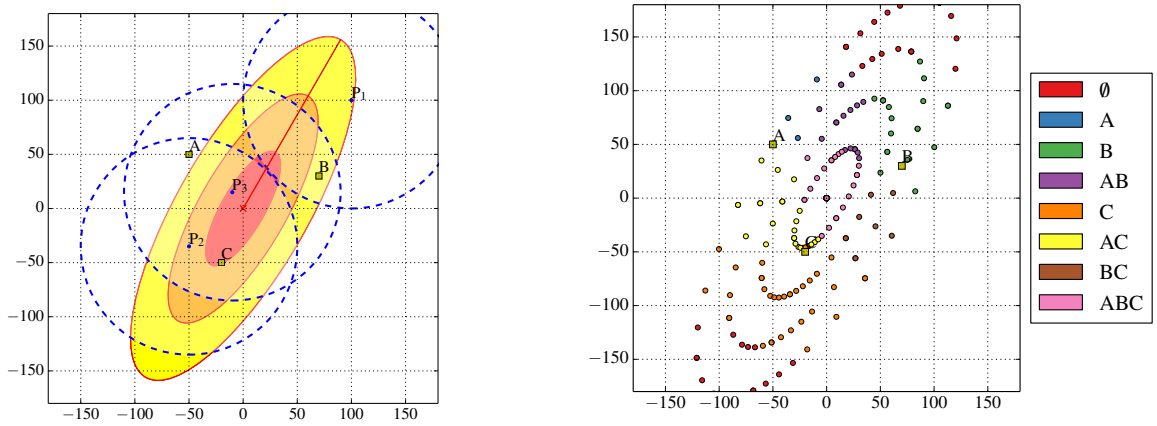

Figure 3. The figure on the left shows the positions of three target elements: A, B and C. The ballistic dispersion of the carrier projectile is marked by ellipses for one, two and three standard deviations. A single submunition is assumed. Three example functioning points P_1, P_2 and P_3 have been plotted, with the sensor footprints outlined with dashed circles. The figure on the right shows the subsets found in each integration point.

Let us define $Q(X)$ as the probability that X is a subset of the set of target elements inside the search area. We can calculate this probability as

$$Q(X) = \sum_{\substack{Y \subseteq T, \\ \text{s.t. } X \subseteq Y}} P(Y \text{ in search area}). \tag{11}$$

The probability that a set of target elements X is inside the search area, but target element T_i is not, is $Q(X) - Q(X \cup \{T_i\})$. Applying this recursively we can rewrite $P(X \text{ in search area})$ in terms of Q as

$$P(X \text{ in search area}) = \sum_{i=0}^{|T \setminus X|} \sum_{\substack{Y \subseteq (T \setminus X), \\ \text{s.t. } |Y|=i}} \begin{cases} Q(X \cup Y), & i \text{ is even} \\ -Q(X \cup Y), & i \text{ is odd} \end{cases} \tag{12}$$

Unlike $P(X_k \text{ in search area})$, which also depends on the total number of target elements in the search area, the value of $Q(X_k)$ does not change when the number of target elements in $T \setminus X_k$ changes. If we write (10) in terms of Q, we can disregard the broken target elements in X_j, reducing the number of subsets to take into account. The probability that a target element T_i is killed is then

$$P(X_j \to (X_j \cup \{T_i\})) = \sum_{\substack{X_k \subseteq T, \\ \text{s.t. } T_i \in X_k}} P(X_k \text{ in search area}) P(1/|X_k \setminus X_j| \text{ killed}) =$$

$$\sum_{\substack{X_k \subseteq (T \setminus X_j), \\ \text{s.t. } T_i \in X_k}} \sum_{i=0}^{|T \setminus (X_k \cup X_j)|} \sum_{\substack{Y \subseteq (T \setminus (X_k \cup X_j)), \\ \text{s.t. } |Y|=i}} \begin{cases} Q(X_k \cup Y) P(1/|X_k| \text{ killed}), & i \text{ is even} \\ -Q(X_k \cup Y) P(1/|X_k| \text{ killed}), & i \text{ is odd} \end{cases} \tag{13}$$

Since all possible $X_k \cup Y$ are equivalent to some value of X_k and the value of $P(1/|X_k| \text{ killed})$ does not depend on Y, the sum can be factorized as

$$P(X_j \to X_j \cup \{T_i\})) = \sum_{\substack{X_k \subseteq (T \setminus X_j), \\ \text{s.t. } T_i \in X_k}} Q(X_k) \sum_{i=0}^{|X_k|-1} \begin{cases} \binom{|X_k|-1}{i} P(1/(|X_k| - i) \text{ killed}), & i \text{ is even} \\ -\binom{|X_k|-1}{i} P(1/(|X_k| - i) \text{ killed}), & i \text{ is odd} \end{cases} \tag{14}$$

$$K(n) = \sum_{i=0}^{n-1} \begin{cases} \binom{n-1}{i} P(1/(n-i) \text{ killed}), & i \text{ is even} \\ -\binom{n-1}{i} P(1/(n-i) \text{ killed}), & i \text{ is odd} \end{cases} \tag{15}$$

We can define a recursive function

$$f(X,Y) = \begin{cases} f(X \setminus \{T_i\}, Y) + f(X \setminus \{T_i\}, Y \cup \{T_i\}), & T_i \in X \\ Q(Y) K(|Y|), & X = \emptyset \end{cases} \tag{16}$$

which has the property

$$f(T \setminus (X_j \cup \{T_i\}), \{T_i\}) = \sum_{\substack{X_k \subseteq (T \setminus X_j), \\ \text{s.t. } T_i \in X_k}} Q(X_k) K(|X_k|) = P(X_j \to X_j \cup \{T_i\})). \tag{17}$$

We notice that by selecting X and Y appropriately, $f(X,Y)$ gives us the nonzero nondiagonal elements of the state transition matrix. All the relevant values of K, Q and $f(X,Y)$ can be precalculated in order to create each element of the matrix in constant time, as demonstrated in the algorithm in Fig. 4. The overall complexity of this algorithm is $O(n^2 \cdot 2^n)$.

Figure 4. Algorithm for creating state transition matrix for a single sensor fuzed submunition.

4.2 Example

With two target elements, A and B, we have state vector $\boldsymbol{v}$

$$\boldsymbol{v} = \begin{bmatrix} P(\emptyset \text{ killed}) \\ P(\text{A killed}) \\ P(\text{B killed}) \\ P(\text{AB killed}) \end{bmatrix} \tag{18}$$

and state transition matrix $\boldsymbol{A}$

$$\boldsymbol{A} = \begin{bmatrix} p_{\emptyset \to \emptyset} & 0 & 0 & 0 \\ p_{\emptyset \to A} & p_{A \to A} & 0 & 0 \\ p_{\emptyset \to B} & 0 & p_{B \to B} & 0 \\ 0 & p_{A \to AB} & p_{B \to AB} & 1 \end{bmatrix} \tag{19}$$

where

$$\begin{aligned} p_{\emptyset \to A} &= f(B,A) = f(\emptyset,A) + f(\emptyset,AB) \\ &= Q(A)K(1) + Q(AB)K(2) && (20) \\ p_{\emptyset \to B} &= f(A,B) = f(\emptyset,B) + f(\emptyset,AB) \\ &= Q(B)K(1) + Q(AB)K(2) && (21) \\ p_{A \to AB} &= f(\emptyset,B) = Q(B)K(1) && (22) \\ p_{B \to AB} &= f(\emptyset,A) = Q(A)K(1) && (23) \\ p_{\emptyset \to \emptyset} &= 1 - p_{\emptyset \to A} - p_{\emptyset \to B} && (24) \\ p_{A \to A} &= 1 - p_{A \to AB} && (25) \\ p_{B \to B} &= 1 - p_{B \to AB} && (26) \end{aligned}$$

and

$$\begin{aligned} Q(A) &= P(A \text{ in search area}) + P(AB \text{ in search area}) && (27) \\ Q(B) &= P(B \text{ in search area}) + P(AB \text{ in search area}) && (28) \\ Q(AB) &= P(AB \text{ in search area}) && (29) \\ K(1) &= \binom{0}{0} P(1/1 \text{ killed}) && (30) \\ K(2) &= \binom{1}{0} P(1/2 \text{ killed}) - \binom{1}{1} P(1/1 \text{ killed}) && (31) \end{aligned}$$

4.3 Projectile with Two Sensor Fuzed Submunitions

We now consider the case where an artillery projectile contains two sensor fuzed submunitions, which are released at some altitude. The release point is still assumed to follow a bivariate normal distribution. The center of the search areas of each submunition is assumed to be located at given distances from the release point in the direction of fire, since the submunitions will have forward motion before being sufficiently slowed down, as illustrated in Figure 5.

For tube artillery projectiles containing two submunitions, the centers of the search areas of the submunitions are separated by approximately 300 m, according to (Dullum, 2008). If the radius of the search area for each

submunition is 100 m, the search areas will not overlap. Therefore, in this paper the search areas are assumed to be non-overlapping. The submunitions are also assumed identical.

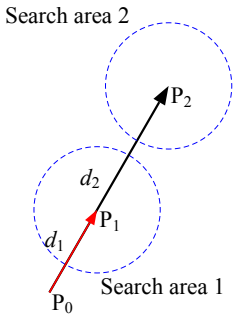

Figure 5. Sensor fuzed munition containing two indentical submunitions, whose non-overlapping search areas are outlined with dashed circles. The release point is at P_0, after which submunition 1 travels distance d_1 and submunition 2 distance d_2. The direction of fire is represented by the vectors.

The encounter probabilities have to be constructed for both search areas. We denote the subset in the first search area by S_1 and the subset in the second search area by S_2, with the constraint that $S_1 \cap S_2 = \emptyset$, i.e., the search areas contain disjoint subsets. The probability vector $\boldsymbol{P}$(sets in search area) can be calculated in a similar manner as in the single submunition case and will have length 3^n. The state transition matrix can be constructed using an approach similar to the single submunition case. Let us redefine the variables as

$$Q(X,Y) = \sum_{\substack{S_1 \subseteq T, \\ \text{s.t. } X \subseteq S_1}} \sum_{\substack{S_2 \subseteq T \setminus S_1, \\ \text{s.t. } Y \subseteq S_2}} P(S_1, S_2 \text{ in search area}) \quad (32)$$

$$P(0/n \text{ killed}) = \begin{cases} 1 - n \cdot P(1/n \text{ killed}), & n > 0 \\ 1, & n = 0 \end{cases} \quad (33)$$

$$K_0(n) = \begin{cases} \sum_{i=0}^{n} \binom{n}{i} P(0/(n-i) \text{ killed}), & i \text{ is even} \\ -\sum_{i=0}^{n} \binom{n}{i} P(0/(n-i) \text{ killed}), & i \text{ is odd} \end{cases} \quad (34)$$

$$f_1(X,Y,Z) = \begin{cases} f_1(X \setminus \{T_i\}, Y, Z) + f_1(X \setminus \{T_i\}, Y \cup \{T_i\}, Z) \\ \quad + f_1(X \setminus \{T_i\}, Y, Z \cup \{T_i\}), & T_i \in X \\ Q(Y,Z)K(|Y|)K_0(|Z|) \\ \quad + Q(Z,Y)K(|Z|)K_0(|Y|), & X = \emptyset \end{cases} \quad (35)$$

$$f_2(X,Y,Z) = \begin{cases} f_2(X \setminus \{T_i\}, Y, Z) + f_2(X \setminus \{T_i\}, Y \cup \{T_i\}, Z) \\ \quad + f_2(X \setminus \{T_i\}, Y, Z \cup \{T_i\}), & T_i \in X \\ (Q(Y,Z) + Q(Z,Y))K(|Y|)K(|Z|), & X = \emptyset \end{cases} \quad (36)$$

$$\begin{aligned} P(X_j \to X_j \cup \{T_1\}) &= f_1(T \setminus (X_j \cup \{T_1\}), \{T_1\}, \emptyset) \\ P(X_j \to X_j \cup \{T_1, T_2\}) &= f_2(T \setminus (X_j \cup \{T_1, T_2\}), \\ &\qquad \{T_1\}, \{T_2\}) \end{aligned} \quad (37)$$

With the above definitions, Q, f_1 and f_2 can be precalculated in the same way as Q and f in Fig. 4. The state transition matrix for two submunitions can be created in time $O(n \cdot 3^n)$, which is the complexity of precalculating $Q(X,Y)$ recursively for all possible $X, Y \in T$.

5 Failure Probability of the System

Arbitrary fault logics may be used to determine which broken subsets correspond to a broken system. The probability that the system breaks is the sum of these subset destruction probabilities in $\boldsymbol{v}(k)$,

$$P(\text{system breaks}) = \sum_{\substack{X_i \subseteq T, \\ \text{s.t. } g(X_i)=1}} v_i(k) \quad (38)$$

where function g contains the fault logics. The value of $g(X)$ is 1 if X corresponds to a broken system according to the fault logic and 0 otherwise.

The smallest number of projectiles needed to guarantee failure of the system with a given confidence level α can be obtained simply by starting at $k = 1$ and calculating P(system breaks) repeatedly while increasing the value of k until $P(\text{system breaks}) \geq \alpha$.

6 Conclusions

The placement of the aimpoint has a significant impact as well as the trajectories of the submunitions, here modeled as offset vectors. The trajectories of the submunitions from expulsion from the carrier projectile to their activation need further study.

We also need to address the target location error and the mean release point error. The mean release point may not necessarily coincide with the actual aimpoint and the aimpoint may also have a systematic error. One approach to handling these errors is to assume that the errors follow a bivariate normal distribution and discretize the region into a number of points and iterating over them.

The method can be generalized to having target elements with different properties, which would translate to different detection, hit and kill probabilities.

Abstract

Helicopter take-off and landing operations on ship carrier are very hazardous and training intensive. Guidance, Navigation and Control algorithms can help pilots to face these tasks by significantly reducing the workload and improving safety level. Anyway, the design and verification of such algorithms require the availability of suitable simulation environments that shall be a trade-off between simplicity and accuracy. This paper presents the simulation models developed to support the design, pre-flight verification and validation of helicopter trajectory generation and tracking algorithms for automated take-off and landing on a frigate deck. The process for generation and testing of the code to be integrated into the real-time Software-In-the-Loop simulator is also described. Such fast time and real-time simulation environments contributed to reduce algorithms design time, risks and costs, by limiting the required flight test activities. Take-off and landing algorithms developed by using the proposed simulation environments were successfully demonstrated in flight.

Keywords: GNC, helicopter, sensor, ship, turbulence

1 Introduction

Vertical take-off and landing operations of aerial vehicle on ship's deck enhance mission capabilities for military and civilian users. Anyway, these operations are the most dangerous flight phases for helicopters (Padfield, 1998; Lee, 2005). Indeed, a pilot have to deal with an invisible ship air wake, poor visible cueing and a landing spot which is heaving, rolling, pitching and yawing. At the same time the pilot shall also monitor vehicle's structural, aerodynamic and control limits. Moreover, operations take place in close proximity to the superstructure of the ship, that means there is little margin for error and the consequences of a significant loss of positional accuracy by the pilot can be severe.

The availability of Guidance Navigation and Control (GNC) algorithms for automatic operations can help pilots to face these tasks by significantly reducing operator workload, improving safety level and flight handling qualities. To develop these algorithms, suitable simulation environments are essential in order to reduce the flight test time and cost and to establish safe operating envelopes. The simulation tools shall be able to model all the relevant phenomena, such as helicopter flight dynamics (including on board sensors and actuators), the motion of the ship for the given sea state, the influence on the helicopter of the ship air wake and of the environment in general.

It is worth to note that modelling and simulation of each of the above listed phenomena is not a trivial task. Indeed, the simulation of the helicopter flight behavior includes kinematics, dynamics and aerodynamics of its subsystems (main rotor, fuselage, empennage, tail rotor, power plant, primary flight control system, on board sensors).

The vehicle's equations of motion, even if presented in several textbooks (Padfield, 1996; Johnson, 1994), are differential high order, nonlinear, coupled, and contain a large number of parameters, which often cannot be directly measured (Tishler et al., 2006). On the other hand, simplified models, which are able to catch the relevant dynamics, are typically required for GNC design purpose (Lee, 2005), to enhance physical understanding and lower the computational load. To this aim, linear parametrized models have been widely used (Tishler et al., 2006), but they are inadequate for accurate simulation of the vehicle dynamics when state variables significantly deviate from the linearization point (Gavrilets, 2006). Therefore, a suitable trade-off between model complexity and simulation accuracy shall be performed.

Another relevant topic concerns ship motion, which is an important issue for helicopter deck operations. For helicopter GNC algorithms design and analysis purpose, ship motion is usually represented through linear models or simplified nonlinear models with benign nonlinearities to capture the essential behavior of the vessel (Li, 2009). Ship motion can also be modelled using pre-computed or measured time histories (Carico et al., 2003). In any case, the ship model shall take into account the effect of the environment, and, in particular,

of the sea waves (Perez, 2005), which lead an undesirable low frequency disturbance into the motion of the vessel.

Finally yet importantly, the ship produces an air wake, which affects the helicopter dynamics. Indeed, ship air wake contains large velocity gradients and area of turbulence, generated by complex mechanisms of vortex dynamics near the ship deck, which greatly impair controllability of the flying vehicle and require additional control efforts to avoid accidents and to compensate abrupt changes in thrust level. Several accurate and complex CFD models of ship air wake are proposed in the literature (Kääriä, 2012), but CFD simulations produce a large amount of data and their use for GNC design and real time testing is usually unfeasible (Lee, 2005).

Stochastic turbulence models have been also proposed to represent the air wake with reasonable accuracy (Lee, 2005; Yang et al., 2009). These models may provide some insight into the effects of the air wake that are typically enough relevant for real-time simulations and flight control systems design.

It is also worth to note that, with reference to all the discussed models, a suitable code generation procedure and testing methodology shall be defined, in order to generate reliable real-time simulation models, applicable for GNC algorithms verification and performance assessment.

This paper presents the simulation environment developed by the Italian Aerospace Research Centre and Finmeccanica in order to support the design and verification of algorithms for helicopter trajectory generation and tracking, during an automated take-off and landing on a frigate deck. Matlab/Simulink was used for implementing such simulation environment, which constitutes an alternative to the already existing Finmeccanica GNC validation environment.

The proposed models, although simplified, are able to take into account the main effects of the sea's disturbance on the ship motion and of the ship air wake on the helicopter trajectory. Concerning the helicopter vehicle dynamics, its model emulates the relevant closed loop performance of the vehicle and includes operating envelope limitations through a model for aerodynamic forces and thrust computation, whose parameters are identified from experimental data.

The paper also includes some fast time simulation results compared to experimental data, demonstrating that the proposed simulation environment is accurate enough for GNC algorithms design.

Finally, some models of the above mentioned simulation environment were also integrated into the detailed Software-in-the-Loop Simulator of Finmeccanica, to perform real-time verification and validation of the whole Flight Management System (FMS). Therefore, a real-time automatic code generation process has been defined and implemented, in order to keep consistency between the simulation environment used for design, and the one used for final software verification. The paper briefly describes such generation process, which allowed producing reliable software code, compliant to DO-178C standard and Finmeccanica own implementation rules.

The proposed fast time simulation environment dramatically reduced the algorithms design time, risks and costs, by limiting the required flight test activities.

The take-off and landing algorithms developed by using the simulation environment described in this paper were successfully demonstrated in flight, by means of a full-size optionally piloted helicopter: the Finmeccanica SW-4 SOLO.

2 Simulation Models

The model based design process of a Guidance Navigation and Control system requires the development of simulation models with different complexity level, to be used in the various development phases, as shown in Figure 1.

The present section describes the mathematical models integrated into the simulation environment that was employed to design the helicopter trajectory generation and tracking algorithms for automated take-off and landing on a frigate deck. Figure 2 shows the functional architecture of such environment.

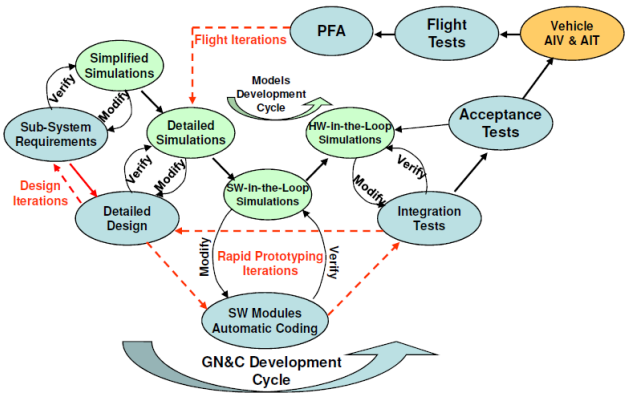

Figure 1. GNC Technology Development Cycle.

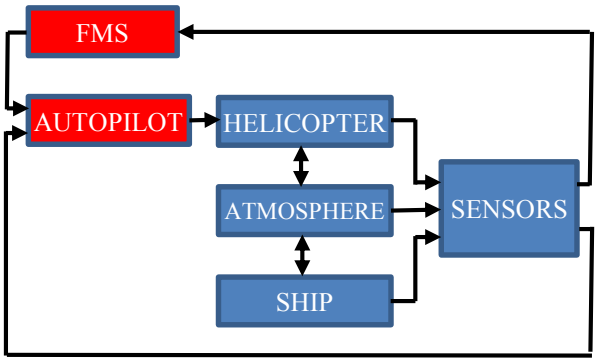

Figure 2. Simulation Environment functional architecture.

The blue blocks represent the simulation models, scope of this paper, whereas the red blocks are the GNC algorithms. The following sub-sections describe in detail each blue block.

2.1 Helicopter Model

Trajectory generation and tracking algorithms typically require the knowledge of vehicle's position and velocity only. Therefore, for the design and preliminary verification of such algorithms, it is sufficient and cost effective to model only the closed loop attitude dynamic response of the vehicle coupled with the high-level modes of the autopilot system. With this approach, a rigid body with three degrees of freedom, subject to external forces, and the rotational dynamic response of the vehicle to the autopilot commands represent the helicopter dynamics.

While this modelling approach is widely used in fixed-wing aircraft for guidance algorithms design, it is quite unusual for helicopters, because it does not take into account the coupled dynamics of the rotor flexibility with the helicopter rigid flight mechanics (Tishler et al., 2006).

Key original contribution of this paper is the development of a mixed empirical and physical formulation of the equations, so that the resulting simulation model includes only the low frequency effects of the neglected helicopter dynamics. As demonstrated by the comparisons with flight data reported in this paper, this allows obtaining enough accurate simulation results during the quasi-static manoeuvers of take-off and landing, while still taking into account the disturbance effects of wind and ship air wake.

The model assumes flat and fixed Earth, with constant gravity acceleration, and quasi-stationary variation of the vehicle mass (only due to fuel consumption).

The model's commands are the reference attitude and collective, while wind velocity ($\underline{V}_W$) is the disturbance input.

The actual attitude (φ_H, ϑ_H, ψ_H) and collective (δ_{coll}) of the vehicle, used in (1) for computation of forces, are modelled by unitary gain second order filters applied to the commands provided as input to the helicopter model. Such filtered Euler angles and collective and their rates are also saturated to account for actuator velocity limitations and some inner autopilot protection functions. Overall, the linear filters and related saturations model the closed loop performance of the inner autopilot modes. The parameters of both these filters and saturations are scheduled with respect to airspeed and they were identified by analyzing flight data gathered in specific manoeuvers.

The outputs are the helicopter position, velocity, load factors, actual attitude and angular rates.

The following equations of motion of the vehicle centre of mass (CoM), in North-East-Down (NED) inertial reference frame (McCormick, 1995), compute such outputs:

$$m\dot{\underline{V}} = \underline{F}\left(\varphi_H, \vartheta_H, \psi_H, \delta_{coll}, \underline{V}_W\right) \quad (1)$$

$$\dot{\underline{P}}_H = \underline{V}_H \quad (2)$$

$$\dot{h} = -w \quad (3)$$

where $\underline{V}$ is the inertial velocity vector, $\underline{V}_H$ and w are its horizontal (included into the North-East plane) and vertical components (positive down), respectively; $\underline{P}_H$ is the horizontal position and h the altitude of the vehicle CoM; m is the helicopter mass and $\underline{F}$ is the resultant force vector acting on the vehicle.

The force vector $\underline{F}$ is composed by gravitational force $\underline{W}$ (constant, and directed along the down axis of the NED reference frame), aerodynamic force $\underline{F}_A$ and propulsive force $\underline{T}$.

The computation of aerodynamic and thrust forces is first performed in the vehicle body reference frame, and then it is rotated in NED reference frame. The aerodynamic forces in body axes (F_{Ai}^B) are as follows:

$$F_{Ai}^B = q_{dyn}\sum_j S_j c_{i,j}(\alpha,\beta) \quad (4)$$

$$V_{TAS}^2 = \left(\underline{V}-\underline{V}_W\right)^T\cdot\left(\underline{V}-\underline{V}_W\right) \quad (5)$$

$$q_{dyn} = 0.5\rho\cdot V_{TAS}^2 \quad (6)$$

$$\alpha = tg^{-1}\left(w_{TAS}/u_{TAS}\right) \quad (7)$$

$$\beta = \sin^{-1}\left(v_{TAS}/V_{TAS}\right) \quad (8)$$

where q_{dyn} is the dynamic pressure, ρ is the air density, $V_{TAS} \equiv (u_{TAS}, v_{TAS}, w_{TAS})$ is the helicopter true airspeed, S_j is the reference aerodynamic surface of the j-th aerodynamic component (that is, fuselage, vertical and horizontal stabilizers) and $c_{i,j}$ the corresponding aerodynamic non-dimensional coefficient, which depends on the angle of attack α and sideslip angle β. Tabled functions express the aerodynamic coefficients using data extrapolated from flight experiments.

It is worthy to note that the aerodynamic angles α and β are not defined when the helicopter airspeed is null, for example in hover condition with null wind speed. In this case, the aerodynamic forces are negligible and the aerodynamic angles are not computed.

The propulsive force is evaluated by using the following semi-empirical linear model (Gavrilets, 2003):

$$T = z_{coll}\left(V_{TAS}\right)\cdot\delta_{coll} + z_w\left(V_{TAS}\right)\cdot w \quad (9)$$

The parameter z_{coll} is a gain between the thrust and the collective command δ_{coll} in level flight trim conditions. It is scheduled as a function of the forward speed of the aircraft with respect to air, and its values were identified applying a best-fit procedure of the rotor thrust data in

different flight conditions provided by the helicopter manufacturer.

The parameter z_w relates the thrust to the vertical speed. Although an analytical relation exists to express these parameters as function of vehicle characteristics (Gavrilets, 2003), in the present work, z_w was computed by fitting experimental data in climb and descent flight, and it is expressed as fraction of z_{coll}.

The thrust vector is assumed to point in the opposite direction of the body Z-axis. This hypothesis allows reproducing in simulation the trim values of pitch angle experimented in flight by the vehicle in level flight conditions.

2.2 Atmosphere Model

This model is in charge to reproduce the environmental conditions, in which the helicopter flies, that can influence the vehicle behaviour.

The model includes computation of atmospheric parameters (air density and temperature, static and dynamic pressure), wind velocity (wind shear, wind gust, atmospheric turbulence), and ship air wake experimented by the helicopter, based on its current position and velocity. International Standard Atmosphere (McCormick, 1995), von Karman model (von Karman, 1948) and standard wind model (MIL-F-8785C, 1991) are used for atmospheric parameters, turbulence and wind shear and gust, respectively.

Another element of originality included in this paper concerns the simplified ship air wake model, which is implemented as a stochastic phenomenon through a parameter modification of the von Karman turbulence model (von Karman, 1948).

In this model, independent white noise processes are suitably filtered to yield the desired forms of output power spectral density. The transfer functions (X_{ug}, X_{vg}, X_{wg}) of these linear filters in the Laplace domain are:

$$X_{ug}(s) = \sigma_u \sqrt{(2 \cdot L_u)/(\pi \cdot V_{TAS})} \cdot \frac{1}{1 + (L_u / V_{TAS}) \cdot s} \tag{10}$$

$$X_{vg}(s) = \sigma_v \sqrt{(2 \cdot L_v)/(\pi \cdot V_{TAS})} \cdot \frac{1 + 2\sqrt{3} \cdot (L_v / V_{TAS}) \cdot s}{\left[1 + (2 \cdot L_v)/V_{TAS} \cdot s\right]^2} \tag{11}$$

$$X_{wg}(s) = \sigma_w \sqrt{(2 \cdot L_w)/(\pi \cdot V_{TAS})} \cdot \frac{1 + 2\sqrt{3} \cdot (L_w / V_{TAS}) \cdot s}{\left[1 + (2 \cdot L_w)/V_{TAS} \cdot s\right]^2} \tag{12}$$

where σ_u, σ_v, σ_w and L_u, L_v, L_w are gains and scale factors, respectively, to be tuned through the analysis of CFD or experimental (wind tunnel or flight test) data.

Anyway, due to the unavailability of these data, such model parameters and their dependencies from helicopter state variables were determined through literature analysis and physical considerations.

The scale factors are set proportional to the characteristic lengths of the ship super-structure, which generates the wake. Since the effects of the wake on helicopter depend also from ship-helicopter relative position, the filters gains varied linearly with the ratio between ship speed and the square of the helicopter-ship distance.

Moreover, to take into account the local effect of the air ship wake disturbance and its dependence on wind direction, the wake's perturbation is only active within a limited size parallelepiped, which is oriented parallel to the wind speed and has width equal to the section of the super-structure orthogonal to the wind direction, length equal to three times the superstructure's section parallel to the wind direction, and height equal to three times the superstructure's height.

2.3 Ship Model

The ship translational motion is represented through kinematic relations, for the computation of undisturbed centre of mass position and velocity, plus an additive stochastic model, which simulates the sea wave disturbance on the ship. The applied equations for nominal position and velocity computation are:

$$\dot{\underline{V}}_{No} = \begin{bmatrix} a_x & a_y & 0 \end{bmatrix}^T \tag{13}$$

$$\dot{\underline{P}}_{No} = \begin{bmatrix} u_{No} & v_{No} & -w_{No} \end{bmatrix}^T \tag{14}$$

where a_x and a_y are the commanded horizontal acceleration of the ship; $\underline{V}_{No} \equiv (u_{No}, v_{No}, w_{No})$ and $\underline{P}_{No} \equiv (x_{No}, y_{No}, h_{No})$ are nominal velocity and position in NED reference frame, respectively. The actual position $\underline{P}_N \equiv (u_N, v_N, w_N)$ and velocity $\underline{V}_N \equiv (x_N, y_N, h_N)$ are calculated by adding the sea disturbance $\underline{\eta} \equiv (\eta_x, \eta_y, \eta_z)$ to nominal values:

$$\underline{V}_N = \begin{bmatrix} u_{No} & v_{No} & 0 \end{bmatrix}^T + \dot{\underline{\eta}} \tag{15}$$

$$\underline{P}_N = \underline{P}_{No} + \underline{\eta} \tag{16}$$

The attitude equations are defined independently as follows:

$$\begin{bmatrix} \varphi_N \\ \theta_N \\ \psi_N \end{bmatrix} = \begin{bmatrix} \varphi_0 \\ \theta_0 \\ \psi_0 \end{bmatrix} + \begin{bmatrix} \eta_\varphi \\ \eta_\theta \\ \eta_\psi \end{bmatrix} \tag{17}$$

It is assumed that the ship does not steer when helicopter is close, therefore its Euler angles (φ_N, θ_N, ψ_N) only depend on their initial values and on the sea disturbance (η_φ, η_θ, η_ψ).

The stochastic variables introduced in (16) and (17) for representing the sea disturbance are generated using the same equations. A mean velocity V_S and displacement D_S produced by the disturbance is associated to each variable. V_S and D_S depend on ship speed and sea state, and are provided by look up tables, which collect experimental data.

The sea disturbance is periodic and it pulsation ω is given by (Holthuijsen, 2017)

$$\omega = 2\pi V_S / D_S \quad (18)$$

The time evolution of the generic component of the sea disturbance η_i is then evaluated as follows

$$\eta_i(t) = A_i \sin(\omega_i t) \quad (19)$$

The gain A_i is a random variable with Rayleigh distribution, whose parameters depend on sea state and ship speed and are provided by a look up table based on experimental observations. During a simulation, the gain A_i is updated at the end of each wave period (that is, each D_S / V_S seconds) by performing a new random draw.

2.4 Sensor Model

Two kinds of sensors are available on-board the helicopter and are included into the simulation environment: a standard navigation suite (composed of an inertial navigation system and an air data system) and a differential GPS, with centimetric precision, denoted as Precision Positioning System (PPS) and needed for accurate relative navigation during take-off and landing operations.

Each measurement (M) is computed starting from its simulated true value ($\overline{M}$) taken from the models of the helicopter, the ship or the atmosphere.

For what concerns the inertial navigation sensor, each true variable to be measured is filtered and sampled. Then it is corrupted by introducing a scale factor deviation (C_{SF}), a bias (e_{bias}), white noise (e_{white}) and an additive magnetic declination error (e_{dec}), which is zero for all the measurements but the helicopter heading:

$$M = C_{SF}\overline{M} + e_{bias} + e_{white} + e_{dec} \quad (20)$$

The air data measurements are generated through the relation:

$$M = \overline{M} + e_{bias} + e_{white} \quad (21)$$

Concerning the GPS sensor, it is simulated corrupting the true measurements with bias, white noise and diluition of precision error (e_{DOP}):

$$M = \overline{M} + e_{bias} + e_{white} + e_{DOP} \quad (22)$$

All the additive errors in (20), (21) and (22) are stochastic and derived from the specification data sheet of the real sensor.

In the GPS model, these errors depend on the configuration of the sensor, which can work in SPS (Standard Positioning Service), DGPS (Differential GPS) and RTK (Real Time Kinematic) mode. The model also allows injecting a failure which degrades the precision of the sensor from RTK mode (also denoted as Precision Positioning System) to SPS mode.

3 Code Generation and Verification

As said, some of the developed models (e.g. ship, ship air wake and GPS sensor) were automatically software coded after the implementation in Matlab/Simulink, in order to allow their integration into the Finmeccanica real-time Software-In-the-Loop (SIL) simulator, which is used to test on ground the GNC prototype. Figure 3 shows the applied code generation process and testing methodology.

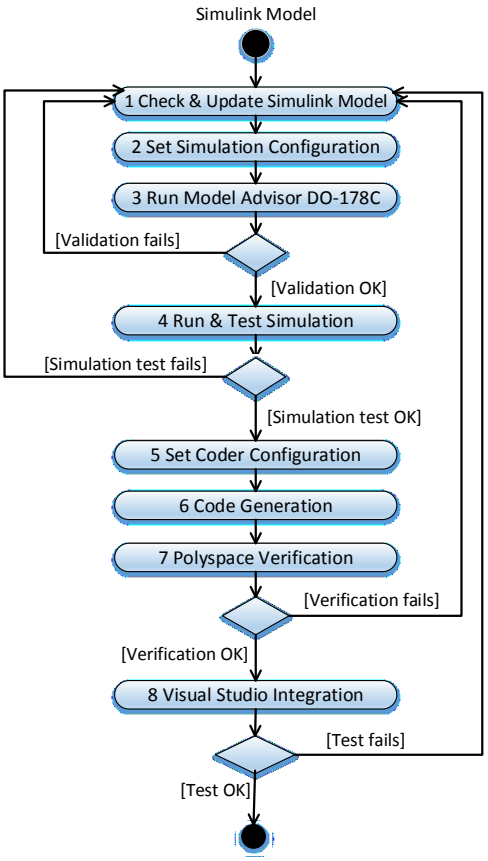

Figure 3. Code generation operational flow.

The flow starts with the selection of the Simulink model from which the code shall be generated. This model shall follow Finmeccanica proprietary design rules and specifications; to this end, a proprietary Simulink library have been developed and used to implement the models.

In step 1, the Model Update command in Simulink environment allows to check for errors and warnings. Then, the configuration settings are applied by running a Matlab script (step 2), that is customized to make the Simulink model compliant to the DO-178C standard. This compliance is verified in step 3 by means of the Mathworks Model Advisor tool. Next, the unit test for each Simulink model is performed, still in Simulink environment (step 4). In step 5, a proprietary Matlab script defines the Code Configuration settings; then the source C Code of the model is automatically generated (step 6) using Real Time Workshop. The Mathworks Polyspace tool is applied in step 7, to perform a static analysis of the generated code in order to check the absence of overflow, divide by zero, out of bounds array access, and other kind of run-time errors. If the generated code passes Polyspace tests, it can be integrated into Microsoft Visual Studio Environment

(step 8) to be tested with the same test vectors used in Step 4. Finally, the test outputs of step 4 and step 8 are compared, in order to check the correctness of the generated code.

After that, the model code can be integrated into the final detailed simulation model, being sure that it performs exactly as the simulation environment used for design.

4 Simulation Results

The principal phenomena that influenced the design of the trajectories and tuning of the tracking algorithm for automatic take-off and landing are the wake phenomenon near the ship, the PPS availability along the trajectory, the disturbance of the sea waves on the ship deck motion and the performance and dynamic behavior of the helicopter.

The validity of the proposed helicopter model for GNC algorithm design can be demonstrated by Figure 4 where comparison of flight data versus simulation data is reported for attitude.

The differences that can be noted have negligible effects on the algorithm design and preliminary testing, as the helicopter low frequency behavior is almost accurately predicted. Similar results hold for acceleration, not reported here for the sake of brevity.

Moreover, Figure 5 compares the collective deflections in trim condition at 650ft altitude computed by using the model with a validation data set provided by Finmeccanica: the model reproduces quite well the vehicle behavior, confirming the validity of the proposed helicopter thrust model.

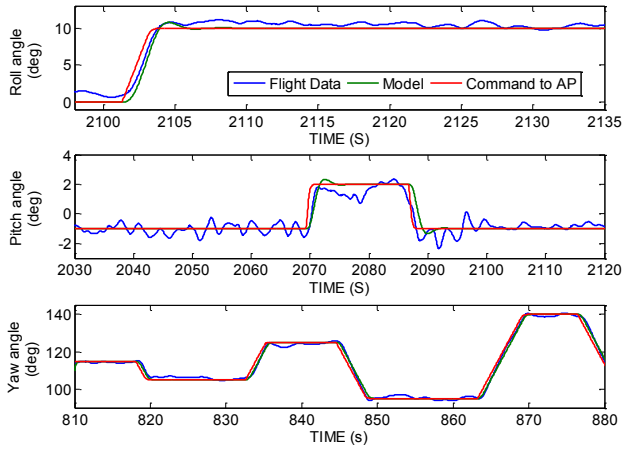

Figure 4. Comparison between simulated and experimental attitudes.

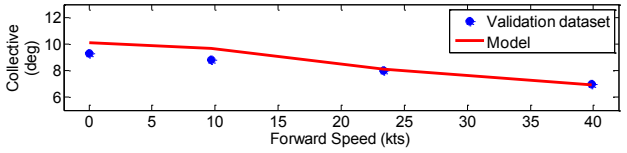

Figure 5. Comparison between simulated collective deflections in trim condition and validation data.

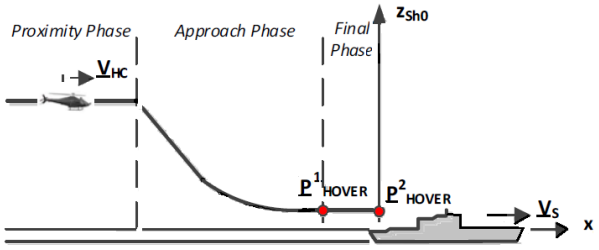

Figure 6. Schematic representation of the landing trajectory.

The other main simulated effects on a sample automatic landing trajectory are also presented below.

The designed landing trajectory, schematically shown in Figure 6, is structured in three phases. In the Proximity phase the helicopter is almost aligned with the ship direction at a desired speed in order to follow properly the descending path to the first relative hovering way point (*Approach phase*). In the Final phase, after the operator acknowledgment, the helicopter moves to the second relative hovering waypoint ($\underline{P}^2_{HOVER}$) and finally lands on the ship deck.

The modelled action of the air wake on the helicopter vertical acceleration, during the automatic landing manoeuvers, is shown in Figure 7.

It is worth to note, in the second graph, how the effect of the air wake is null until the helicopter enters in a proper area (near $\underline{P}^1_{HOVER}$). As said, such area depends on the ship super-structure and wind direction (which in the test is aligned with the ship speed). When the ground operator gives the acknowledge command, the relative distance between the ship and the helicopter decreases while the wake effect increases. The same happens as the relative altitude decreases in the last manoeuver for deck landing.

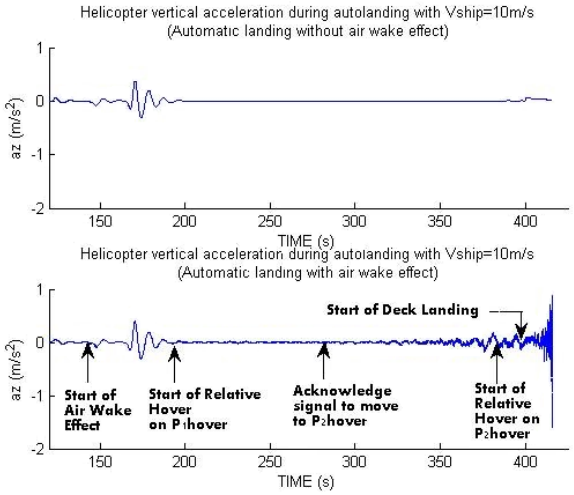

Figure 7. Air wake effect on the helicopter vertical acceleration.

Figure 8 presents the effect of the sea waves on the ship. It refers to Type 23 frigate at two different speeds for see state level six.

As expected, it is highlighted how the frequency and the mean amplitude of ship deck motion decrease with the increase of the ship speed. Indeed wave disturbances are low pass filtered by the ship inertia, and the cut off frequency of this filter decreases when ship speed increases. Such movements are taken into account in the last part of the landing manoeuver when the helicopter waits for a quiescent state of the ship deck before landing.

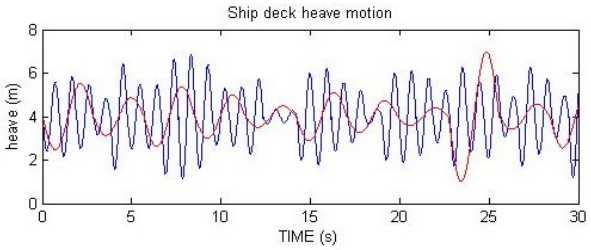

Figure 8. Ship deck motion under sea state level six at 30 knots ship speeds (red) and null ship speed (blue).

5 Conclusions

Accurate, yet simple, simulation environments are fundamental tools to develop GNC algorithms.

This paper presented an effective simulation environment to be used specifically for design, preliminary test and software implementation of automatic take-off and landing algorithms on a ship deck.

With reference to rotary-wing applications, an original modelling approach based on both empirical relations and appropriate mathematical formulation has been proposed that still accurately reproduce helicopter and ship transactional motion and ship air wake.

Simulation results demonstrate effectiveness and accuracy of such modelling approach.

The developed simulation environment contributed to reduce design time, risks and costs of automatic take-off and landing algorithms on a ship deck that were successfully tested in flight.

Future work will be focused on the refinement of the model's parameters (especially for what concern the ship air wake model) based on the analysis of flight data.

Simulation Model of a Piston Type Hydro-Pneumatic Accumulator

Juho Alatalo Toni Liedes Mika Pylvänäinen

Mechatronics and Machine Diagnostics, University of Oulu, Finland,
{juho.alatalo,toni.liedes,mika.pylvanainen}@oulu.fi

Abstract

Hydro-pneumatic accumulators are used to improve the features of different kinds of hydraulic systems and they are common in industry and mobile applications. In order to include functionality of accumulators to hydraulic system models, an accurate yet light simulation model of hydro-pneumatic accumulator is needed. In this paper a simulation model of a piston type hydro-pneumatic accumulator is presented. The simulation model takes into account of the behavior of friction, nitrogen gas and hydraulic fluid. The simulation model was validated by comparing the simulation results to measurement results obtained from laboratory tests, and strong correlation was found between them. The model is suitable for researchers as well as for engineers in designing work in industry.

Keywords: gas-charged accumulator, computer simulations, modelling

1 Hydro-pneumatic Accumulator

Storing the energy in hydraulic fluid is very tricky. That is why there is a separate component for storing and releasing energy in hydraulic systems, an accumulator. In the accumulator energy can be bound for example to the gas pressure or potential energy of the spring. This study focuses on examining the gas-operated accumulator, so called hydro-pneumatic accumulators.

Hydro-pneumatic accumulators are conventionally utilized in hydraulic systems in several ways. One of the most common way is to improve the features of the hydraulic system, for example, in order to absorb the pressure impulses in the hydraulic line. The other main method of application for the hydro-pneumatic accumulator is to secure the safe operation of the machine, and in applications of this kind the accumulator usually operates as a reserve volume flow source. One of the main advantages of the hydro-pneumatic accumulators is their capability to act as a local and distributed energy storage and volume flow source.

Hydro-pneumatic accumulators are widely used in industry and mobile applications. In industry, the hydro-pneumatic accumulators are common in power plants such as windmills and wave power plants. In mobile applications, hydro-pneumatic accumulators are also common in different kinds of mobile working machines like mine loaders, harvesters and load-haul-dump machines. Hydro-pneumatic suspension is a widespread solution in a variety of mobile applications: cars, trucks, agricultural vehicles and military vehicles.

Three main types of accumulators exist with different kinds of properties: a diaphragm accumulator, a bladder accumulator and a hydro-pneumatic piston accumulator. Bladder and diaphragm accumulators are very much alike, but the piston type accumulator has some pros and cons compared to the two mentioned above. The main disadvantages in a piston type accumulator compared to the bladder and diaphragm type accumulators are its insensitivity to small and rapid pressure fluctuations and the greater weight of the accumulator, which may be essential in mobile machines, but not necessary in an industrial environment. The main advances in a piston type accumulator compared to the bladder and diaphragm type accumulators are its ability to handle a wider range of pressure changes and its ability to be entirely depleted from hydraulic fluid. In addition, a piston type accumulator is less sensitive to temperature changes and its installation orientation is not predefined. Also, using the sensors is easier in piston type accumulators, which means that the state of the accumulator is easier to monitor (Palomäki, 2012). In most applications all of the accumulator types mentioned above can be used, but in research and development the piston type is preferred because of its wider ranges of temperature and pressure, its modifiability, durability and the ability to be easily monitored by sensors. The structure of a piston type hydro-pneumatic accumulator is shown in in Figure 1.

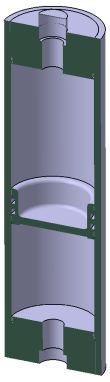

Figure 1. Cross-section of a piston type hydro-pneumatic accumulator.

1.1 Recent Research

The focus of recent studies in this field is on energy consumption and energy storing, and the potential of the hydro-pneumatic accumulator in this research areas has been realized. Even though the hydro-pneumatic accumulator is an old invention, the research and development of piston type accumulators is constantly ongoing and some popular development areas can be introduced: the improvement of piston type accumulator energy storing capacity (Tavares, 2011) and the improvement of a piston type accumulator's efficiency by utilizing heat regeneration (Stroganov and Sheshin, 2011). Both these areas are closely linked with research into energy recovering systems (Achten, 2008; Ancai and Jihai, 2009; Lin et al., 2010; Zhang et al., 2010), which in particular is a contemporary research area in the field of mobile working machines.

Minav et al. (2012) have studied means of improving the energy efficiency of a mobile working machine. In their conclusion the storing of the hydraulic energy in piston type accumulators was seen as a waste of energy in a given type of energy storing method. Instead, Minav et al. proposed that energy should be stored in electric form. Their research shows the need for additional research into hydraulic systems and hydraulic energy storing methods. Instead of abandoning the idea of using hydro-pneumatic accumulators as energy storages in a mobile working machine, it would be economically reasonable to redesign and improve the old accumulator design and inefficient energy storing methods. This is due the fact that hydraulics are still widely favored in industry and especially mobile working machines due to its good power-to-weight-ratio and the ease of maintenance.

1.2 Purpose of This Study

Despite the simplicity of the piston type hydro-pneumatic accumulator's structure, it is fairly complex to model, because from the modelling point of view it is a multi-domain system. This means that it has several different parts: mechanics, thermodynamics, pneumatics and hydraulics.

This study presents an advanced but yet feasible simulation model of a piston type hydro-pneumatic accumulator. The aim of the simulation model is to be an easy-to-use but yet accurate tool for researchers or engineers and designers in industry, for example, providing information on how an accumulator works in larger hydraulic systems, such as energy storing or suspension systems.

2 Logical Structure of Simulation Model

In this section the relevant physical phenomena of a piston type hydro-pneumatic accumulator are examined and the conceptual model is created on which the simulation model is based. The conceptual model is used to ensure that the logical structure of the model is correct and that all the essential elements that describe the behavior of the real hydro-pneumatic accumulator are included in the simulation model. When all the interactions between these elements are properly described, the structure of the simulation model is verified allowing the simulation model to achieve the desired accuracy.

2.1 Physics of Piston Type Hydro-Pneumatic Accumulator

In a piston type hydro-pneumatic accumulator, part of the energy adhered to the hydraulic fluid is converted to the energy adhered to the nitrogen gas with the help of the motion of the piston.

2.1.1 Nitrogen gas

In the regular duty cycle of the hydro-pneumatic accumulator, the volume V_{gas}, pressure p_{gas} and temperature T_{gas} of the nitrogen gas change and their values are dependent on each other. The volume of the gas, naturally, follows the position of the piston and volume and temperature increase and decrease in relation to the position of the piston. The nitrogen gas interacts with its environment not only via piston displacement, but also by the transition of heat energy through the piston wall. The heat exchange between the environment and the gas depend on the temperatures of the gas and the environment. In this case the environment of the gas is considered to be the interior of the cylinder wall. Also the amount of nitrogen gas usually decreases slowly over the time, due to the leakage past the piston or through the gas valve.

2.1.2 Mechanical Structure

There are two main mechanical structures in piston type hydro-pneumatic accumulators: the piston and cylinder wall. The piston is the only moving part of the mechanical structure and the kinetic energy is bound to the piston when it is moving. There is friction between the seal of the piston and the cylinder wall, which should be noted especially when the piston is starting to move from the rest position. The friction also heats up the piston and cylinder wall. The seal of the piston is a flexible element and together with piston inertia and static friction it causes the piston type accumulator to be insensitive to the small and high frequency fluctuations of pressure. The cylinder wall mainly acts as a thermal energy reservoir, which interacts with nitrogen gas and the ambience of the accumulator. All the mechanical parts are subject to constant changes in pressure and temperature, which affects the dimensions of these mechanical parts.

2.1.3 Hydraulic Fluid

The pressure, volume and the temperature of the hydraulic fluid also change during the regular duty cycle of the accumulator, but compared to nitrogen gas the changes in volume and temperature are much less significant. If the hydraulic fluid contains a lot of air bubbles, changes of volume occur at the lower pressure levels. There is also

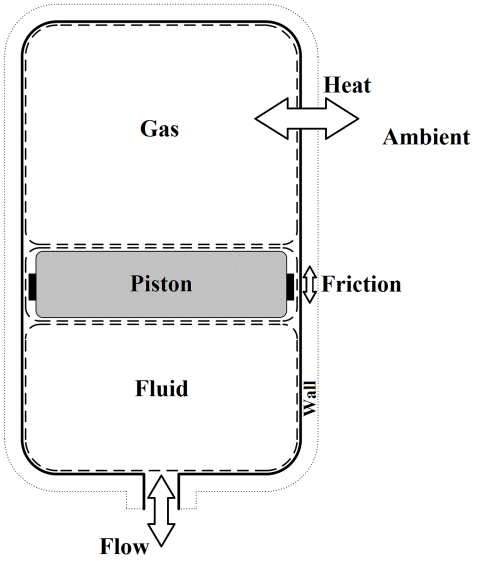

Figure 2. Conceptual model of a hydro-pneumatic accumulator.

one major difference between the nitrogen gas and the system that the hydraulic fluid forms: the amount of hydraulic fluid in a hydro-pneumatic accumulator varies dramatically during the regular duty cycle of the hydro-pneumatic accumulator due to the input and output flow. When flowing, the hydraulic fluid has some kinetic energy adhered to itself and also some dissipation occurs.

2.2 Conceptual Model

In this study the accumulator is considered to be a system that consists of several subsystems. These subsystems represent the essential elements needed to create the model. Figure 2 shows the subsystems that form the whole system of an accumulator. The subsystems are nitrogen gas, piston and hydraulic fluid. Everything outside of these subsystems is assumed to be ambient. It is important to note that some assumptions are made in order to simplify the model. It is good to keep in mind that we want the model to be feasible but yet accurate enough, so some assumptions and idealizations have to be made. One main simplification is that cylinder walls are not part of this model. The walls of the cylinder store thermal energy and play quite a significant role in the accumulator. The role of the cylinder wall can be taken into account when choosing the mathematical representation of the nitrogen gas, which will be discussed in the next section. All the material in each subsystem is predicted to be homogenous, which means that air bubbles in the hydraulic fluid are not part of the model. Changes in the dimensions of the cylinder wall and piston are not taken into account. Also the subsystem of gas is assumed to be a closed system, which means that the amount of substance in this subsystem is constant. The kinetic energy adhered to the motion of the hydraulic fluid is considered negligible.

3 Mathematical Model

This simulation model was made using MATLAB/Simulink, which is advisable for modelling a multi-domain system of this kind. The approach of this simulation model was chosen to be a lumped model, which at best keeps the simulation model light. In this section we will go through the equations used in this model.

3.1 Equations for Nitrogen Gas

In this simulation model the nitrogen gas was described with a real gas model, which has been used in several investigations. Heat transfer in a hydro-pneumatic accumulator has been studied by Els and Grobbelaar (1999), Pourmovahed and Otis (1990) and Giliomee (2003). The advantages of this real gas model compared to the commonly used ideal gas model in a piston type hydro-pneumatic accumulator have been investigated by Puddu and Paderi (2013) and Kroneld (2018) used real gas model in his research.

In this real gas model, the pressure, volume and the temperature of the gas are described using three equations. (1) describes the heat transfer between the gas and the environment,

$$\dot{T}_{\text{gas}} = \frac{(T_{\text{amb}} - T_{\text{gas}})}{\tau_{\text{therm}}} - \frac{\dot{v}}{C_v}\left[\frac{RT_{\text{gas}}}{v}\left(1+\frac{b}{v^2}\right) + \frac{1}{v^2}\left(B_0 RT_{\text{gas}} + \frac{2C_0}{T_{\text{gas}}^2}\right) - \frac{2c}{v^3 T_{\text{gas}}^2}\left(1+\frac{\gamma}{v^2}\right)e^{-\frac{\gamma}{v^2}}\right], \quad (1)$$

where $\dot{T}_{\text{gas}}$ is change in gas temperature, T_{amb} is ambient temperature, T_{gas} is gas temperature, τ_{therm} is thermal time constant, $\dot{v}$ is change in specific volume of the gas, C_v is constant volume-specific heat capacity of gas, v is the specific volume of the gas and parameters R, b, B_0, C_0, c, and γ are specific constants for nitrogen gas and their values can be found in (Giliomee, 2003).

(2) is the Benedict-Webb-Rubin -equation of state (Cooper and Goldfrank, 1967),

$$p_{\text{gas}} = \frac{RT_{\text{gas}}}{v} + \left(\frac{B_0 RT_{\text{gas}} - A_0 - \frac{C_0}{T_{\text{gas}}^2}}{v^2}\right) + \left(\frac{bRT_{\text{gas}} - a}{v^3}\right) + \frac{a\alpha}{v^6} + \left[\frac{c\left(1+\frac{\gamma}{v^2}\right)e^{\frac{-\gamma}{v^2}}}{v^3 T_{\text{gas}}^2}\right], \quad (2)$$

where p_{gas} is gas pressure and parameters A_0, a and α are specific constants for nitrogen gas and their values can be found in (Giliomee, 2003).

(3) is the equation for the specific heat capacity of the

gas,

$$C_v = R\left[\frac{N_1}{T_{\text{gas}}^3}+\frac{N_2}{T_{\text{gas}}^2}+\frac{N_3}{T_{\text{gas}}}+(1-N_4)+N_5T_{\text{gas}} + N_6T_{\text{gas}}^2+N_7T_{\text{gas}}^3+\frac{N_8\left(\frac{N_9}{T_{\text{gas}}}\right)^2 e^{\frac{N_9}{T_{\text{gas}}}}}{\left(\frac{N_9}{e^{T_{\text{gas}}}-1}\right)^2}\right], \quad (3)$$

where parameters N_1-N_9 are specific constants for nitrogen gas and their values can be found in (Giliomee, 2003).

As mentioned before, the cylinder wall is not included in this model. The lack of this kind thermal energy storage can be taken into account with the thermal time constant, which must be determined by measuring. This restricts the range of use of the model to situations where the system has been settled to the thermal balance e.g. for sinusoidal use. Also the ambient temperature must be measured. The mass of the nitrogen gas must also be measured in order to calculate the specific volume of the gas.

The way how the state variables of the real gas model are connected and how they depend on the other state variables of the simulation model can be seen from Figure 3.

3.2 Equations for Piston

The piston in this simulation model is constantly subjected to three different forces: the force caused by the hydraulic fluid pressure F_{hyd}, the force caused by the gas pressure F_{gas} and friction force F_μ. This means that the total force on piston F_{piston} can be written as:

$$\begin{aligned} F_{\text{piston}} &= F_{\text{hyd}} - F_{\text{gas}} \pm F_\mu \\ &= \Delta p_{\text{piston}} A_{\text{piston}} \pm F_\mu \\ &= (p_{\text{hyd}} - p_{\text{gas}}) A_{\text{piston}} \pm F_\mu, \end{aligned} \quad (4)$$

where Δp_{piston} is pressure differentiation over the piston, A_{piston} is the area of the piston, p_{hyd} is pressure of the hydraulic fluid and p_{gas} is pressure of the gas.

From Newton's second law we get:

$$F_{\text{piston}} = m_{\text{piston}}\ddot{x}_{\text{piston}}, \quad (5)$$

where m_{piston} is the mass of piston and $\ddot{x}_{\text{piston}}$ is the acceleration of piston.

The mass of the piston is easy to measure and no other parameters are needed to determine the piston.

The way the state of the piston depends on the other state variables of the simulation model of the accumulator can be seen from Figure 3.

3.3 Equations for Friction

The friction in this simulation model has been described with the friction model introduced by Olsson (1996). The friction model for the pre-sliding displacement is described with the help of bristles. After the bristles have deflected a certain amount, the surfaces start to slide with respect to each other. Friction plays important role in a piston type accumulator especially when the piston is changing direction or is at rest, and without such a complex friction model the accuracy of the simulation model would not be satisfying.

The friction force F_μ is written as:

$$F_\mu = \sigma_0 z + \sigma_1(v_{\text{frict}})\dot{z} + F_{\text{v}} v_{\text{frict}}, \quad (6)$$

where σ_0 is the stiffness of the bristle, z is the deflection of the bristle, $\sigma_1(v_{\text{frict}})$ is velocity dependent damping coefficient, $\dot{z}$ is the rate of change of deflection of the bristle, F_{v} is viscous friction coefficient and v_{frict} is relative velocity between surfaces.

The velocity dependent damping coefficient can be written as:

$$\sigma_1(v_{\text{frict}}) = \sigma_1 e^{-\left(\frac{v_{\text{frict}}}{v_{\text{d}}}\right)^2}, \quad (7)$$

where σ_1 is damping coefficient and v_{d} is the velocity when the damping affects.

The damping coefficient σ_1 can be chosen by using the equation:

$$0.5 \ldots 2\sqrt{\sigma_0 m_{\text{piston}}}. \quad (8)$$

The rate of change of deflection of the bristle can be written as:

$$\dot{z} = v_{\text{frict}} - \frac{|v_{\text{frict}}|}{g(v_{\text{frict}})} z, \quad (9)$$

where the equation $g(v_{\text{frict}})$ can be written as:

$$g(v_{\text{frict}}) = \frac{1}{\sigma_0}\left[F_{\text{C}} + (F_{\text{S}} - F_{\text{C}}) e^{-\left(\frac{v_{\text{frict}}}{v_{\text{S}}}\right)^2}\right], \quad (10)$$

where F_{C} is Coulomb friction, F_{S} is static friction and v_{S} is Stribeck velocity.

The parameters in the friction model are strongly dependent on the materials used and they must be figured out by measuring in order to make the friction model work. These measured parameters are F_{C}, F_{S}, F_{v}, σ_0, σ_1, v_{d} and v_{S}. The way the state variables of the friction model are connected to each other and how they depend on the other state variables of the simulation model of the accumulator can be seen from Figure 3.

3.4 Equations for Hydraulic Fluid

To figure out the pressure of the hydraulic fluid, the following equation were used (Merritt, 1967):

$$\dot{p}_{\text{hyd}} = \frac{B_{\text{hyd}}}{V_{\text{hyd}}}\left(\sum q - \dot{V}_{\text{hyd}}\right), \quad (11)$$

where $\dot{p}_{\text{hyd}}$ is the rate of change of the pressure of the hydraulic fluid, B_{hyd} is the bulk modulus of the hydraulic fluid, q is flow and $\dot{V}_{\text{hyd}}$ is the rate of change of the volume of the hydraulic fluid.

The pressure of the hydraulic fluid can be solved by integrating (11). The bulk modulus must be defined before this model can be used as a part of the simulation model

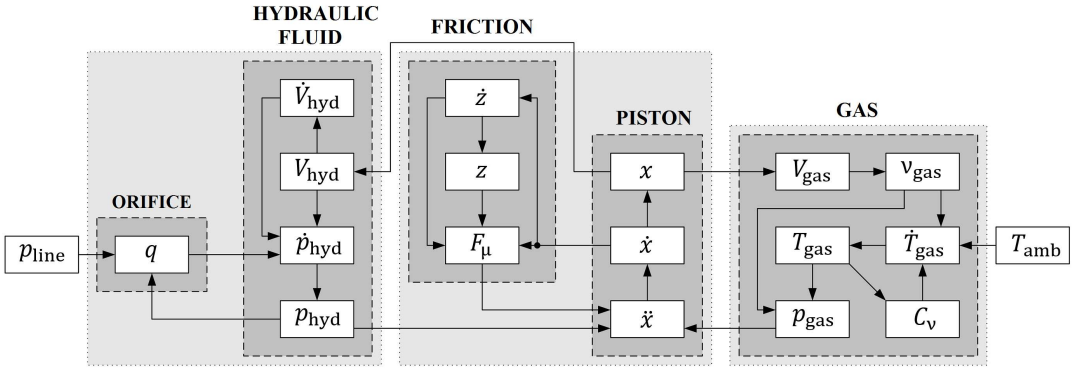

Figure 3. State variables and their connections in the simulation model.

and it is assumed to be constant. The way the state variables of the hydraulic fluid model are connected to each other and how they depend on the other state variables of the simulation model of the accumulator can be seen from Figure 3.

3.5 Equations for Orifice

If it is desired to use the pressure of the hydraulic line as an input for the whole simulation model, the input information is needed in order to convert to the quantity of the flow q before we can utilize it in a hydraulic fluid model. For this purpose the orifice model is placed between input pressure information and hydraulic fluid model. Also this model can be used to describe the dissipation that occurs when hydraulic fluid is flowing.

The orifice model used was introduced by Åman (2011) and it is a two regional orifice model that describes the laminar flow more accurately than the commonly used turbulent flow model. The difference between these two models becomes notable especially at zero flow and when the flow is changing direction. The model describes the flow with a piecewise defined equation:

$$q = \begin{cases} a_1\Delta p_{\text{orif}} + a_2\Delta p_{\text{orif}}^2 + a_3\Delta p_{\text{orif}}^3 & \text{if } |\Delta p_{\text{orif}}| < |\Delta p_{\text{trans}}| \\ K\sqrt{|\Delta p_{\text{orif}}|}\,sign(\Delta p_{\text{orif}}) & \text{if } |\Delta p_{\text{orif}}| \geq |\Delta p_{\text{trans}}| \end{cases}, \tag{12}$$

where Δp_{orif} is the pressure difference over the orifice.

When the density of the hydraulic fluid is assumed to be constant, the parameter K can be written as:

$$K = C_{\text{q}} A_{\text{orif}} \sqrt{\frac{2}{\rho_{\text{hyd}}}}, \tag{13}$$

where C_{q} is discharge coefficient, A_{orif} is the area of the orifice and ρ_{hyd} is the density of the hydraulic fluid.

According to Åman, the pressure limit Δp_{trans} can be defined as:

$$\Delta p_{\text{trans}} = \frac{Re^2 \upsilon^2 \pi \sqrt{\rho_{\text{hyd}}}}{\sqrt{32} C_{\text{q}} K}, \tag{14}$$

where Re is the Reynolds number and υ is kinematic viscosity of the hydraulic fluid.

The parameters a_1, a_2 and a_3 can be expressed as matrix $\mathbf{A}$:

$$\begin{aligned} \mathbf{A} &= \begin{bmatrix} a_1 & a_2 & a_3 \end{bmatrix} \\ &= \begin{bmatrix} \frac{5K}{4\sqrt{\Delta p_{\text{trans}}}} & 0 & -\frac{K}{4\Delta p_{\text{trans}}^{\frac{5}{2}}} \end{bmatrix}. \end{aligned} \tag{15}$$

The parameters C_{q}, Re, ρ_{hyd} and υ must be defined before this model can be used as part of the simulation model. Also the parameter A_{orif} must be adjusted so that the pressure drop over the orifice corresponds to the measured values. The way how the variable of the orifice model depends on the other variables of the simulation model of the accumulator is shown in Figure 3.

All the variables presented in Figure 3 can be solved either by means of the given equations or by integrating them. The inputs for the whole system are the pressure of the hydraulic line and environment temperature. If necessary, the flow can be used as an input too, but then the pressure of the hydraulic line and the orifice model must be ignored.

4 Modelling in MATLAB/Simulink

The layout of the simulation model built in MATLAB/Simulink follows the structure represented in Figure 3. In order to keep the layout of the simulation model lucid, the subsystems were used in Simulink. The named blocks in Figure 3 (Orifice, Hydraulic fluid, Friction, Piston and Gas) represent the contents of these subsystems. As an example of the method how the equations in the orifice subsystem are used in Simulink is shown in Figure 4. As can be seen from Figure 4 the inputs for the subsystem are the pressure of the hydraulic line, p_{line}, and the pressure of the hydraulic fluid, p_{hyd}. The output of this subsystem is the flow q. The parameters needed in the subsystem are read from a separate file, and the new set of parameters are extremely easy to feed to the model by just modifying the file where the parameters are read from. This makes the use of this simulation model flexible. The rest of the Simulink model is built by using the same kind of approach for every subsystems as described above.

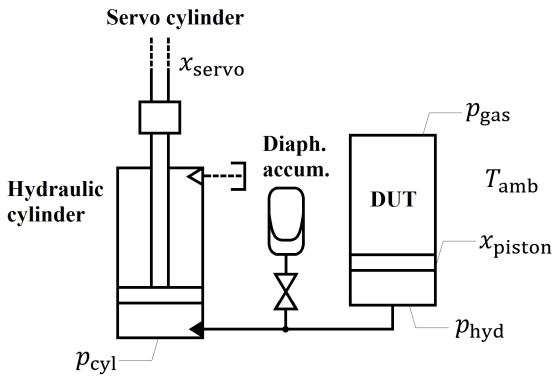

Figure 5. Schematic figure of the testing setup.

5 Calibration and Validation of the Simulation Model

The equations used in the simulation model were introduced in the previous section. These equations contained unknown parameters, excluding some parameters in the real gas model, which had to be defined. In order to define these parameters for this application, a testing setup was built and measurements were performed. The goal is to determine these parameters so accurately that our accumulator model is well calibrated and its performance can be validated by comparing the simulation results to the result obtained from the measurements for the real piston type hydro-pneumatic accumulators. The parameters were determined for five different piston type hydro-pneumatic accumulators, with piston diameters 60 mm, 80 mm, 100 mm, 125 mm and 140 mm and a nominal volume of 2 liters.

5.1 Testing Setup

The testing setup was built in the testing laboratory of the department of mechanical engineering at the University of Oulu. The schematic picture of the testing setup can be seen in Figure 5. The testing setup is a closed hydraulic system, which consist of a hydraulic cylinder that is directly connected to the piston type hydro-pneumatic accumulator. There is also a parallel diaphragm hydro-pneumatic accumulator that is only used in certain measurement runs. The piston of the hydraulic cylinder is driven by a hydraulic servo.

The pressure of the hydraulic fluid was measured directly from the bottom of the hydraulic cylinder and the piston type hydro-pneumatic accumulator and the pressure of the nitrogen gas was measured from the gas side of the piston type hydro-pneumatic accumulator. The pressures were measured using IFM PT9541 sensors. The position of the piston of the hydro-pneumatic accumulator was measured with a non-contact sensor in order not to disturb the performance of the accumulator with additional friction. The position of the piston was measured with a Temposonics MH Series sensor. Also the position of the servo cylinder and the outside temperature were measured. The servo position sensor was HBM 1-WA/500MM-L and the temperature was measured with an ordinary K-type thermocouple. The wall of the 140 mm diameter accumulator was so thick that the Temposonics sensor was unable to measure the position of the piston. Instead, the position of the piston of the 140 mm diameter accumulator was calculated from the position of the servo cylinder and by estimating the compression of the hydraulic fluid. The data acquisition was performed using NI cDAQ-9174, with NI 9215 and NI 9211 modules and with 250 Hz sampling rate. The variables at Figure 5 represent the measured quantities.

5.2 Laboratory Tests

Three different kinds of calibration runs were performed with the testing setup in order to determine the parameters named in Section 3.

The parameters F_C, F_S, F_v, v_d and v_S for the friction model were determined with the sinusoidal motion input excitation of the servo cylinder. The Stribeck curve could be created from the information on pressure differential over the hydro-pneumatic piston and the position information of the piston. The values for the parameters could be derived from the Stribeck curve.

The parameters σ_0 and σ_1 for the friction model were determined with the help of a diaphragm hydro-pneumatic accumulator. The pressure in the hydraulic system was raised slowly and the pressure and the maximum presliding deflection of the piston seals were measured. From this information the desired parameters could be derived.

To determine the thermal time constant τ_{therm} of the piston type hydro-pneumatic accumulator, step-type excitation was introduced to the accumulator. The pressure and the volume of the nitrogen gas was measured and the value of the τ_{therm} in the simulation model was iterated in so that the pressure of the simulation model behaved accurately enough.

5.3 Validation

The simulation models were validated by comparing their results to the measured values. Measured and simulated results are presented Figure 6 – Figure 9 and as can be seen, the simulation results correspond really well to the

measured data. Some of the curves appear to be one on the other, but on the *pV* chart some difference can be seen. Note that in Figure 8 the position of piston is estimated.

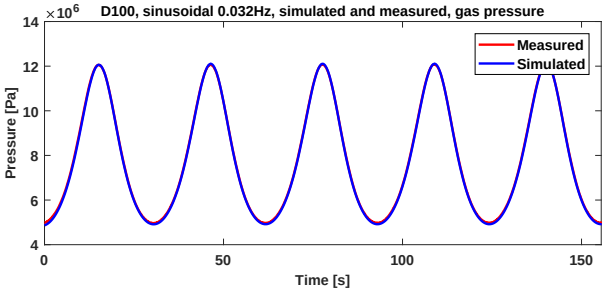

Figure 6. The gas pressures of the 100 mm diameter accumulator when the input for the accumulator is the sinusoidal 0.032 Hz flow.

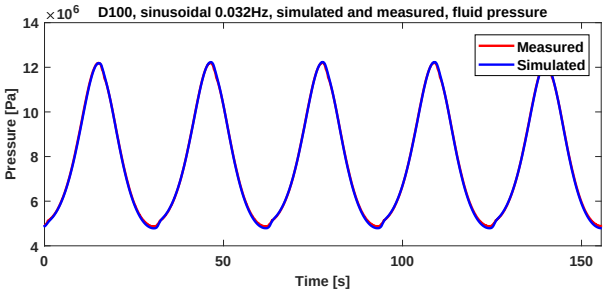

Figure 7. The hydraulic fluid pressures of the 100 mm diameter accumulator when the input for the accumulator is the sinusoidal 0.032 Hz flow

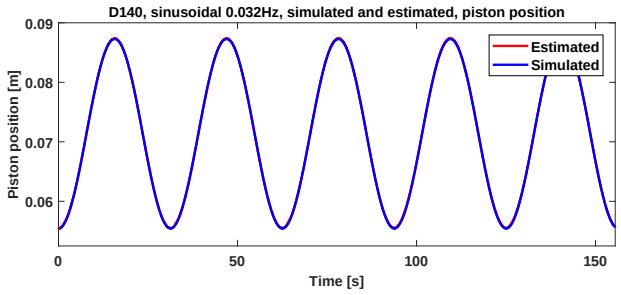

Figure 8. The piston position of the 140 mm diameter accumulator when the input for the accumulator is the sinusoidal 0.032 Hz flow.

6 Conclusions

The simulation model of the piston type hydro-pneumatic accumulator met the demand for an easy-to-use but yet accurate simulation model and it can be used either in research or in mechanical design work. The results of the simulation model were very accurate and there was strong correlation between the simulation and the measured data. The model itself appeared to be fairly easy to simulate. The simulation model is capable of simulating the performance of the piston type hydro-pneumatic accumulator in situations where the system is in thermal balance.

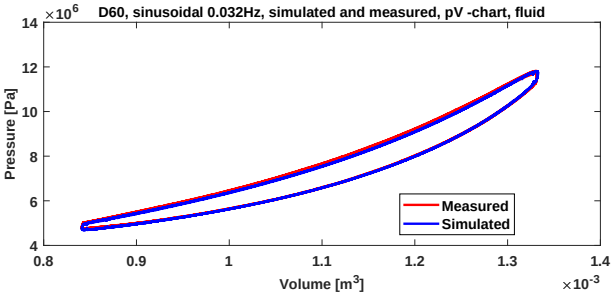

Figure 9. The *pV* chart of the 60 mm diameter accumulator when the input for the accumulator is the sinusoidal 0.032 Hz flow.

Real-time model-based condition monitoring can be regarded as an important method in future and these kinds of simulation models of different components play an important role in it. This simulation model provides a good foundation when heading towards this new practice.

There is need for further development in modelling the cylinder walls, which probably also allows the possibility to simulate situations where the accumulator is on the transition between thermal balance situations, thus extending the range of use of the simulation model.

Abstract

Emergency officers could often benefit from a route planning system that is based on constant traffic monitoring and complex decision making, seeking to give victims another breath of hope by assisting emergency units with reaching them on time. The main challenge is providing responses in a continuously evolving environment within a prescribed time frame, while using limited resources and information that is often incomplete or uncertain. This paper presents a route control concept for emergency vehicles through urban traffic. The proposed genetic controller is designed to dynamically reassess the route while the vehicle passes through the road network, continuously generating new routes based on current traffic. The algorithm is tested in an agent based simulation model that includes both traffic participants and a distributed traffic control system.

Keywords: genetic algorithm, emergency response, control systems, distributed control, agent based simulation model

1 Introduction

In complex and distributed urban environments, the services that provide quality of life and safety have to deal with unpredictable events and incomplete data. Moreover, intelligent transport systems are becoming increasingly important as they aim to provide solutions to crucial issues related to transportation networks, such as congestion and various incidents. One of the most important activities in the protection of human life is the intervention of emergency responders, for which an important issue in the unpredictable urban road networks is the time required for an emergency vehicle to reach an event scene. Congestion and the various obstacles that may appear during the journey on the chosen path can increase travel time and therefore reduce the chances of ensuring the safety of human life (Blackwell et al, 2002; Pons et al 2005; Sladjana et al 2011; Rushworth et al 2014).

Thus, re-calculating the routes of emergency vehicle during their journey based on environmental changes is a way to avoid these obstacles.

Real-time decision problems are also playing an increasingly important role in transportation management, as advances in communication and information technologies allow real-time information to be quickly obtained and processed. Therefore, dynamic vehicle route generation has become more and more efficient, especially in urban areas.

The problem of finding the most efficient routes for the quick access of the emergency vehicles in the current urban traffic is very important in terms of protecting and saving human lives. From an economic and social point of view, implementing the developed algorithms would increase the number of saved lives, reduce congestion and accident risk, would reduce fuel consumption and the time spent in traffic and by doing so, would also reduce the number of people affected by stress on the road.

The most important technological benefit regarding evolutionary computing is the possibility to integrate techniques typically associated with modeling complex systems in representing the possible solutions to optimization problems solved with the help of evolutionary algorithms. This opens the way to using these class of algorithms for solving problems that cannot be modeled using formal techniques and that can only be solved by using heuristic methods. The future applications of evolutionary computing are not restricted to vehicle routing; they include different other optimization problems, from designing control systems for processes affected by non-linearity and uncertainties, modeling complex and biological processes, algorithms for the optimization of sensor spreading over an area, to designing and tuning the command rules for distributed control systems applied to large-scale processes.

The initial route generation problem has been initially regarded as a variant of the travelling salesman problem (Dantzing et al 1959). Beside this classical formulation of the routing problem, a series of other approaches have been studied (Toth et al 2002). For route reconfiguration, the initial studies (Seguin et al 1997) have first taken into account the static routing problem (Psaraftis 1980; Madsen et al 1995), followed by more in depth analyses of the differences between dynamic and static routing (Psaraftis, 1988; Goel et al 2006).

Another perspective for solving the problem of dynamic vehicle routing takes into account evolutionary computing algorithms, either by using algorithms inspired from biology (Potvin, 2009) or

machine learning techniques such as supervised learning or genetic programming (Benyahia et al 1998). A technique based on hybrid genetic algorithms was used (Jih et al 1999) for solving the problem of routing a vehicle with size constrains. Another example relies on Dijkstra algorithms (Barrachina et al 2014) and evolutionary strategies for finding an optimum path in a short period of time. Another approach presented in the project Emergency Vehicle Priority implies controlling the traffic lights in favor of the emergency crews (White, 2012), but this solution affects the rest of the urban traffic. A way of solving the routing problem using genetic algorithms is by combining (Chand et al 2010) the Bin Packing (BPP) with the traveling salesman problem. In the most recent approaches, the solution to this problem was obtained using the Intelligent Water-drop algorithm (Kaur et al 2014).

There are multiple approaches to the application of multi-agent systems in dynamic reconfiguration of routes (Shah 2012), such as MARS, Jabatos or Ant System, but they were used for management problems of transport resources (e.g. assigning buses to routes by minimizing the number of vehicles required and maximizing the number of requests in the system).

One solution (Darbucha 2013) for the dynamic routing problem is a combination of agent-based systems and dispatcher-based routing strategies. Other similar approaches (Talbot et al 2010) using multi-criteria decision-making, but at a global level dispatcher. In this case, real time data is received by the dispatcher which computes the emergency vehicle route. If an obstacle is blocking this route, the dispatcher is informed and can take other decisions. This simulation is limited at dispatcher level by introducing an additional node between data processing and decision-making algorithm.

This paper is organized as follows. In section 2, the authors present the design of the proposed control system, along with the principles of genetic algorithms. In section 3 a case study is discussed, for which an agent based simulation model has been developed in order to simulate traffic in an urban area. Finally, section 4 contains the conclusions.

2 Proposed system design

The concept introduced in this paper focuses on obtaining routes for emergency crews in an urban environment. Urban conglomerates (especially in areas that had not been initially developed for the amount of vehicles that can be found in today's society) suffer from traffic congestions. Therefore, the shortest path between two points is not necessarily the fastest. In this paper, the objective is to find the shortest routes with the least amount of traffic at any moment, while also considering that the occupancy of a road segment might change during travel.

In order to achieve this goal, we propose the use of a Genetic Algorithm (GA) for computing the shortest of the least occupied routes through a network of intersections. The algorithm takes into account the degree of occupation for each intersection and chooses the route with the least amount of traffic.

Genetic Algorithms (GAs) are optimization heuristics able to perform rapid searches in large amounts of uncertain or incomplete data, with an inherent structure that allows parallelization. Given how GAs most often offer sub-optimal solutions is not a deterrent for the considered routing problem, because the urban traffic is in constant evolution and change. Thus, it is unadvisable to spend too much time and/or computing power on searching for a route that might not be as viable in the next minutes.

GAs are designed to search in multiple directions at once through the solution space, starting even from the initialization phase, in which a random pool of solutions (called a population) is generated. These solutions, known as individuals, are then allowed to evolve based on the principles of the Darwinist natural selection. Using mechanisms of selection (choosing certain individuals to contribute to creating the next generation as parents), recombination (generating new individuals by combining the characteristics of the selected parent), and mutation (necessary to maintain population diversity), a GA runs continuously, evaluating at each step all the possible solutions of the considered problem until a stop criterion is met (for instance, after a certain number of generations, or after reaching a certain tolerance for the solution). The evaluation procedure is run through what is known as a fitness function, that returns to which degree an individual can be deemed fit or not to be a viable solution.

Due to their heuristic nature, GAs can integrate, within the fitness function, objectives and performance indexes that are not necessarily defined in a formal manner. Moreover, adding more and more conditions in order to declare a possible individual as a fit solution to the considered problem is not computationally taxing (for instance, due to objective fusion techniques that might be hard to do with non-heuristic descriptions).

In recent research, GAs have been applied to problems in various fields. Their popularity keeps increasing due to their ease of use, effectiveness, or applicability. In control systems design (Fleming et al 2002) GAs have been efficiently used with both feedback (Lewin 1994) and feedforward controllers (Lewin 1996), modelling (Huang 2012) and parameter estimation (Bush et al 2011). In other fields, GAs have been used for various problems, either as stand alone procedures (Patrascu et al 2016), or in combinations

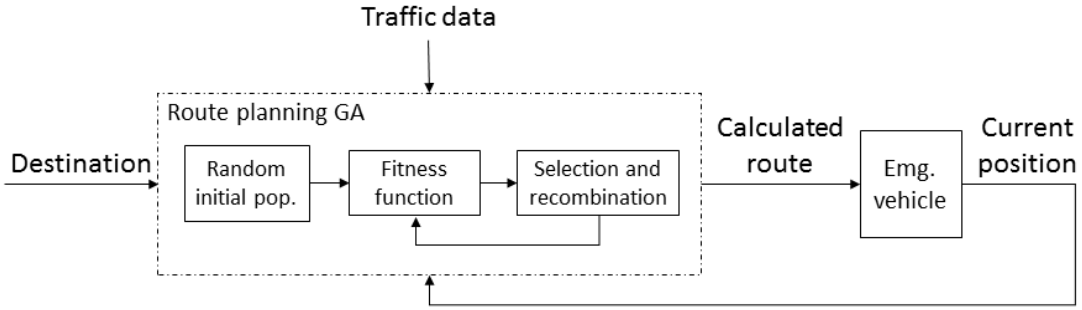

Figure 1. General principle of the dynamic route generation with genetic algorithms.

with other intelligent methods, like fuzzy systems (Alcala-Fdez et al 2009) or neural networks (Tao et al 2004).

In a real world implementation, the dynamic route generation algorithm would be developed to run independently onboard emergency vehicles, integrating traffic data from sensors throughout the city. It uses mobile computational resources available locally to the vehicle, thus eliminating the need for a central aggregation hub and offering scalability in case of major disasters, when more emergency crews are required in different parts of the city.

As the vehicle travels to the destination, the degree of occupation of the intersections along the route can change. In this case, the route is updated taking into account the new traffic data. The least occupied route is chosen based on the value of the corresponding fitness function (that computes a total degree of occupation for the entire suggested route).

Figure 1 presents the general principle of the proposed system. After a random initialization of the solution population, the GA computes the fitness function for each individual and, if necessary, genetic operators are applied to the population. The processes of evaluation, selection, and recombination are repeated until an individual with a high enough fitness is found or up to a maximum number of generations. Once a new route is generated by the GA, it is then transmitted to the driver.

At this point, whether the driver chooses to follow the suggested route or not, the GA starts its next run, in order to generate a new route by the time the vehicle reaches the next intersection along its path.

The entire system presented in figure 1 can be regarded as a control system in which the Genetic Algorithm (as *controller*) receives a destination (as a *setpoint*) and adjusts the trajectory (*controlled output*) of the emergency vehicle (*plant*) through a geographical area. The other traffic participants and the driver decision to ignore the suggested route are integrated into the control loop as *disturbances*. Each new suggested route is being transmitted to the driver at each node of the road network (intersection) as a *command*.

Thus, the control problem of emergency crew routes can defined as: an emergency vehicle (ambulance, fire truck, police car, etc.) receives a respond request to a given site while encountering as little traffic as possible during its journey. The emergency vehicle must travel from point A to point B, through an urban area comprised of a road network and traffic participants (regular vehicles and pedestrians).

The objective of the GA is to dynamically generate new routes for the emergency vehicle, supply these routes to the driver as the vehicle approaches each intersection, while taking into account traffic data that might be incomplete or inaccurate.

In what concerns the GA encoding of the vehicle routes, these are formed of a numeric representation in vectorial form, in which each position contains a route section identifier and the degree of occupation on the road segment leading to its associated intersection. The entire route is given by the position of each route section in the vector (its index).

Thus, an individual (or chromosome) is formed of genes that represent a route section each.

A route section is formed of that segment of a road between two intersections, on the traveling direction of the emergency vehicle. One road segment is associated with the intersection it travels towards, while the position of the emergency vehicle through a route is given by the road section & intersection pair it currently travels through. Thus, a path is formed of a starting point (either the initial position point A, or the current position), and as many route sections (road segment & intersection) as there can be delimited until the destination point B. For example, a path through 3 intersections will contain 4 genes.

A route section identifier can be defined as a coordinate pair or an unique identifier. This coordinate point can be, for instance, a physical geographical location for the beginning of each route section, a pair of coordinates for the start and finish of the route section, or even an ID number associated with each route section. For simplicity, in what follows, the

notation r will be used to denominate route section identifiers.

Thus, a route φ is comprised of n route sections defined by their position r_i in the urban area and their degree of occupancy D_i. Each pair $(r_i, D_i)_i$ has an associated index i that depicts their order in composing the route:

$$\varphi = [(r_0, D_0)_0 \quad (r_1, D_1)_1 \quad \dots \quad (r_i, D_i)_i \quad \dots \quad (r_n, D_n)_n] \quad (1)$$

When computing the fitness of an individual, the algorithm takes into account both the degree of occupation of the road segments on the possible paths to the event site and the distance the destination.

For a path formed of n intersections, the route fitness F is computed by analyzing each section and cumulating the results for the entire route:

$$F^{-1} = \sum_{i=1}^{n} \frac{\delta \cdot D_i}{g(r_0, r_i)} \quad (2)$$

where δ is a scaling factor, D_i is degree of occupancy on the i-th section of the route, and $g(r_0,r_i)$ is a function that scales the penalty given to those sections of the route that are farthest from the starting section r_0 (either the initial section or the current section the emergency vehicle is traveling through).

The fitness value F of the route needs to be maximized, therefore the best routes are the ones with the lowest degree of occupancy.

The closer a road section (delimited by the intersections through which the vehicle must travel), the more it is contributing to the computed fitness value than the further ones. In this way, when calculating the fitness of a possible route, less importance is given to the degree of occupancy of farther intersections, as it may change by the time the vehicle is actually there.

3 Case Study

In order to test the proposed system, a simulation model needs to be designed that incorporated the complexity of urban traffic systems. In this respect, the most recent development in complex systems modelling belong to the field of Agent Based Modelling and Simulation (Patrascu et al. 2015), which provides engineers with Agent Based Simulation Models (ABSM) that are able to describe the behaviours of heterogeneous traffic participants, as well as their interactions and interdependencies.

In an ABSM, an agent is a persistent entity characterised by internal states. This entity interacts with its environment or with other agents, ultimately causing changes in the environment or in the states of the other agents. An ABSM is a collection of agents, their states, and the rules that govern interactions from agents to agents, from agents to the environment, and from the environment to the agents.

Every agent of an ABSM has inputs and outputs, but it can also regulate their own internal states through local feedback loops. The internal state of an agent is governed by rules. Moreover, the behaviour of an agent is represented by the set of actions it performs (outputs) according to internal state and inputs.

As a whole, the ABSM has its own states, inputs, and outputs, but from a holistic perspective, the states of the entire simulation model integrates the complex interactions between the agents involved, by using rules to describe these behaviours. Most often, ABSM are evolving complex systems, used in generative experiments (Bertolotti, 2014), in order to test the viability of a solution that has little chance to be formally evaluated in realistic computing times (much like in the case of heuristics).

3.1 ABSM description

The agent-based simulation presented in this paper was implemented using the NetLogo (Wilensky et al 2015) environment, which offers access to the advantages of using agent based simulation models (ABSM) previously stated. Moreover, NetLogo offers way to implement user interfaces that is easy and accessible to researchers who don't necessarily have a strong programming background. NetLogo has been sucessfully used for proving and testing complex systems theorems and hypotheses. An in depth discussion on the advantages and disadvantages of using NetLogo for the simulation of complex control systems can be found in our previous work (Patrascu et al. 2015).

Thus, we illustrate the application of genetic algorithms in computing the quickest route (from the degree of occupation perspective) of an emergency vehicle through a simulated urban environment. The simulation application allows the user to set the number and types of crossroads present in the world model. Before starting the simulation, one can also chose the duration of different traffic light phases, the priorities for incoming traffic in a crossroad, as well as the rate at which new vehicles are inserted in the simulation. In this setup stage, the user can also chose the parameters that control the genetic algorithm responsible for planning the quickest route for the emergency vehicle.

For simulation purposes, the generated environment contains roads with four lanes (two lanes per travel direction) and specific traffic lights for turning left or going straight in order to increase the complexity of the road network model, as would be expected to happen in real urban areas: multiple lanes, directional traffic lights and so on. After starting the simulation, an emergency vehicle can be added to the environment. The parameters indicating the start and destination

position of the emergency vehicle, as well as its priority, can be set from the model's interface.

The traffic participants are simulated using mobile agents and consist of normal and emergency vehicles and pedestrians. The simulation environment, NetLogo, uses two types of agents: fixed and mobile. The fixed agents build the static parts of the simulation model, which, for the agent-based model compose their relevant environment, while the mobile agents are used to simulate dynamic entities. In this case, vehicles are mobile agents. Their behaviour is modelled using knowledge-based representations in a manner that most accurately describes the decision making processes of drivers. NetLogo offers the possibility of modelling these entities as complex or simplistic as the user desires. In this paper, the vehicle (and thus driver) behaviour is as close as possible to the behaviour of vehicles in real world traffic.

Emergency vehicles have a higher priority through traffic than civilian ones. The pedestrians behave similarly to the vehicles, with the exception that they can only move on the sidewalks. In figure 2 an example of simulated environment is presented, highlighting the intersection that the emergency vehicle (police) is currently traversing. The police car can be seen entering the inner crossroad area from the east and traveling west.

After creating the emergency vehicle, the user can chose to highlight and inspect the police car as it travels through the urban environment. This is implemented by opening a new window (presented in figure 2) that shows a zoom of the world model, centered on the emergency vehicle, and that follows it as it travels. In the zoom window presented here, we can see the state of the traffic lights in each intersection. The pedestrians obey the traffic lights placed in the corners of the intersection, while the vehicles follow the signals of the lights placed between the lanes. For vehicles, the traffic light closer to the center of the crossroad is for turning left and the other one for going straight. In figure 2, on the east-to-west road, we can see the traffic light for going straight showing a green light and the one for turning left showing red, thus allowing the police car to traverse the intersection and stopping the two civilian cars occupying the next lane from turning left. The route for the emergency vehicle is computed when the agent that models this vehicle is inserted in the simulation environment. The user can chose to have the route updated each time the vehicle crosses an intersection, or just request one calculation, at the beginning of the vehicle's journey.

During the simulation, at each time step, the phases of the traffic lights are computed for each crossroad, using a distributed traffic control system based on vehicle priority. Each traffic light phase (North, East, West, South) is computed using the corresponding road occupancy data, which is obtained from sensors placed on each road section entering the intersection. When a civilian vehicle enters a road section, the occupancy is increased by 1 and when the vehicle leaves the road section, it is decreased by the same amount. In the case of an emergency vehicle, the occupancy is modified according to the priority of the vehicle. For more information regarding these types of control systems and their simulation using ABSM, please consult our previous work (Patrascu et al 2015).

Figure 2. ABSM world overview.

As the simulation runs, at each time step, new vehicles are inserted in the simulation environment. The user can set the frequency for inserting vehicles from the east and west or north and south side of the map. The vehicles can only be inserted on a lane connected to the edge of the map if there is available room. Depending on a user setting, the civilian vehicles can give way to the emergency vehicles by temporary switching lanes.

3.2 A simulation example

For a more facile visualization, the world model presented in this case study has the road sections (segment & intersection pairs) displayed in a grid. In what follows, we have chosen a 4x4 grid of intersections. Each route section is depicted by an identifier of the form (x, y) where x is the position on each line of the grid, while y is the position on each column. For example, (1, 3) is the intersection marked A in figure 3. The starting point of the emergency vehicle (police car) is marked A in figure 3, while the final destination is B, at coordinates (4, 2).

For the first experiment (Exp.1), the GA presented in the previous sections will be run as the vehicle departs from point A. In the second experiment (Exp.2), the GA will be run at the entry of each route section, re-generating the vehicle's route dynamically

as it travels through the urban area. The results of both experiments are presented in table 1 (where D is a matrix containing the degrees of occupancy for each route section, and φ is the route returned by the GA). For Exp.1, the GA is run only at point A. For Exp.2, the table shows the first 2 runs of the GA, first in point A and then in the next intersection, showing how the occupancy of the road segments has changed while the vehicle has travelled through the first route section, from (1, 3) to (2, 3).

In the first experiment, the vehicle's route is computed only once, at the beginning of its journey. As the vehicle travels through the area, the degree of occupancy might change on the previously selected routes. For instance, there is an alternate route starting at (2, 3) that has less vehicles traveling through it. To account for the changes in the environment, in the second experiment, the GA has been run at the beginning of each route section in order to determine if the route should be kept or dynamically changed. In table 1 a new and old route comparison is shown to illustrate this phenomenon.

The system we proposed in section 2 achieves its objectives of selecting the routes with the lowest degree of occupancy in a given urban area. Moreover, the system is capable of dynamically re-generating the emergency vehicle's route based on new traffic data and changes in the urban road network.

The preliminary testing conducted in this study shows great potential for the further development of evolutionary algorithms as controllers in closed loop systems. The next step in a thorough validation procedure is to develop simulation models that use real world maps, followed by real world testing. These are some of the main steps in the cycle of control systems development, which are designed to take a formal idea and make sure the final product works smoothly and within required performances.

4 Conclusions

In this study, a system for generating emergency vehicles routes has been presented. The system is able to account for changes in the environment or in urban traffic and dynamically supply new, better routes to the emergency vehicle drivers.

For this, a genetic algorithm has been designed that can recalculate the paths of the emergency responders while they are already on their journey to an event site. The entire route adjustment procedure is encapsulated in a control system scheme, in which the controlled variable is the route of the vehicle, while the other traffic participants are disturbances. The proposed system has been tested in a simulated environment specifically designed to emulate the complexity of the urban traffic.

Among the advantages of this type of system are: the possibility to run locally, on each emergency vehicle, thus eliminating the need for a central server type entity and overloaded communication networks; the possibility of implementation on devices that are already available (smartphones or tablets); not relying on traffic control systems, that can sometimes be overwhelmed, that can only manage an intersection at a time, or that can, at times, be offline (for maintenance or other reasons).

Moreover, for this type of system, context awareness is implicitly achieved. The intrinsic nature of control systems allows them to both collect information from the environment (either by direct sensing or by accessing real time traffic databases), and to interact with the it via the driver. Complete automation, although attractive from a point of view of vehicle autonomy, removes the driver from the decision making process. Thus, the middle ground we proposed seems the most reasonable.

Some of the limitations of this sort of system are related to the inherent heuristic nature of genetic algorithms, the proposed method requiring perhaps a sort of hybridization with formal methods, metaheuristics, memetic algorithms.

Further research endeavours in what concerns the proposed dynamic route generation using genetic algorithms include the design of specialized selection methods and chromosome encoding for routes and the test of the presented system, first in simulated environments with higher complexity, and then in real world scenarios.

The Effect of Pressure Losses on Measured Compressor Efficiency

Kristoffer Ekberg Lars Eriksson

Vehicular Systems, Linköping University, Sweden, {kristoffer.ekberg, lars.eriksson}@liu.se

Abstract

While measuring the compressor behavior at different load points in for example a gas stand, the inlet and outlet pressures are not always measured directly before and after the compressor. The friction inside the pipes and the physical piping configuration affect the measured compressor efficiency, due to the induced change of fluid enthalpy. If the measured pressures at the end of the inlet and outlet pipes are not the same as the actual pressure before and after the compressor, the acquired compressor map does not give the right description of it as an isolated component. The main contribution of this paper is the analysis of the impact of gas stand energy losses due to pipe friction on the compressor map. As a result the paper suggests a way to take the pressure losses in the inlet and outlet pipes into account. The suggested model takes pipe friction, diffuser, nozzle and pipe bends into account. The potential measurement error in compressor efficiency due to energy losses in the pipes in this experiment is 2.7% (percentage points) at maximum mass flow of air through the compressor.

Keywords: gas stand, pipe, bend, diffuser

1 Introduction

Gas stand testing of turbochargers is a time consuming process where one of the goals is to determine the compressor efficiency. Turbochargers are modeled in computers to perform more cost efficient tests and experiments. Softwares today are used to solve and compute the dynamic behaviors of complex engine systems involving turbochargers. Turbocharger models are often adjusted to fit measured data, from for example a gas stand test. Most of the analysis assume that the turbocharger models represent the turbocharger as a single component. This means that to have accurate turbocharger models, the measurement data should represent the turbocharger only, and not include any pipes or other objects connected to the turbocharger housing. The pipes in a gas stand, connecting the turbocharger to measurement instruments, induces errors into the computer models if the data is used without correction. Since the pressures and temperatures are measured some distance away from the actual inlet and outlet on the compressor, the physical setup of the gas stand may need to be accounted for to get a more accurate result of the compressor efficiency. In both the inlet and outlet pipes there are pressure losses due to friction inside the pipes, also if the gas flow path contains bends or area changes, these could induce pressure losses. There are different ways to develop a gas stand (see for example (Venson et al., 2006) or (Young and Penz, 1990)), the idea is to simulate engine conditions to find the turbocharger characteristics. When making measurements in a gas stand, the monitoring of the pressures and temperatures before and after the compressor are important to get accurate results of the compressor efficiency (Kumar et al., 2014). The compressor efficiency is determined by using measured values of temperatures and pressures before and after the compressor. Studies with focus on the heat transfer inside the turbocharger (Nick Baines and Karl D.Wygant and Antonis Dris, 2009) and how the heat transfer affects the compressor efficiency have been performed (Marelli et al., 2015), while others focusing on the possible measurement errors due to sensor inaccuracy (Guillou, 2013). No papers are found where the actual placement of the sensors are examined up or downstream from the compressor, SAE standard J1826 recommends placing the static pressure taps 2 to 3 pipe diameters downstream of the rotor (SAE, 1995). The sensor placement is crucial to achieve a reliable result during testing. Different test rigs may give different results due to environmental conditions, if the inlet air is not conditioned, the efficiency uncertainty will fluctuate (Guillou, 2013). The impact from inlet air being dry or humid on compressor efficiency has been studied in (Serrano et al., 2009), the impact is small and should only be considered if very high accuracy is wanted. The enthalpy loss between the measurement positions and the compressor due to the pressure loss indicates that the compressor efficiency is actually better than measured.

1.1 Contributions

This paper is the first to analyze the gas stand pressure losses. The effects of the pressure losses on measured compressor efficiency are analyzed and ways to compensate for them are developed. Influences of the gas stand pressure losses are displayed on the compressor map.

1.2 Setup for the analysis

The main scope of the paper is to show how the change of enthalpy in the inlet and outlet pipes affect the compressor efficiency. The inlet and outlet enthalpies ($\dot{h}_{in}$ and $\dot{h}_{out}$ in Figure 1) are not the enthalpies actually entering and leaving the turbocharger compressor, the actual values are $\dot{h}'_{in}$ and $\dot{h}'_{out}$, which are corrected to exclude the friction in the inlet and outlet pipes ($\dot{w}_{f,pipe,in}$ăand $\dot{w}_{f,pipe,out}$). In

equation (1a) the work used by the compression process is described as it is used today, where the connecting inlet and outlet pipes are included, since the measurement positions are not located directly at the inlet or outlet of the compressor. Equation (1b) describes the work required by the compressor as a single component, describing the compression work made by the turbocharger compressor only.

$$\dot{w}_{c,Old} = \dot{w}_{compression} + \dot{w}_{f,pipe} + \dot{w}_{f,pipe} \quad (1a)$$

$$\dot{w}_{c,New} = \dot{w}_{compression} \quad (1b)$$

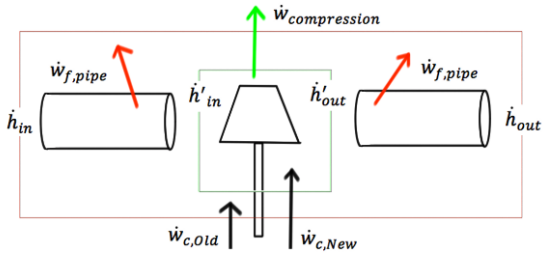

Figure 1. Energy flow in the compressor. The outer box (red) represents the system that is measured in a gas stand, the inner box (green) is the preferred system that is to be described by the model.

To quantify the impact from the inlet and outlet pipe frictions ($\dot{w}_{f,pipe,in}$ and $\dot{w}_{f,pipe,out}$) on the measured compressor efficiency, three cases are investigated. The three cases investigates:

1. straight inlet and outlet pipes, see Figure 2. The diameter of the pipes (d_{inlet} and d_{outlet}) are assumed to be equal to the compressor inlet and outlet diameters ($d_{c,inlet}$ and $d_{c,outlet}$).
2. using pipes with diffuser and nozzle. See Figure 3.
3. adding a 90^o smooth bend on the inlet pipe. See Figure 4.

1.3 Experimental data

Data used during the analysis is a measured compressor map from a commercial turbocharger, the measured mass flow range [0, 0.21] kg/s and pressure ratio between [1, 2.8] $\frac{p_{02}}{p_{01}}$. The sensor errors effect on the achieved results from a gas stand have been studied in (Guillou, 2013). The measured data used in this analysis are assumed to be correct, i.e. all measured values are assumed to be perfect, no sensor errors are assumed to be present.

1.4 Compressor Map

One of the main ideas behind testing the turbocharger in a gas stand is to determine the compressor efficiency and flow characteristics at different work points. The compressor behavior is presented on a compressor map, where the corrected compressor mass flow and pressure ratio defines

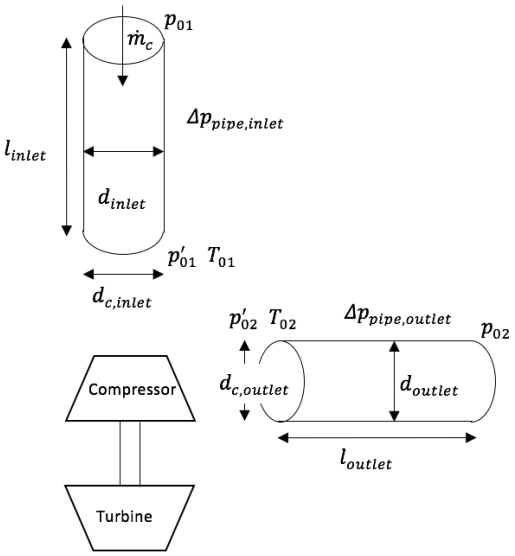

Figure 2. Pressure drops are represented by Δp_n, the total pressures by p_{01} and p_{02}, the corrected total pressures by p'_{01} and p'_{02} and the measured temperatures by T_{01} and T_{02}. The mass flow of air inside the pipes are represented by $\dot{m}_c$. The physical dimensions on pipe lengths and pipe diameters are described by l_n and d_n.

a plane where the compressor efficiency is displayed. In the evaluation of the results, the effects from the pressure losses on compressor efficiency are presented on the compressor map. The reference compressor efficiency is calculated using measured data, and later recalculated when taking the pressure losses in the gas stand into account.

1.5 Compressor Isentropic Efficiency

The compressor isentropic efficiency is defined as the smallest amount of power needed to compress the air without heat exchange with the environment (isentropic process), divided by the actual amount of power consumed by the process. Using measured total temperatures and total pressures (calculated from static pressures, see equation (4)) from a gas stand, the compressor total to total isentropic efficiency can be calculated using equation (2). (Eriksson and Nielsen, 2014)

$$\eta_c = \frac{\Pi_c^{\frac{\gamma-1}{\gamma}} - 1}{\frac{T_{02}}{T_{01}} - 1}, \text{ where } \Pi_c = \frac{p_{02}}{p_{01}} \quad (2)$$

where p_{01} and p_{02} are total pressures, T_{01} and T_{02} are total temperatures and γ is the ratio of specific heats (assumed to be constant).

1.6 Corrected Mass Flow

Corrected mass flow is used to display the mass flow in the compressor map. The corrected mass flow is used instead of the measured mass flow, to take surrounding conditions during measurements into account. The surrounding conditions are the reference temperature, T_{ref} and the refer-

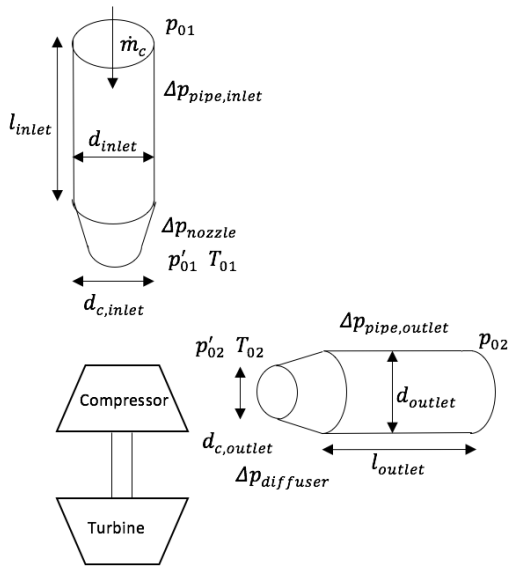

Figure 3. Pressure drops are represented by Δp_n, the total pressures by p_{01} and p_{02}, the corrected total pressures by p'_{01} and p'_{02} and the measured temperatures by T_{01} and T_{02}. The mass flow of air inside the pipes are represented by $\dot{m}_c$. The physical dimensions on pipe lengths and pipe diameters are described by l_n and d_n.

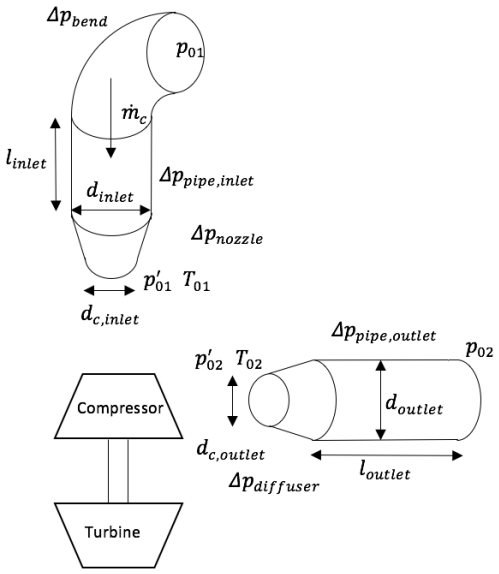

Figure 4. Pressure drops are represented by Δp_n, the total pressures by p_{01} and p_{02}, the corrected total pressures by p'_{01} and p'_{02} and the measured temperatures by T_{01} and T_{02}. The mass flow of air inside the pipes are represented by $\dot{m}_c$. The physical dimensions on pipe lengths and pipe diameters are described by l_n and d_n.

ence pressure, p_{ref}. The corrected mass flow is calculated according to equation (3). (Eriksson and Nielsen, 2014)

$$\dot{m}_{c,corr} = \frac{\dot{m}_c \sqrt{\frac{T_{01}}{T_{ref}}}}{\frac{p_{01}}{p_{ref}}} \tag{3}$$

1.7 Data Treatment

The pressures and temperatures used when calculating the compressor efficiency should be the total pressures and total temperatures. The relation between the measured static pressure p_i and the total pressure p_{0i} is displayed in equation (4), where $C_i = \frac{\dot{m}_c}{\rho_i A}$ is the fluid velocity inside pipe i.

$$p_{0i} = p_i + \frac{\rho_i C_i^2}{2} \tag{4}$$

To convert the measured total temperature T_{0i} to static temperature T_i equation (5) from (Eriksson and Nielsen, 2014) can be used.

$$T_i = \frac{A^2 p_i^2 c_p}{R^2 \dot{m}_c^2} \left(\sqrt{1 + 2\frac{R^2 \dot{m}_c^2 T_{0i}}{A^2 p_i^2 c_p}} - 1 \right) \tag{5}$$

where $\dot{m}_c$ is the mass flow of air through the pipe, ρ_i is the air density and A is the cross section area of the pipe at the measurement position. The air inside the system is treated as an ideal gas, following this assumption, the density is calculated using equation (6). (Eriksson and Nielsen, 2014)

$$\rho_i = \frac{p_i}{RT_i} \tag{6}$$

2 Pressure Losses in Gas Stand

Pressure losses in different piping systems and pipe configurations have been examined for many years. The formulas and expressions are empirical or semi-empirical correlations that are created from experiments to describe specific objects or system configurations. The different pressure losses in different parts in the gas stand are calculated according to empiric formulas, these formulas are valid for fully developed turbulent flow, the turbulent flow in the parts taken into account is therefor assumed to be fully developed. Both the total temperature and the density of the fluid are assumed to be constant along the inlet and outlet pipe sections.

2.1 Pressure Loss in Straight Pipe

Straight pipes in for example a gas stand causes pressure losses due to friction inside the pipes. The selection of pipe material and manufacturing method of the pipes are important to get a low friction pipe. The surface roughness inside the pipe induces pressure loss when the flow is turbulent, when the flow is laminar, the friction factor $f_{pipe,i}$ is independent of the surface roughness. The pressure loss in a straight pipe is calculated with equation (7) (Cengel et al., 2008).

$$\Delta p_{pipe} = f_{pipe,i} \frac{l_i}{d_i} \frac{\rho_i v_i^2}{2} \tag{7}$$

Where $f_{pipe,i}$ is a friction factor, ρ_i is the density of the fluid inside the specific pipe section i, l_i is the pipe section length, v_i is the mean velocity of the fluid inside the

specific pipe section i. The friction factor $f_{pipe,i}$ is dependent on the flow characteristics inside the pipe. The flow characteristics could be either laminar or turbulent. The flow characteristics inside the pipes are determined by Reynolds number, Re. Reynolds number is calculated according to equation (8). (Cengel et al., 2008)

$$Re = \frac{v_i d_i \rho_i}{\mu_i} \tag{8}$$

Where v_i is the mean velocity of the fluid inside the pipe, ρ_i is the fluid density, d_i is the hydraulic diameter (hydraulic diameter equals pipe diameter for circular pipes) and μ_i is the dynamic viscosity of the fluid. The dynamic viscosity of air is described as a function of air temperature:

$$\mu_i = \mu(T_i) \tag{9}$$

According to (White, 1999), the change in μ is around 10% for air when the pressure is increased from 1 to 50 atm, and that it is customary in most engineering work to neglect the pressure variations. The viscosity of a gas is by (Massey and Ward-Smith, 1998) said to be independent of its pressure (except at very high or very low pressures). In this study, the change in pressure ranges from around 1 bar to 2.85 bar, therefore the fluid dynamic viscosity is assumed to be independent of the pressure variations. The function in equation (9) describes the fluid dynamic viscosity $\mu(T_i)$, as a polynomial function of fluid temperature T_i, the function parameters are adapted to fit data from table A-22 in (Cengel et al., 2008) (Properties of air at 1 atm pressure), the function is displayed in equation (10).

$$\mu(T_i) = -3.0777 \times 10^{-11} T_i^2 + 4.8218 \times 10^{-8} T_i + 1.7299 \times 10^{-5} \tag{10}$$

For low Re, the flow is considered to be laminar, for higher Re, the flow is considered to be turbulent. In-between the laminar and turbulent region there is a region where the flow is called transitional flow. When the flow is transitional, the flow is frequently shifting between laminar and turbulent. The limits on Re is shown in equation (11). (Cengel et al., 2008)

$$\begin{cases} Re \leq 2300 & \text{Laminar flow} \\ 2300 < Re < 10000 & \text{Transitional flow} \\ Re \geq 10000 & \text{Turbulent flow} \end{cases} \tag{11}$$

Laminar and turbulent flow are the two flow characteristics that will be taken into account. The flow is mostly turbulent during the gas stand test performed, but the laminar region will be described to make the model complete.

2.2 Friction Factor - Laminar Flow

To calculate $f_{pipe,i}$ when the flow is laminar, equation (12) is used. (Cengel et al., 2008)

$$f_{pipe,i} = \frac{64}{Re} \tag{12}$$

2.3 Friction Factor - Turbulent Flow

During turbulent flow inside the pipe, the surface roughness of the pipe ε affects the pressure loss inside the pipe (assuming pipe material to be stainless steel with surface roughness $\varepsilon = 0.002mm$ from table 14-1 in (Cengel et al., 2008) during calculations). To calculate $f_{pipe,i}$ when the flow is turbulent, either equation (13), known as Colebrook equation, is used and iterated until $f_{pipe,i}$ is accurate enough, or equation (14) could be used. The result of equation (14) is within 2 % of the result from equation (13). (Cengel et al., 2008)

$$\frac{1}{\sqrt{f_{pipe,i}}} = -2.0 log\left(\frac{\varepsilon/d_i}{3.7} + \frac{2.51}{Re\sqrt{f_{pipe,i}}}\right) \tag{13}$$

$$\frac{1}{\sqrt{f_{pipe,i}}} \cong -1.8 log\left(\frac{6.9}{Re} + \left(\frac{\varepsilon/d_i}{3.7}\right)^{1.11}\right) \tag{14}$$

2.4 Pressure Loss In Bend

Pipe bends are treated as one-time losses, a smooth 90^o bend has a loss coefficient of $K_L = 0.3$. The value of K_L is strongly dependable on the type of pipe, size of bend etc., the coefficient value is found in table 14-3 in (Cengel et al., 2008), it is used to give a hint about how the losses affect the measured compressor efficiency. The pressure drop due to a pipe bend is calculated according to equation (15).

$$\Delta p_{bend} = \frac{K_L v_i^2 \rho_i}{2} \tag{15}$$

2.5 Pressure Loss in Inlet Nozzle and Outlet Diffuser

Inlet nozzle and outlet diffuser can be used to connect the inlet and outlet pipes to the turbocharger. The inlet nozzle is treated as a convergent pipe, a convergent pipe is not inducing any pressure loss over the area change, other than the friction in the pipe. This is due to the contraction of the pipe, a gradually contracting pipe is normally not inducing any extra turbulence, other pressure losses than the pipe friction is normally neglected (Nakayama and Boucher, 1999), the pressure loss in the nozzle is neglected in this study (see equation (16b)). The friction loss in the inlet nozzle is assumed to be included in the pressure loss inside the inlet pipe. The outlet diffuser induces a pressure loss, due to the extra turbulence induced in the divergent region. The pressure drop in the outlet diffuser is calculated according to equation (16a), the pressure drop due to pipe friction is assumed to be included in the expression.

$$\Delta p_{diffuser} = \frac{K_{L,exp} v_i^2 \rho_i}{2} \tag{16a}$$

$$\Delta p_{nozzle} = 0 \tag{16b}$$

The value of $K_{L,exp}$ is found using tables, the used value is found in table 14-3 in (Cengel et al., 2008) (assumption of the diffuser angle 20^o results in $K_{L,exp} = 0.1$, when $d_{c,outlet}/d_{outlet} = 0.8$). The fluid velocity inside the pipe v_i is the fluid velocity at the diffuser inlet.

2.6 Adjust Measured Data

The measured data is adjusted by summarizing and withdrawing the pressure losses in the gas stand, from the measured values. The adjustments made are shown in equation (17a) and (17b). The inlet and outlet total pressures are adjusted by adding or subtracting the pressure losses, depending on if the losses occur up or downstream from the measurement positions.

$$p'_{01} = p_{01} - \Delta p_{pipe,inlet} - \Delta p_{bend} - \Delta p_{nozzle} \quad (17a)$$

$$p'_{02} = p_{02} + \Delta p_{pipe,outlet} + \Delta p_{diffuser} \quad (17b)$$

2.7 Calculate New Compressor Efficiency

The new corrected compressor efficiency is calculated using the total pressures that are adjusted to measurement data (see equation (17a) and (17b)) and the measured total temperatures. The equation to calculate the corrected efficiency is the same as equation (2), but with the new corrected pressures p'_{01}ăand p'_{02} (see equation (18)).

$$\eta'_c = \frac{\left(\frac{p'_{02}}{p'_{01}}\right)^{\frac{\gamma-1}{\gamma}} - 1}{\frac{T_{02}}{T_{01}} - 1} \quad (18)$$

3 Effect of pressure losses on measured compressor efficiency

Different simulation cases are performed to quantify the pressure losses main impacts on the measured compressor efficiency. The first case investigates the usage of straight inlet and outlet pipes, with the same diameter as the compressor inlet and outlet. The second case studies the usage of nozzle and diffuser on the inlet and outlet pipe, to connect a larger inlet and outlet pipe to the compressor. The third case is the same as the second, but a 90^o bend is added on the inlet pipe.

3.1 Compressor and Pipes Dimensions

A measured compressor map from a gas stand test is used to quantify the error in compressor efficiency due to the pressure drop between measurement positions and the turbocharger compressor. Compressor inlet outlet diameters and diameters at measurement locations are displayed in Table 1, these dimensions are needed to calculate the pressure drops in the different pipe sections. The results in Table 2 shows the maximum pressure loss over the different components. The inlet pipe is assumed to be 100 mm long and the outlet pipe is 3 or 10 times the outlet pipe diameter, both inlet and outlet pipe diameters are assumed to be the same as compressor inlet and outlet diameter when analyzing Case 1. According to SAE standard J1826 (SAE, 1995), the distance from the rotor down to the measurement location (if measuring static pressure) should be 2 to 3 pipe diameters downstream. In many pipe flows of practical engineering interest, the effects due to the entrance region become insignificant when the pipe length is longer than 10 pipe diameters (Cengel et al., 2008). Two different selections of outlet pipes lengths (10 and 3 times the outlet pipe diameter) are studied and compared in terms of measurement error due to the simulated pressure losses.

Table 1. Diameter of compressor inlet and outlet on the turbocharger, diameter on the inlet and outlet pipe at the measurement positions. Pipe lengths are assumed.

Measurement	Value
$d_{c,inlet}$ (inlet compressor)	56.5 *mm*
d_{inlet} (measurement position p_{01})	58 *mm*
$d_{c,outlet}$ (outlet compressor)	40 *mm*
d_{outlet} (measurement position p_{02})	50 *mm*
l_{inlet}	100 *mm*
l_{outlet}	
3 $d_{c,outlet}$ or 10 $d_{c,outlet}$	(case 1)
3 d_{outlet} or 10 d_{outlet}	(case 2, 3)

Table 2. Maximum pressure loss in the different components, for all 3 cases. The pressure losses are presented in Pascal.

Case	Δp_{inlet}	Δp_{outlet}	$\Delta p_{diff.}$	Δp_{bend}	Δp_{nozzle}
1	72	305	0	0	0
1	72	1016	0	0	0
2	71	315	1637	0	0
2	71	1050	1637	0	0
3	71	315	1637	803	0
3	71	1050	1637	803	0

3.2 Case 1: Straight Pipes

The first case investigates the use of straight inlet outlet pipes. Figure 5, Case 1, show the change in compressor efficiency for both short and long outlet pipe. In figure, it is visual that the pressure losses does not affect the compressor efficiency more than 0.8% (percentage points) at maximum mass flow of air when analyzing the long outlet pipe.

3.3 Case 2: Pipes with Diffuser and Nozzle

The diffuser and nozzle are used to either increase or decrease fluid pressure or velocity. The simulated inlet and outlet pipes with the pressure sensors mounted are assumed to have the same diameter as the pipe at the static pressure sensor location. The size of the diffuser is chosen to connect the pipe diameter where the pressure measurement is made, and the diameter of the compressor outlet. The results for both short and long outlet pipes are displayed in Figure 5, Case 2. Since the pressure loss

caused by the nozzle is assumed to be zero, the pressure loss caused by the diffuser and the pipe friction causes the efficiency calculation error to be 1.4% (percentage points) when analyzing the short outlet pipe and up to 1.9% when analyzing the long outlet pipe.

3.4 Case 3: Pipes with Diffuser, Nozzle and Bend

A 90^o smooth bend is added to the simulated inlet pipe, between the pressure sensor and the pipe connecting to the compressor, to find its impact on the measured compressor efficiency, see Figure 5, Case 3. The pipe bend clearly affects the results, this is visual if comparing Case 2 with Case 3. The maximum error in the calculated compressor efficiency is 2.7% (percentage points), when analyzing the long outlet pipe.

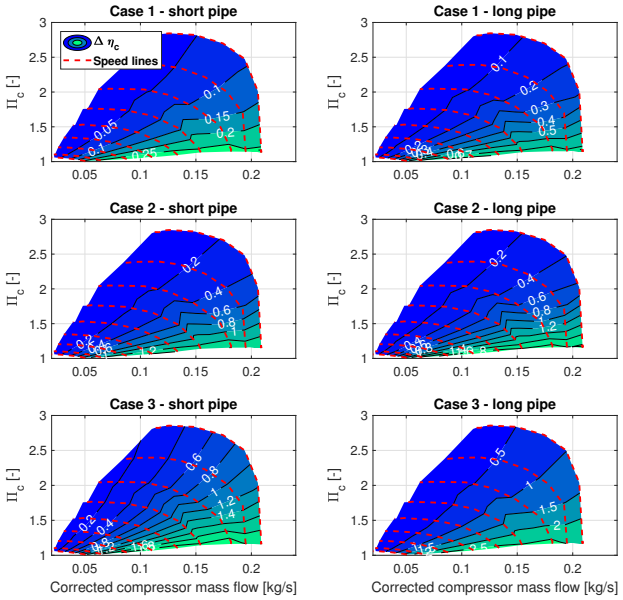

Figure 5. Displays the change in compressor efficiency $\Delta\eta_c = \eta_c' - \eta_c$ (color scale) compared against Π_c and $\dot{m}_{c,corr}$. Short pipes corresponds to outlet pipe length equal to 3 times the pipe diameter, long pipes corresponds to 10 times the pipe diameter.

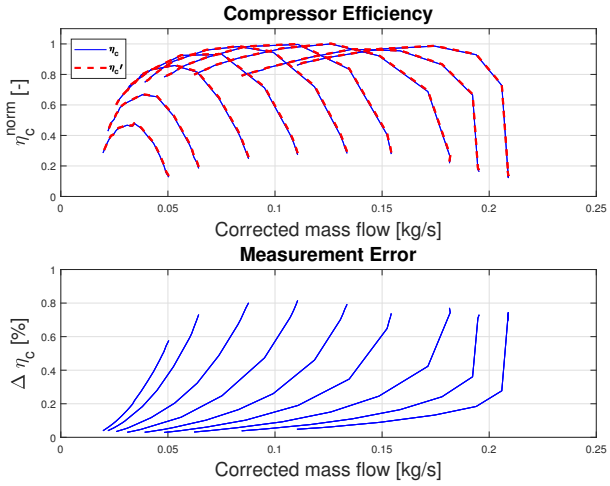

Figure 6. Case 1, the pipe length is 10 times the outlet pipe diameter. Top figure shows the normalized compressor efficiency with and without correction for the pressure losses in the gas stand, the bottom figure shows $\Delta\eta_c = \eta_c' - \eta_c$.

4 Summary and Discussion

Three different cases have been investigated to find and quantify the error in compressor efficiency due to enthalpy change in the inlet and outlet pipes. The enthalpy change present between the pressure sensors and the compressor affects the compressor map the most in the high flow low pressure region, for each speed line. This is visible in both Figure 5 and Figure 6. For all the displayed cases, the error in compressor efficiency increases with increasing mass flow. Case 1 shows that a longer pipe between the compressor outlet and the measurement location induces larger error in measured compressor efficiency. Case 2 studies the use of pipes with nozzle and diffuser, the nozzle is assumed to not induce any pressure loss, which shows that the diffuser induces a large pressure loss, which affects the compressor efficiency. Comparing Case 2 with Case 3, where the difference is the introduced pipe bend, clearly shows that a pipe bend induces errors in the calculated compressor efficiency. If a pipe bend is present between the pressure sensor and the compressor, it should be taken into account to correct measurements. The magnitude of the pressure losses in Table 2 are small, but they still affect the compressor efficiency noticeably.

5 Future Work

If this study is to be extended, one interesting aspect would be to investigate the impact on engine performance, if the compressor efficiency is corrected according to the study. The study could also be extended to take the heat transfer inside the inlet and outlet pipes into account.

6 Conclusions

For the selected set of gas stand physical dimensions, the change in compressor efficiency due to the calculated

pressure losses is compared to original compressor efficiency calcuations. The results show:

- Due to the friction work, the enthalpy of the fluid between the pressure sensors and the compressor inlet and outlet changes.
- The measured compressor efficiency is lower than the actual efficiency, due to pressure losses between compressor and the pressure sensors.
- The induced error $\Delta\eta_c$ shows that the error is getting larger with increased mass flow for each speed line.
- If a 90^o bend is present between the measurement position and the inlet to the compressor, and the diffuser is connected on the outlet, the error in calculated compressor efficiency is up to 2.7% for compressor maximum mass flow with used parameters.
- The pressure losses in the inlet and outlet pipes are affecting the compressor efficiency most at the high flow low pressure region for each speed line, where the compressor efficiency is generally low.

Abstract

In this paper is presented a methodology that uses simulation together with optimization techniques for a conflict detection and resolution at airports. This approach provides more robust solutions to operative problems, since, optimization allows to come up with optimal or suboptimal solutions, on the other hand, simulation allows to take into account other aspects as stochasticity and interactions inside the system. Both the airport airspace (terminal manoeuvring area), and airside (runway taxiways and terminals), were modelled. In this framework, different restrictions such as speed, separation minima between aircraft, and capacity of airside components were taken into account. The airspace was modeled as a network of links and nodes representing the different routes, while the airside was modeled in a low detail, where runway, taxiways and terminals were modeled as servers with a specific capacity. The objective of this work is to detect and resolve conflicts both in the airspace and in the airside and have a balanced traffic load on the ground.

Keywords: optimization, modeling, simulation, airport

1 Introduction

Capacity at airports has become a very delicate problem due to the increase of traffic demand and the scarcity of facilities at airports. In Europe it has been seen a growth of traffic of 1.5\% from 2014 to 2015, and the forecasts say that this growth will continue also for the coming years (Eurocontrol, 2016). Airports are getting busier and busier, especially at the major hubs in Europe, with visible effects as delays occurrences. Looking at the delay from all causes, it can be seen that in the first three months of the year there were between 34\% and 38\% flights delayed on departures, where only delays greater or equal than five minutes are considered (Eurocontrol, 2016). So far, many studies have been conducted in order to alleviate airports from congestion and improve the capacity, some of them focused on the airspace and some other only on the airside. Concerning problems related to the airspace, we can find many works about the sequencing and merging or scheduling of arrivals in the TMA (Beasley et al., 2000; Beasley et al., 2001; Hu and Chen, 2005; Michelin et al., 2009; Balakrishnan and Chandran, 2010; Zuniga et al. 2011). On the other hand we can also find studies related to ground issues such as gate assignment problem (Bolat, 2000; Dorndorf et al., 2007; Kim and Feron, 2012; Narciso and Piera, 2015), scheduling of departures (Pujet et al., 1999; Rathinam et al. 2009; Sandberg et al., 2014; Simaiakis and Balakrishnan, 2015) or airport surface management (Montoya et al., 2010; Simaiakis et al., 2014; Khadilkar and Balakrishnan, 2014). In order to conduct a more precise analysis and obtaining an integrated view of the system, it is better to consider airspace and airside together, so that we can also consider the interactions between the two environments.

The contribution of this paper is that it considers the airport from a holistic perspective, including most of the factors that link airspace and airside and affect the overall airport capacity. Furthermore, another contributions of this work is the employment of an approach that uses optimization together simulation, with the objective of obtaining more robust solutions. On one hand, optimization allows to come up with optimal or suboptimal solutions and, on the other hand, simulation allows to take into account other aspects as stochasticity and interactions inside the system. In literature we can find similar works that employ optimization together with simulation techniques, like in (Mujica, 2015) where an evolutionary algorithm together with discrete event simulation was proposed for the improvement of the check-in allocation, or (Arias et al., 2013), where was presented a model for solving the stochastic aircraft recovery problem employing constraint programming together with simulation.

In this paper a methodology for detecting and resolving conflict at airports is presented, it considers the airport from a holistic view, taking into account both airspace and airside components together. In the methodology presented in this paper an optimal or sub-optimal solution is found applying a sliding window approach (Hu and Chen, 2005; Zhan et al., 2010; Furini et al., 2015) together with a meta-heuristic (simulated annealing) (Kirpatrick et al., 1983), after that, the solution provided from the optimization model is tested and validated with the use of a discrete event simulation

model. Using simulation, it is possible to take into account the stochasticity of the system and the interactions between the entities in the system.

The paper is organized with the following structure, in Section 2 the methodology is explained, in Section 3 a scenario is tested, providing preliminary results and in Section 4 some conclusions are drawn and next steps for this research are delineated.

2 Methodology

The methodology presented in this work is constituted by three main steps (Figure 1). The first step aims at modeling the airport taking into account both airspace and airside. In this case the airside was modeled in a "macro" level, where runway, taxiway and terminals were modeled as servers with a specific capacity. The second step consisted in the implementation of an optimization model to obtain a solution for the conflict detection and resolution problem. Finally, in the third step, the solution provided by the optimization model is evaluated by the means of a simulation model in order to test the effectiveness and feasibility of the solution.

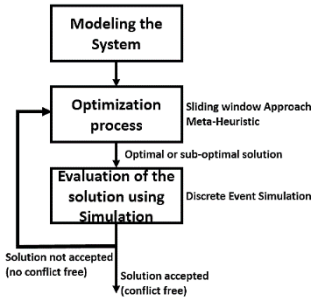

Figure 1. Methodology steps.

2.1 Airport Modeling

One of the main contribution of this work is that it considers both airspace and airside of the airport. Concerning the airspace, landing routes in the TMA were modeled, and separation minima between aircraft as well as speed restrictions were included. Regarding the airside, since the objective did not require a detailed evaluation, runway, taxiway and terminals components, were modeled as servers with a specific capacity. First, it is fair to explain the concept behind airspace and airside conflicts. In this framework, it was assumed that any violation of separation minima between aircraft along the airspace routes and at the merging point was considered as a conflict. Values about separation minima are in accordance with the ICAO standards for separation minima due wake vortex turbulence, they are based on the aircraft type which could be light, medium or heavy (see Table 1). Concerning the airside, conflicts were detected when the capacity of runway, taxiway and terminal was exceeded. It is clear that, the objective of detecting and resolving conflict in the airspace and in the airside lead to have a smooth flow of aircraft in the airspace and a balanced load on the airside, which is the main scope of this work. In this work, the case of Paris Charles de Gaulle Airport was considered. Regarding the airspace, standard approach routes (STAR) and final approach segment were modeled. In total there are four different routes coming from different entry points, all of them merge at the merging point before the final approach segment. In Figure 2 the airspace routes taken into account in the model are shown.

Table 1. ICAO wake vortex turbulence separation minima.

		Leading Aircraft		
		Heavy	**Medium**	**Light**
Trailing Aircraft	**Heavy**	4	3	3
	Medium	5	4	3
	Light	6	4	3

As a preliminary test, in the model there were considered only one of the three terminal and only two runway (one landing and one departing) of the four runways (two landings and two departing) that constitute the airport airside. Concerning the values chosen for the capacity of the airside components, it is intuitive that runways have the value of capacity equal to one since only one aircraft is allowed to cross the runway at a time. Of the three terminal, terminal 2 was chosen for being tested, due to the availability of data concerning inbound and outbound flight to and from this terminal. Terminal 2 is the biggest of the three terminals in Paris CdG airport, it accommodates all the flights of Air France and SkyTeam members. In Table 2 all the characteristics concerning airside components are listed with their respective values.

Table 2. Characteristics of airside components.

Airside Component	Capacity
Runway 26 R/L	1
Taxiway Network	20
Terminal 2	176 (152 considered)

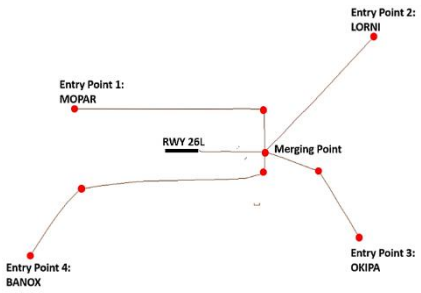

Figure 2. STAR and final approach segment for Rwy 26L.

2.2 Optimization Model

The optimization model proposed to solve the conflict detection and resolution problem is based on (Ma et al., 2015), where a sliding window approach (Hu and Chen, 2005; Zhan et al., 2010; Furini et al., 2015) is used together with a meta-heuristic (simulated annealing) (Kirkpatrick et al., 1983) to solve conflicts in the airspace. The sliding window approach allows to consider an extended time horizon in smaller time frames, dividing the overall problem in sub-problems of smaller size, therefore, decreasing the computational time. Moreover, it allows to treat the problem in a dynamical way, where decisions that are made in each window will affect the decisions to be made in the successive window. The main parameters of the sliding window approach are the size of the window and the size of the shift.

The meta-heuristic used is the simulated annealing (Kirkpatrick et al., 1983), this heuristic is a local search algorithm which is able to escape from local optimum by allowing hill-climb moves in order to find a global optimum.

The main aspect that differentiates this work from the other aforementioned works is that, beside the airspace, airside operations were also included. The new objective becomes the detection and resolution of conflicts both in the airspace and in the airside. The objective of this optimization model is twofold, first it aims at detecting and resolving conflicts in the airspace and also capacity conflicts in the airside, and second is to ensure a smooth flow of aircraft in the airspace and a balanced load on the ground. The decision variables for the problem are: entry time change, entry speed change and pushback time change. The first is the time when aircraft enter the airspace route, the second is the speed that aircraft have when they enter the airspace route and the third is the delay allowed to the aircraft, that are parked at the gate, before they leave the gate and reach the runway for taking off. In Table 3 are shown the values that the decision variables can assume.

Table 3. Value range of the decision variables.

Decision Variable	Value
Entry Time	Between -5 and + 30 min
Entry Speed	Between -10 and + 10
Pushback Time	Between 0 and 5 min

In this context, conflicts in the airspace are detected in the following way: node and link detection. Routes are modeled as a network made by nodes and links, in every node and in every link aircraft are tracked by their "time in" and "time out". If the time interval between "time in" and "time out" overlaps for two or more aircraft then a conflict is detected, the same principle is applied for nodes and links. In Table 4 are described the four routes of the airspace plus the final approach route.

Table 4. Characteristics of the routes modeled in the optimization model.

STAR (Entry point)	Number of nodes (links)
STAR1 (MOPAR)	4 (4)
STAR2 (LORNI)	2 (2)
STAR3 (OXIPA)	2 (2)
STAR4 (BANOX)	4 (4)
Final Approach segment (Merging point)	3 (3)

Concerning airside components as runways, taxiway network and terminal, there were made some assumption about runway occupancy time (for landings and take offs), taxiway occupancy time and turnaround time, they were based on fixed values, in Table 5 these values are listed.

Table 5. Times for airside components in the optimization model.

Airside component	Time
Runway	60 sec landing – 25(H)-30(M)-35(L) sec take off
Taxiway	10 min
Terminal	OffBlockTime-InBlockTime

2.3 Simulation Model

The simulation model is built using a discrete event simulation approach. The employment of this approach allows to take into account the stochasticity of the system and also the interactions inside the system (Banks et al., 2010). For example, values related to runway occupancy time, taxiway occupancy time and turnaround time were modeled following probability distributions, whereas, in the optimization model these values were assumed as deterministic. Another factor that differentiate the simulation approach from the optimization one is the speed profile. In the optimization model the acceleration used is fixed and the time in and time out for each node and link is calculated in a static way based on the length of the link, whereas in the simulation model, speed is regulated using a fixed acceleration that is updated each second. In this way, the speed profile will be more realistic. Moreover, during the descending approach the simulation model does not allow aircraft to fly below a certain speed threshold, indicated as lower bound speed. In the simulation model, although were modeled the same routes, these routes were modeled using more nodes and links. The theory behind this approach is to construct a network of equidistant nodes in order to detect conflict more accurately along the route. In the model nodes are distanced by 5 NM from each other, which is assumed as an acceptable distance to make sure to do not miss any conflict along the route. Based on that,

it is likely to find, under the same conditions, more conflicts in the simulation model than in the optimization model. Due to this network structure, in the simulation model conflicts are detected only on the nodes and not on links. Concerning the detection of conflicts, it is applied the same principle as in the optimization model. In Table 6 the main characteristics of the airspace network are listed.

Table 6. Route network in the simulation model.

STAR (Entry point)	Number of nodes (links)
STAR1 (MOPAR)	11 (11)
STAR2 (LORNI)	7 (7)
STAR3 (OXIPA)	7 (7)
STAR4 (BANOX)	15 (15)
Final Approach segment (Merging point)	3 (3)

The main objective of the simulation model is to test if the solution that comes from the optimization model is feasible also in a more accurate scenario.

Regarding the detection of conflicts on the airside, in the simulation are used the same principles as in the optimization model, with the only difference that times are based on probability distributions and therefore also variability is included, instead, in the optimization model times were based on fixed values, making it more predictable and static.

2.3.1 Validation of the Simulation Model

In order to validate the model, we have conducted a cross validation (Geisser, 1975). This type of validation consists in dividing the set of data in two parts, called set training set and testing respectively, and then using the training set for calibrating the simulation parameter in order to get an outcome that resembles the trailing set data sample. After that, the testing set and the simulation outcome are compared in order to see if the simulation is a good predictive of the data. In this case it was used the first half of the input flight schedule as training set and the second half of the input flight schedule as testing set. Figures 3 and 4 show the daily trend of traffic of the testing set and the simulation outcome after the calibration of the data. In Table 7 are shown the parameters that were used in the simulation model. Figures 5 and 6 show the outcome from the simulation and the testing set. In both sets, Figures 3 and 4 and Figures 5 and 6, it can be seen that the hourly traffic from the simulation and the hourly traffic obtained from the real flight schedule follow the same trend. The mean square error estimator was used to estimate the accuracy of the result obtained from the simulation compared to the real data set.

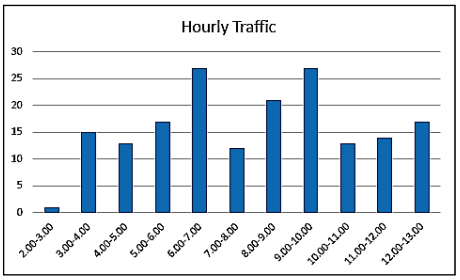

Figure 3. Trend of the daily traffic from the training set.

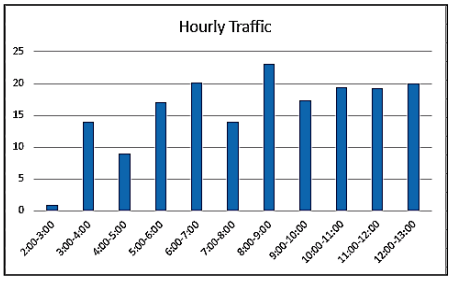

Figure 4. Outcome from the simulation model using the training set as data sample.

In Tables 8 and 9 the values of mean square errors for each hour of traffic are listed, for the training set and testing set, respectively. By observing these values it can be noticed that the ones related to the testing set are not that high which means that the simulation is relatively reliable in predicting the system.

Table 7. Parameters of the airside components in the simulation model.

Airside component	Time
Runway	Triangular(0.5,0.75,1) min
Taxiway network	Triangular(8,10,12) min
Terminal	Triangular(25,35,45) min

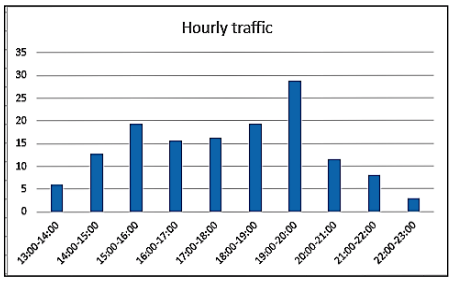

Figure 5. Outcome from the simulation model for the second half of the data sample (testing set).

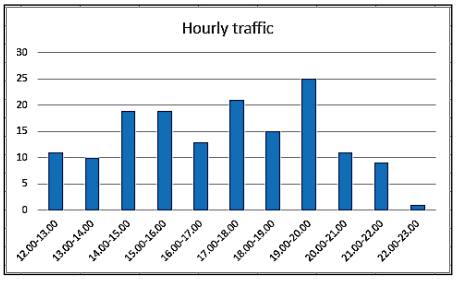

Figure 6. Trend of the daily traffic from the testing set.

Table 8. Mean square error values for training set.

Hour	mean square error
2:00-3:00	0
3:00-4:00	1
4:00-5:00	15.76
5:00-6:00	0.2
6:00-7:00	47.16
7:00-8:00	8.73
8:00-9:00	93.76
9:00-10:00	43
10:00-11:00	29.2
11:00-12:00	10.53
12:00-13:00	9

Table 9. Mean square error values for testing set.

Hour	mean square error
13:00-14:00	16
14:00-15:00	38.6
15:00-16:00	0.66
16:00-17:00	7.6
17:00-18:00	23.8
18:00-19:00	20.2
19:00-20:00	16.5
20:00-21:00	0.7
21:00-22:00	9.3
22:00-23:00	4

3 Scenario and Results

In order to test the goodness of the methodology there have been conducted a series of preliminary tests primarily to tune the parameters of the optimization model in the specific the parameters of the sliding window approach and of the simulated annealing meta-heuristic. Values related to the sliding window parameters are listed in Table 10.

Table 10. Sliding window parameters.

Parameter	Value
Window duration	2Hrs
Shift	30 min

Concerning the experiments, one scenario was tested based on a flight schedule related to a specific day. Once the optimized solution is ready it will be tested with the use of the simulation model developed and discussed in Section 2.3.

3.1 Scenario

In the flight schedule that was used, three different typology of flights were identified: arrivals, departures and arrivals and departures. The first type means that aircraft will arrive and stay at the gate for the whole day without departing again to another destination, in the flight schedule you can find most of them during the middle of the day and in the evening. The second type, is departure flight which means that those aircraft are already parked in one of the gate and they will depart to a destination, usually you can find those type of flights during the morning. Finally, the third type, arrivals and departures, are those flights that arrive from an origin, they park at the gate and then they depart to another destination, these flights represent the majority of the flights in the schedule. In Table 11 the structure of the flight schedule, according to the flight type, is showed.

Table 11. Flight schedule structure for the scenario.

Scenario	
Arrivals	149
Departures	48
Arrivals and departures	91

As it can be seen from the figures above, in the first schedule there are 3 peaks: 7.00-8.00, 10.00-11.00 and 20.00-21.00, with 31, 24 and 25 air traffic movements, respectively.

3.2 Results from the Optimization Model

Table 12 summarize the results obtained running the optimization model before and after the implementation of the simulated annealing meta-heuristic. Looking at the table above, it can be noticed that the optimization model is able to reach a conflict free situation in 120 sec., when the initial solution without optimization registered in total 307 conflicts, 121 on nodes, 144 on links and 42 on the runway. Moreover, it can be noticed that taxiway and terminals are not affected by conflicts both before and after the optimization process, proving that under the given traffic, the capacity of the two components is able to handle this traffic without incurring in congestion problems.

Table 12. Results before and after optimization process.

	before opt	after opt
Computational time	101.883 sec	120.18 sec
Total objective	307	0
Node conflicts	121	0
Link conflicts	144	0
Runway conflicts	42	0
Taxiway conflicts	0	0
Terminal conflicts	0	0

3.3 Results from the Simulation Model

After running the optimization model and obtaining an optimal solution, this solution has been tested by means

of a discrete event simulation model. It was simulated the whole day and there were run 30 replication. Tables 13 and 14 show the results obtained by the simulation model. For simplicity, we have named as the conflict detected on the nodes in the airspace routes were named "airspace conflicts". Moreover, in order to have a better idea of how many aircraft are involved in the conflicts, the number of aircraft affected by at least one conflict in the airspace were collected.

Table 13. Results from simulation model before the optimization process.

	Min	Avg	Max	St. dev
Aircraft conflicts	57	57	57	0
Airspace conflicts	256	256	256	0
Runway In conflicts	86	92	98	1.139
Runway Out conflicts	1	1.55	3	0.4255
Taxiway conflict	0	0	0	0
Terminal conflicts	0	0	0	0

Table 14. Results from simulation model after the optimization process**.**

	Min	Avg	Max	St. dev
Aircraft conflicts	38	38	38	0
Airspace conflicts	180	180	180	0
Runway In conflicts	49	51.3	55	0.7385
Runway Out conflicts	1	1.41	2	0.3272
Taxiway conflict	0	0	0	0
Terminal conflicts	0	0	0	0

In the simulation model it is likely to find more conflicts in the airspace than in the optimization model, due to its different route structure that provides more nodes and links than the route structure of the optimization model. Another distinction was made between "runway in" and "runway out", which refers to runway used for landings and runway used for departures, respectively. Looking at the results, we can see that there are still conflicts, they are mainly concentrated in the airspace were we have 180 conflicts on nodes occurred to 38 aircraft. No source of variability affect these results because there is not any source of stochasticity in the values related to the airspace. We have in average 51.53 conflicts for runway in and 1.41 conflicts for runway out, while no conflicts are detected for taxiway and terminal. It is noticeable that, even though after the optimization process in the simulation model there are still conflicts, they have decreased sensibly, compared with the scenario without optimization process. It proves that the solution provided by the optimization process is able to reduce the number of conflicts, but it is not enough to achieve a conflict free solution.

4 Conclusions and Future Work

In this paper, a methodology for detecting and resolving conflicts at airports is presented. The methodology consists in the implementation of optimization together with discrete event simulation techniques in order to come up with more robust solutions. The optimization model was solved using a sliding window approach and the simulated annealing meta-heuristic. With the use of a discrete event simulation model, the methodology aimed at evaluating the solution given from the optimization model, in a real and more accurate environment. In this work, Paris Charles de Gaulle Airport was taken as a case study and one scenario was tested based on the flight schedule of a specific day.

From the results, we found that the optimization was able to find an optimal (conflict free) solution. When the solution was tested using the simulation model it was found that, although conflicts were sensibly decreased compared to the non optimized scenario, there were still a lot of conflicts both in the airspace and on the runway. From this results it is possible to conclude that the solution from the optimization model was not feasible, and therefore, the optimization model needs further refinements in order to produce a more robust ad feasible solution.

Next steps for this research are in accordance with the results, therefore, the optimization model needs to be refined in order to be more accurate. Furthermore, the airside can be modeled in a more detail, including taxiway routes and gate assignment.

Abstract

Evaluation aspects of alternative traffic signal control strategies for an arterial network are studied. The traffic evolution of a signalized road network is modelled as a Store and Forward (SF) network of queues. The system state is the vector of all queue lengths at all intersections. The signal control at any time permits certain simultaneous turn movements at each intersection at pre-specified saturation rates. Two control categories, open loop and traffic-responsive policies are compared under fixed and time-varying demand. The behaviour of the underlying queuing network model manifesting asynchronous nature over time while involving concurrence is modelled according to an event-driven approach virtually reproduced by discrete event simulations. Exploration of the implementation outputs results a pertinent mathematical framework for traffic movement, analysis and signal control design. Subsequently, various metric measurements such as queue bounds, delays, trajectory travel times quantify the actual policy. Moreover, aggregate behaviour as in a macroscopic queuing model is also prompted. Experiments are performed using real data for a section of the Huntington-Colorado arterial adjacent to the I-210 freeway in Los Angeles. Lastly, the meso-micro simulation issues resulting from the employed decision tool, PointQ, are compared with microsimulation and mesosimulation forms of other traffic simulation programs.

Keywords: traffic responsive signal, adaptive control, pre-timed control, max-pressure practical policy, discrete event simulation

1 Introduction

The *management* of an arterial traffic network is considered. Currently open loop plans are frequently employed often associated with optimised offsets aiming to create green waves in order to minimise trajectory delays. (Muralidharan et al., 2015) studies the traffic dynamics in a network of signalised intersections. It is shown that when the control can accommodate the demand then the network state converges towards a periodic orbit while any effects of the network initial state disappears. Adaptive controls are expected to improve the network performance since they the current network state is taken into consideration in real time. (Varaiya, 2013) studies a traffic-responsive "Max-Pressure" traffic control, (Mirchandani and Head, 2001) proposes an adaptive control predicting demand patterns and queues to compute timings to minimize average delay. (Aboudolas et al., 2009) suggests an optimal formulation designing a feedback policy. Research studies (Gomes et al., 2008) characterise the behaviour of the cell transmission model of a freeway divided into N cells each with one on-ramp and off-ramp. It is shown that ramp metering eliminates wastefulness of freeway resources.

The present work, appraises the performance of versions of the adaptive Max-Pressure algorithm under unpredicted demand fluctuation. In particular, feedback signal control designs and their related effectiveness are presented and analysed when applied to a network while they are also compared with open loop schemes. Queueing models are employed when designing closed loop signal control plans evaluated by queue based criteria such as queue delays. Thus, traffic evolution is modelled as a controlled store and forward (SF) queuing system. Identified vehicles arrive in iid (independent, identically distributed) streams at entry links, travel along non-saturated (internal) links, join appropriate queues and leave the network upon reaching exit links. At each time and at each intersection, a set of simultaneously compatible movements or *phases* is actuated. Vehicles are discharged at a service rate determined by the *phase* saturation flow rate. When finite internal link capacities are considered, the vertical point queues become horizontal in the sense that interfere in the link vehicle storage capacity and the related link travel times.

A separate queue is considered for each turn movement at each intersection.

Aiming at evaluating the network performance under different control policies a decision making tool is necessary in order to virtually reproduce the considered structure (intersection node and links, vehicle movements and the related control plans) under multiple traffic conditions for both closed and open loop actuation plans. Thus, measurements of various metrics such as delays, travelled times, vehicle queues etc. will be able to quantified according to the employed strategy.

When considering "driver-behaviour", differential

equations are required, emulating "car-following" and "lane-changing" aspects. Microsimulation models are necessary for which queue sizes are not state variables and saturation flow rates are not input data. Instead, they are derived from the simulation analysis. Consequently, it is not possible to relate delays to timing schemes and these models are unsuitable for traffic control conception.

Macroscopic simulators often based on the cell transmission model (CTM) (Lo, 2001) represent traffic flow as a fluid. Spatial density is required as a state variable which is hard to measure. Furthermore, modelling turns, shared lanes, queues or introducing sensor behaviour for actuated signal control, under such approach is rather a hard work.

A made-to-measure micro-meso simulation decision making tool called *PointQ* maintaining the identity of each single vehicle while ignores the vehicle interaction is introduced. It has minimal data requirements and receives saturation flow rates as explicit input values. The PointQ decision tool is developed according to discrete event approach (Baccelli et al., 1992) in order to accurately reproduce the evolution of the asynchronous system while it is appropriate for modelling open and closed loop timing control schemes.

The rest of the paper is organised as follows. Section 2 presents the problem formulation and briefly recalls the utilised control schemes. Section 5 introduces PointQ and reasons the employed model approach. Section 5 and Section 6 discuss the performed experiences. Finally, Section 7 compares PointQ with other micro and mesosimulation modes.

2 Traffic Regulation: Stage selection

The simultaneously compatible movements of an intersection are represented by a binary matrix U, the *intersection stage* of which the (i,j) entry equals one if the corresponding phase is actuated, zero otherwise. Let $\mathscr{U}$ be the set of admissible *stages* of a given intersection and $\gamma(l,m)$ the turning ratio of phase (l,m), expressed as the probability of a vehicle to choose as destination link m when joining link l. The optimisation horizon is divided into intervals or cycles of fixed width, each one comprising of T periods. Within each cycle, there exist $T-L$ available planning periods where $L<T$ represents the idle time corresponding to pedestrian movements, amber lights, etc. Let q be the array of which the (i,j) entry is the length of queue related to phase (i,j). The system state at time $t, X(t)$ is defined by $X(t)=q(t)$. A control *stabilises* the network, if the time-average of every mean queue length is bounded. At a given time *stage* $u(t)=U, U\in\mathscr{U}$ and $\lambda_{u(t)}$ cycle proportion have to be decided such that:

- $u(t)$ *stabilises* $X(t)$
- if $\tilde{c}(l,m)$ denotes the service rate of phase (l,m) and f_l represents the vehicle flow in link l, then the following stability condition has to be verified,

$$\tilde{c}(l,m) > f_l\gamma(l,m), \tag{1}$$

- $\sum_{u\in\mathscr{U}} \lambda_u T + L \leq T$.

3 Signal Control Schemes

A brief description of the utilised traffic control algorithms is now presented. The related theory is explicitly developed and analysed in (Varaiya, 2013).

3.1 Pre-timed network control

A *fixed-time* control (FT) is a periodic sequence, $\{\lambda_U, U\in\mathscr{U}\}$, actuating each *stage* $u(t)=U^i$, $U^i\in\mathscr{U}$ for a fixed duration $\lambda_{U^i}T$ within every cycle of T periods.

3.2 Max-Pressure Practical (MPract)

Max-Pressure is a distributed policy selecting a stage to actuate as a function of the upstream and downstream queue lengths. The pressure $w(q(t),U)$ exerted by *stage* $U\in\mathscr{U}$, is defined by

$$w(q(t),U) = \sum_{(l,m)} \varsigma(l,m)(t) S\circ U(l,m)(t) \tag{2}$$

where

$$\varsigma(l,m)(t) = \begin{cases} q_{(l,m)}(t) - \sum\limits_{p\in\mathscr{O}(m)} \gamma_{(m,p)} q_{(m,p)}(t), \\ \qquad\qquad\qquad \text{if } q_{(l,m)}(t)>0, \\ 0, \text{ otherwise.} \end{cases} \tag{3}$$

At time t, *Max-Pressure* control, selects to actuate the *stage* exerting the higher pressure to the network,

$$U^*(q)(t) = \operatorname{argmax}\{w(q(t),U), U\in\mathscr{U}\}, MP\ stage \tag{4}$$

The MPract algorithm applies the new selected MP stage if significantly larger pressure w,

$$\max_U w(U,q(t)) \geq (1+\eta) w(U^*,q(t)). \tag{5}$$

Parameter η is related to the desired degree of stage switches.

4 Modelling and Simulation Overview

4.1 An event-driven approach

Traffic control constitutes an asynchronous, complex structure where uncertainty and concurrence are naturally inherent. Many theoretical questions related to which models and methods are best to utilise for evaluating the network performance exist. However, one observes that there are queue-based models and car-following models. To our knowledge, all signal control algorithms use queue-based models. Since, we are concerned by signal control designs, a queue-based approach is appropriate to the needs of the study. Queueing theory is intended to be *descriptive*, given a model and control policies, after analysis, verification issues examine whether the desired objectives are attained and (potentially) performance is obtained.

A Discrete Event System (DES) is a dynamical system the behaviour of which is ruled by occurrences of different types of events over time rather than fixed time steps. Although time evolves within two consecutive events, the sole responsible for state transitions is the event realisation. Differential equations (developed for the analysis of time-driven systems) form no longer an adequate setting. Simulation means consist a reliable way to describe the DES dynamics.

For the study of the arterial management a mesoscopic-microscopic discrete event decision tool, "PointQ", is developed. Vehicle identities are preserved but driver-interaction is intentionally ignored. Vehicle routes are observed and travel times are measured. Moreover, PointQ requires similar model parameters as macroscopic approaches (network geometry, demand and signal control). Since elementary calibration is required based on commonly available field data, PointQ can efficiently evaluate the influence of traffic control algorithms to the network. However, PointQ is inadequate for studies related to driver behaviour effects or specific network geometry.

In a DES approach the system evolution is represented as a chronological sequence of events of the form $\{\ldots, s_i, e_i, s_{i+1}, e_{i+1}, \ldots\}$, where s_i is the system state at time t_i and e_i is an event occurring at time t_i marking changes to the system bringing it to state s_{i+1} and so forth. It is assumed that the system is *deterministic* in the sense the state resulting from an event realisation is *unique.* PointQ model involves events on vehicle arrivals, departures and signal actuation.

4.2 PointQ design

The entire structure is split into two independent but also closely interacting parts according to the task nature. The mechanical part virtually represents the system entity interactions. It receives tow types of entries:

- input data such as network geometry (link capacity, speed limit or mean travel time, turn pocket capacity, phase saturation flow rates which can either be measured or estimated during implementations), initial traffic state, sensors etc.
- controls ruling the system.

On the other hand, the real time management comprised of all the decision algorithms required by the mechanical part involving signal controls, vehicle arrival/departure decisions, demand patterns, routing algorithms, queue estimation models etc.

5 Case Study-Data description

A section of the Huntington-Colorado arterial near the 1-210 freeway in Los-Angeles, comprised of 16 signalised intersections, 76 links and 179 turn movements, is considered. Figures 2 and 3 illustrate the network map and its abstraction as a directed graph. Stochastic (Poisson) external arrivals are employed, generating approximatively $14,500$ vehicles per hour. Utilisation of an identical demand contributes to the accuracy of measurements related to the influence of each control scheme on the network. Vehicle routing is based on turning probabilities. The Fixed-Time plan and the turn ratio values are provided by the local traffic agency. The cycle T is of 120 seconds (with some exceptions at two nodes where the cycle is of 90 and 145 secs). The idle duration corresponding to each cycle is between 0 and 2 seconds. Internal links are of finite vehicle storage capacity. Stochastic travel times based on the free flow speed and the current link state are considered. Time granularity is taken equal to 0.1 seconds while the network evolution is reproduced over a period of 3 hours.

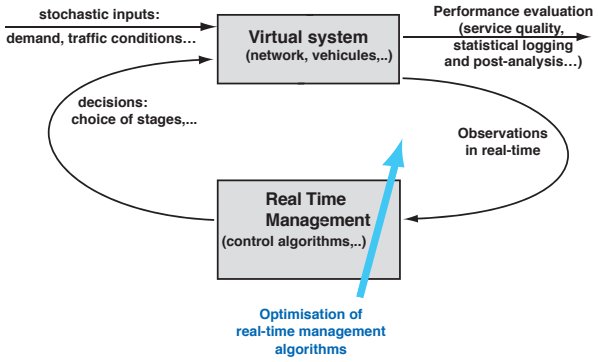

Figure 1. The simulator in two parts.

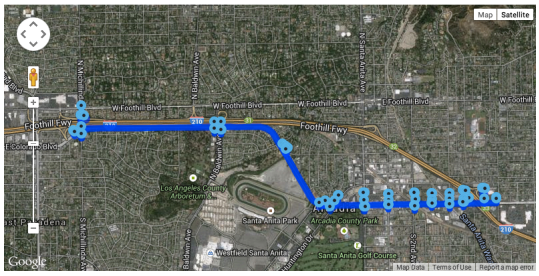

Figure 2. Huntington-Colorado site map.

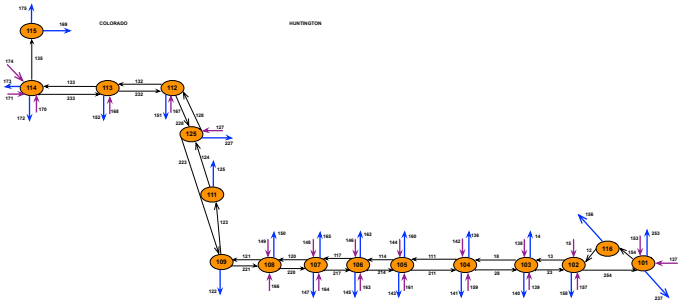

Figure 3. Directed Network graph.

6 From theory to applications

In what follows, we focus on the network performance evaluation for both timing plans, FT Offset and MPract. Metrics on queue lengths, travel times and delays are investigated for two demand patterns, the baseline demand provided by the data and a time-varying one.

6.1 System Stability

Figure 4 plots the network state evolution for both the Pre-timed and MPract signal controls. The theoretically expected demand accommodation is also experimentally verified. Moreover, one observes that the feedback plan (blue curve) maintains lower queue values.

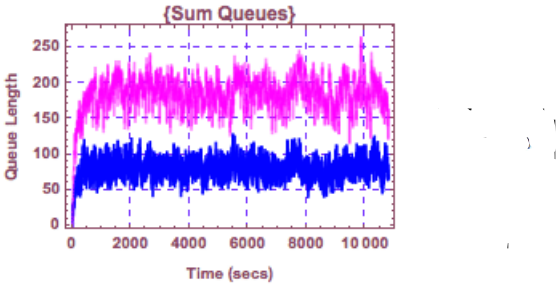

Figure 4. Sum network queues: MPract 8-blue curve, FT Offs-purple curve.

6.2 Trajectory Delay Measurement

For each realised trajectory (sequence of entry, internal and exit links) delays faced by all vehicles followed the related path are measured. The corresponding distribution is computed and the CDF function is represented in Figure 5. MPract (purple curve) reduces delays almost four times in comparison with the fixed time plan (green plot).

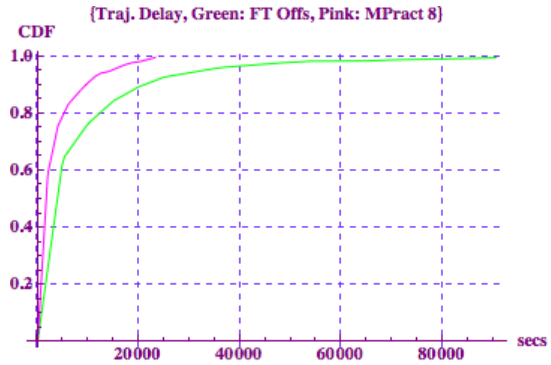

Figure 5. CDF Trajectory Delays: MPract (purple), FT-Offs (green).

6.3 Queue Delay Measurement

Delays on distinct queues on link 114 (incoming link at node 106, Huntington region) are now measured.

Three phases are associated with link 114. Figures 8, 9 and 10 depict the evolution of cumulative delay values for each phase according to the Pre-timed and MPract policies. Observe that for phase $(114,145)$ the pre-timed scheme implies lower delays. Mainly, this is due to the fact that $q(114,145)$ and $q(114,145)$ head vehicles towards exit links. More precisely, phases $(114,145)$ and $(217,214)$ are simultaneously actuated by stage 1. Similarly phases $(114,117)$ and $(217,214)$ are actuated by a concurrent stage 2. At any decision time the MPract stage is the one exerting the higher pressure. According to equation 2 and since no output queues are associated with the exit links 145, 162, the pressure exerted by stage 2 is determined by the queue lengths of the related phases. Taking into consideration the flows and queue demand on link 114, stage 2 often exerts higher pressure regarding stage 1. Thus, it receives increased green time duration. Figures 6, 7 plot the evolution of queues $q(114,145)$ and $q(114,117)$ for both policies. Lower queues result under MPract for phases of stage 2. The evolution of cumulative delay values for each phase of link 114 is represented in Figures 8, 9 and 10 (saturation flow rates remain unchanged for both policies).

Tables 1, 2 resume the mean time spent by vehicles in four queues and the average vehicle sojourn time in all queues respectively. Obviously, MPract appears more refined although for phase$(170,173)$ FT-Offset implies smaller delays. Table 3 presents the total travel time between three entry-exit links.

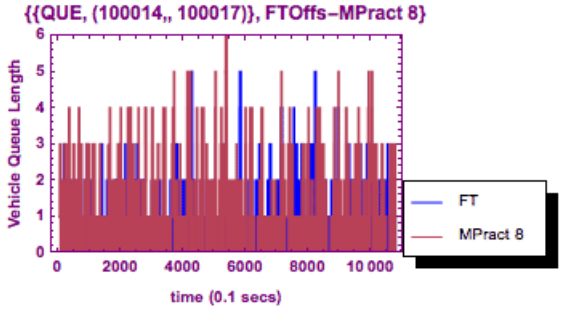

Figure 6. Evolution q(114,117), FT Offs-MPract 8.

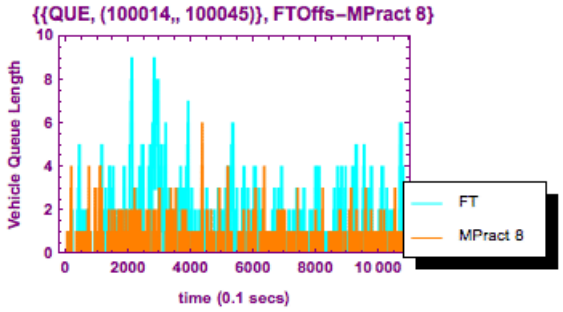

Figure 7. Evolution q(114,145), FT Offs-MPract 8.

6.4 Varying Traffic Conditions

The network stability is now examined under time-varying traffic intensity. During a given period, demand gradu-

Que ID		Mean Veh. Sojourn Time (secs)	Mean Veh. Sojourn Time (secs)
		MPract	FT Offs
164	1020	49.96	79.72
167	228	12.16	51.32
117	120	10.72	33.35
170	173	78.46	49.61

Table 2. Average Mean Time spent by vehicles in all queues.

AVERAGE MEAN VEH SOJOURN TIME IN QUEUES	MPract (secs)	FT Offs (secs)
	12.05	22.32

Table 3. Travel Time Entry-Exit Link.

Entry link	Exit link	Travel ttime (secs)	Travel time (secs)
		MP	FT Offs
127	145	204.4	230.8
164	173	364.7	462.2
138	1069	395.2	519.6

ally increases and potentially temporary congested conditions may result (representing peak hours or unpredicted demand variation). Thus, within period $[0, 36,000]$ external demand increases every two hours by a factor c_1 equal to $1.05, 1.15, 1.3, 1.5$. For the following two hours, that is from $t = 36000.1$ to $t = 43,200$ seconds, demand decreases every half an hour by a factor c_2 taking progressively values $1.3, 1.15, 1.05, 1$.

Figure 11 illustrates the evolution of all the network queues when the pre-timed actuation durations are employed. While demand remains inferior to $1.15d$ (d is the initial demand level), that is while time $t < 14,000$ secs the system remains stable. Congestion spreads during period $[14,400, 36,800]$ when the current demand intensity values $1.15d$, $1.3d$, $1.5d$. During this time a significant portion of the network links become congested, strongly increasing the number of vehicles in the network. Obviously, this Fixed-Time plan cannot accommodate the new demand intensity. The resulting FT behaviour is theoretically expected from the stability condition presented in §2. When the demand level decreases link saturation progressively diminishes (from $t = 36,000$ to $43,200$ seconds).

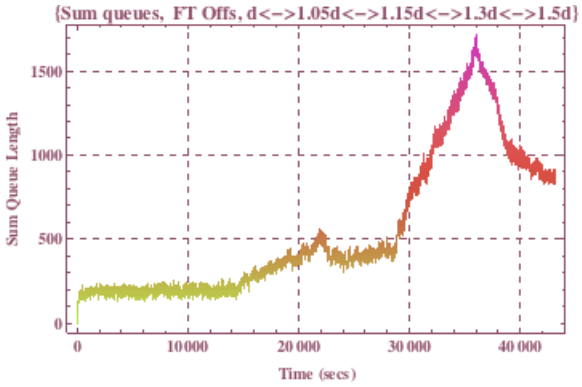

Figure 11. Evolution sum queues, varying demand level, FT Offset.

In contrast, the network behaviour differs when a MPract policy defines signal plans. Figure 12 depicts the sum of the network queues for the $c_i d$, $i = 1, 2$ demand intensities. Clearly, the feedback policy prohibits link saturation. The sum of all the network queues rises during period $[21,600, 36,000]$ when a 30% and 50% increase of the initial demand takes place but still the network remains stable.

Figures 13 and 14 plot the aggregate entry (blue

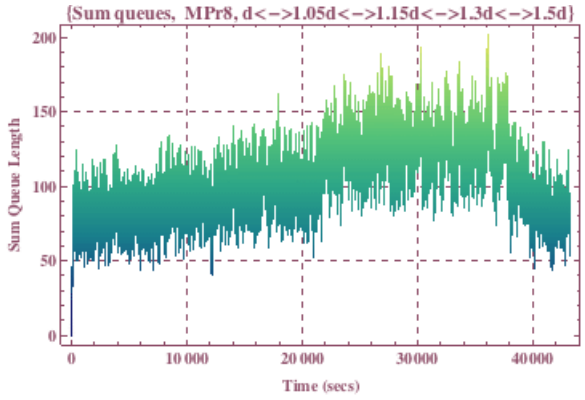

Figure 12. Evolution sum queues, varying demand intensity, MPract 8.

curve) end exit flows (red, purple curves) during period $[29,000, 31,000]$ for FT and MPract policies respectively. Since, the pre-timed control cannot accommodate $c_1 d$, demand for $c_1 = 1.3, 1.5$ the number of vehicles exiting the network drops below the external arrivals. This phenomenon disappears under MPract.

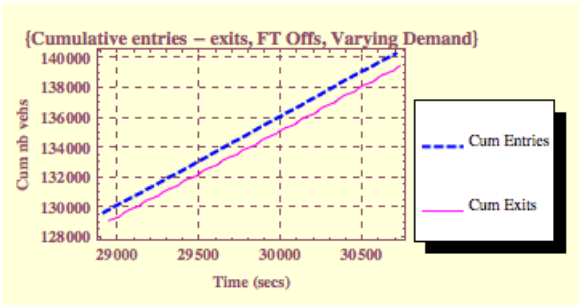

Figure 13. Aggregate entries-exits, varying demand, FT Offs.

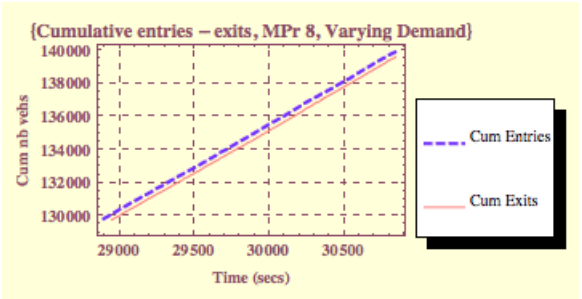

Figure 14. Aggregate entries-exits, varying demand, MPract 8.

7 PointQ versus AIMSUN Network Performance

As previously discussed, PointQ is a micro-meso decision tool, approaching a SF network queue model by a discrete event technique.

AIMSUN is a vehicle traffic software offering mesoscopic, microscopic and hybrid simulation approaches.

Aiming at a comparison of the two simulation tools, the section of Huntington-Colorado arterial is modelled in AIMSUN. Both approaches employ stochastic demand of intensity d (baseline demand), Pre-timed signal plan as governing control and consider the turn ratio values and link free flow speeds as provided by the data. Microscopic and Mesoscopic AIMSUN simulations are performed for a three hours duration. The state of intersection 101 (first node at the Huntington area) is investigated according to PointQ and AIMSUN implementations.

Five controlled movements exist at node 101 corresponding to queues $q(137,154)$, $q(153,154)$, $q(153,237)$, $q(254,237)$ and $q(254,253)$. We focus on the behavior of two representative movements. Phase $(137,154)$ brings vehicles into the network from the entry link 137 and head them towards the internal link 154 while phase $(254,237)$ moves vehicles from the internal link 254 towards the exit link 237.

7.1 Evolution of phase $(137,154)$

Figure 15 represents the evolution of queue $q(137,154)$ under a PointQ simulation. Figures 16 and 17 illustrate the queue behaviour when micro and meso AIMSUN simulations are performed.

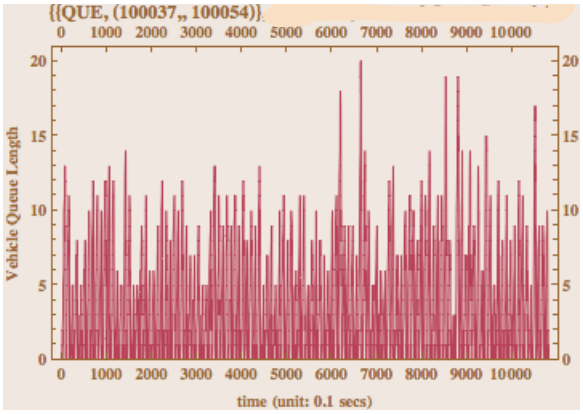

Figure 15. Evolution of q(137,154), PointQ.

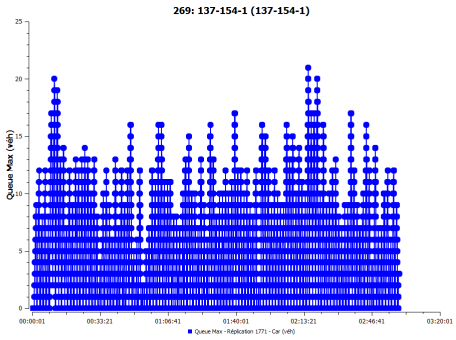

Figure 16. Evolution of q(137,154), AIMSUN Micro.

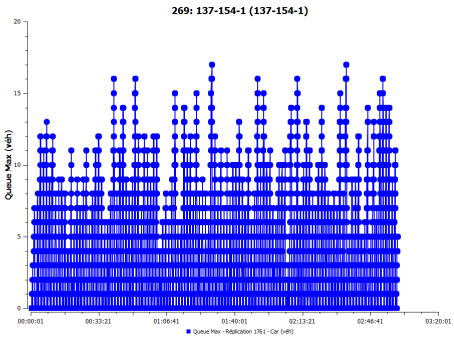

Figure 17. Evolution of q(137,154), AIMSUN Meso.

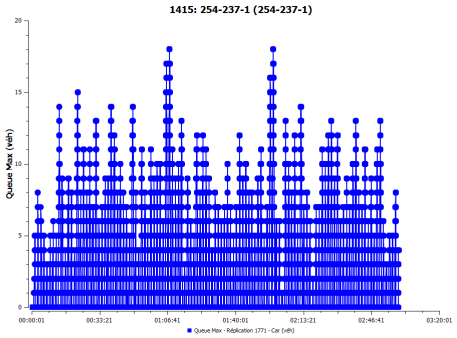

Figure 19. Evolution of q(254,237), AIMSUN Micro.

Although stochastic external demand and link travel times are considered, one observes that the three approaches, PointQ model and AIMSUN micro and meso versions provide close results. Queues resulting from the three simulation modes verify the theoretically resulting stability. Furthermore, queue lengths vary within similar bound values over time.

7.2 Evolution of phase $(254, 237)$

Figure 18 plots the behaviour of queue $q(254, 237)$ when PointQ while Figures 19 and 20 describe the resulting queue state under micro and meso AIMSUN approaches.

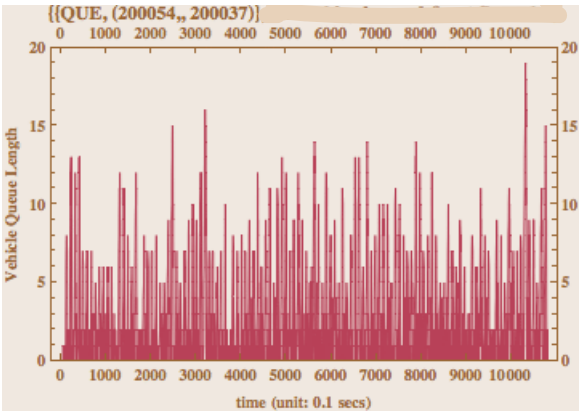

Figure 18. Evolution of q(254,237), PointQ.

As in the case of phase $(137, 154)$, queue $q(254, 237)$ shows the same behaviour for both PointQ and AIMSUN models and all modes (micro-meso, micro and meso).

An extended analysis of all the network queues implies that the resulting network state is similar under the two models.

8 Conclusions

Aiming at a further improvement of traffic, new signal schemes are designed, evaluated and potentially optimised before a real time application. The key contribution of this paper is to present the extended options of a microscopic-mesoscopic decision tool, called PointQ destined for an

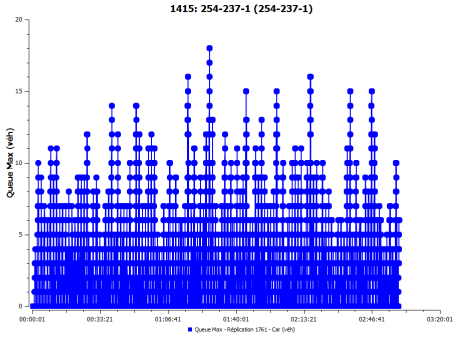

Figure 20. Evolution of q(254,237), AIMSUN Meso.

an ameliorated study of arterial traffic. PointQ relies on the principle of discrete events and models arterials as a Store and Forward queuing network. Thus, queues form state variables of the system. Minimal explicit input information is needed amongst which the saturation flow rates. These values are necessary to signal control development since most feedback algorithms follow queue-based approaches. Experiments are performed under real data for a section of Huntington-Colorado near Los Angeles. Two control policies are employed, Pre-timed and Max-Pressure Practical plans under fixed and time-varying demand intensity. The expected theoretical results concerning the network stability are verified and the network performance is quantified in terms of queue bounds, delay metrics and travel times. Finally, PointQ accuracy is observed in comparison with a simulation program providing both micro and meso simulation modes. Useful directions of future work worthing to be pursuing is the development of queue estimation algorithms, employed in feedback controllers (e.g. versions of MP algorithm) and actuated controls as well. Moreover, introducing additional modes of sensor behaviour the combination of which would improve precision in the computational results (actuated controls).

Abstract

Multifunction Vehicle Bus (MVB) is a critical component in the Train Communication Network (TCN), which represents a challenging problem for model checking. Although model checking is widely used in circuit and software verification, it is hardly for verification of the MVB or TCN, in terms of modelling of MVB components and making appropriate specification. The study described in this paper aims at evaluating and experimenting the industrial application of verification by model checking, and provides a complete system modelling and specification describing technique. The model of MVB consists of device model, communication model and specification model translated from LSCs, a scenario description. Experiments results with SPIN checking tool illustrate effectiveness of our approach.

Keywords: vehicular communication, protocol verification, model checking, specification

1 Introduction

Multifunction Vehicle Bus (MVB) in Train Communication Network (TCN) is widely used in most of the modern train control techniques of transportation software system. MVBs change roles of master or slaves under mastership transfer protocol in IEC standards (Kirrmann and Zuber, 2001). How to ensure security of an embedded vehicle control software system which implements the function and protocol has become an important issue.

The traditional method to verify MVB uses simulation technique (Jiménez et al., 2006) or test methods (Zhiwu et al., 2008). These approach need semi-finished MVB devices and programs, error-tolerance decode algorithm and samples of transmitted data among devices. However, simulation and test cannot provide completeness verifica-tion.

Model checking (Queille and Sifakis,1982; Clarke et al., 1999) is a method for automatically verifying finite state systems, using an exhaustive search of the state of a system model to determine whether a specification is satisfied or violated, which has been applied in circuit and software verification. Although model checking is widely used, it is hardly for verification of the MVB or TCN, in terms of modelling of MVB components and making appropriate specification. System modelling prefers fewer states, avoiding states space explosion, and specification making requires different properties synthesis with light weight manual work.

This paper presents a modelling approach for MVB based on finite state model checking and a specification generated method. The remainder of this paper is organized as follows. The following section gives background details of MVB, mastership transfer protocol and preliminaries model checking with temporal logic. Section 3 propose a modelling method for system component and communication with process and finite state automata. Section 4 show property generated and modelling method compound with previous system model. Experiment results in Section 5 demonstrate our methods and Section 6 make conclusion.

2 Background

In this section, we first introduce the MVB and the master transfer protocol. Then model checking with temporal logic is reviewed.

2.1 MVB and Master Transfer

2.1.1 Multifunction Vehicle Bus

The on-board train communication system has been widely used for modern railways. The MVB is a component of the TCN which is used in most of the modern train control systems. The TCN has been defined by the IEC(international Electrotechnical Commission); it is the Vehicle Bus specified to connect standard equipment. It provides both the interconnection of programmable equipment pieces amongst themselves and the connection of this equipment with its sensors and actors. It can also be used as a Train Bus in trains which are not separated during normal operation.

The MVB defines two types of devices: Master and Slave. Each Vehicle Bus and Train Bus has one Master node and several Slave ones. The Master sends information, the *Master_Frame*, to a number of Slave devices. The Slave receives information from the Bus and sends information, the *Slave_Frame*, in response to the Master. A Master_Frame and the corresponding Slave_Frame form a telegram. All devices decode the Master_Frame. The addressed source device then replies with its Slave_Frame, which may be received by several other devices.

2.1.2 Mastership Transfer

Since a single Master presents a single point of failure, mastership may be assumed by several Bus Administrators(BAs), one at a time. To increase availability, mastership can be shared by two or more BAs, which both take charge of mastership for the duration of a turn. Mastership is transferred from BusAdmin to BusAdmin within a few milliseconds in case of failure. To exercise redundancy, mastership is transferred every few seconds by a token frame. Consequently, all BAs are organized in a logical ring. A token passing mechanism ensures that only one BusAdmin become Master.

In the IEC 61375-1 international standard, Mastership Transfer describes the protocol which selects a Master form one of several BAs and ensures Mastership Transfer at the end of a turn or upon the occurrence of a failure. A token passing algorithm is defined in the IEC standard to ensure a round-robin access of all BAs to the Bus:

1. after the loss of the Master, staggering of the timeouts ensures that only one of the BAs become Master;
2. a Master exercise mastership for the duration of one turn;
3. after its turn, the Master looks for the next BusAdmin and reads its Device Status, which indicates if this device is a configured BusAdmin;
4. a Master may only pass mastership to a configured and actualized BusAdmin;
5. if the device is not a configured and actualized BusAdmin, the Master looks for the next BusAdmin after the next turn;
6. if the device is a configured and actualized BA, the Master offers mastership to it by sending a Mastership Transfer Request;
7. if the device accepts mastership in its Mastership Transfer Response, or if no answer comes, the Master retires to become a standby Master and monitors the Bus traffic for mastership offer or Bus silence;
8. if the other device rejects mastership, the current Master retains mastership for one more turn, after which the Master tries the next device in its BAs list;
9. a standby BusAdmin becomes Master if it accepts a Mastership Transfer Request or if it detects no Bus activity during a time greater than a defined timeout;

2.2 Model Checking with temporal logic

For model checking system against some specification, we need both system model structure and description of property. Communicating Finite State Machines (CFSMs) are natural models for systems of concurrently running process, especially asynchronous reactive system. The concurrency of process is captured at the semantics level of CFSMs by the interleaving of processes executions. Process exchange messages between each other asynchronously over a set of message channels, which are interpreted at the semantic level as unbounded FIFO message queues. A sender process continues its local execution after sending a message to a channel, and a receiver process is blocked when it tries to receive a message that is not available in the respective channel.

Definition 1 *(Communicating Finite State Machines). A system of communicating finite state machines (CFSM) is a tuple* $\mathscr{S} = (P,V,M,C,succ)$*, where*

- *P is a finite set of* process*. Each process* p_i *is a pair* (S_i, s_0^i) *where* S_i *is a finite set of states of* p_i *and* $s_0^i \in S_i$ *is the initial state. For any two different process* p_i *and* p_j*, we put the restriction that* $S_i \cup S_j =$*, i.e., their sets of states are disjoint.*
- *V is a finite set of* variable*, may be global or local in process.*
- *M is a finite set of* message symbols*.*
- *C is finite of* messages channels*. Each channel is associated with a subset of message symbols* $M' \subset M$ *such that only the messages in* M' *can be exchanged in the buffer. Moreover, for each channel* $c \in C$ *and each message symbol m in the subset of M associated with c, we call* (c,m) *a message type.*
- *succ is a finite set of* local transitions (s,e,s') *where s and* s' *are states of some same process* p_i*, and e is* (g,u)*: g is* guard condition *consist of both boolean formula with or without a message passing event in the form b*!*m or b*?*m such that (1)*$c \in C$ *and (2)*$m \in M$ *can be exchanged in the buffer c; u is updates of variables as* $v' = u(v)$*.*

The semantics of CFSMs is defined using the concepts of configurations and reachability.

Definition 2 *(Configuration). Given a CFSM system* $\mathscr{S} = (P,V,M,C,succ)$*, a* configuration*(or* global state*) of the system is a tuple* $(s^1,...,s^{|P|},v,q^1,...,q^{|C|})$ *such that*

- *each* s^i *is a state of the process* p_i*, and*
- *each* q^i *is a queue of messages exchangeable in the channel* c_i*, and*
- *v is a valuation of all variables.*

Consider two configuration s_1 *and* s_2*, let* $s_1 = (s_1^1,...,s_1^{|P|}, v_1, q_1^1,...,q_1^{|C|})$ *and* $s_2 = (s_2^1,...,s_2^{|P|}, v_2, q_2^1,...,q_2^{|C|})$*. We define that* s_2 *is a successor of* s_1*, denoted by* $s_1 \Rightarrow s_2$*, if the following is satisfied:*

- *There exists a process $p_i \in P$ such that (1) for all $j \neq i$ we have that $s_1^j = s_2^j$; and (2)$(s_1^i, e, s_2^i) \in succ$.*
- $(v_2, q_2^1, ..., q_2^{|C|}) = post_e(v_1, q_1^1, ..., q_1^{|C|})$, *where $post_e$ update the valuation of variables from v_1 to v_2 and change message queues contents of respective channels.*

After modelling system, we should describe specification under which the model to be verified. Temporal logic, such as Linear Temporal Logic, which extends proposition logic with temporal operator, is a good choice of description of system properties.

Definition 3 *(Linear Temperoal Logic). Linear Temporal Logic(LTL) has the following syntax given in Backus Naur form:*

$$\phi ::= \bot \mid \top \mid p \mid (p) \mid \neg\phi \mid \phi \wedge \psi \mid \phi \vee \psi \mid \phi \rightarrow \psi \mid X\phi \mid F\phi \mid G\phi \mid \phi U \psi \mid \phi W \psi \mid \phi R \psi \quad (1)$$

where p is any proposition atom from sone set of atoms. Temporal operator X means next state, F means some future state, and G means all states. The next three, U, W and R, are called Until, Release, *and* Weak-until, *respectively.*

According to the requirement specified in the standard, suppose that there are n BAs altogether, the Mastership Transfer must satisfy the following properties:

1. there cannot be more than one Master at one time; it is written in the LTL as shown in

$$G\neg(BA\_Master_i \wedge BA\_Master_j), i, j = 1, ..., n, i \neq j$$

2. there cannot be no Master at one time; it is written in the LTL as shown in

$$G\neg(\bigwedge_{i=1}^{n} BA\_Standby_i).$$

3 System Modelling

MVBs under Mastership Transfer protocol has two main component to be modelled. In this section, we present our modelling approach for both BusAdmins and the communication mechanism amongst BAs.

3.1 Bus Administrator Modelling

3.1.1 basic data structure

First we define the data structure of Bus Administrator and message frame exchanged amongst different BAs. Bus Administrator data structure defines local variables used for BA itself, including different timers, flag, address, etc. Most important fields of BA structure are *send* and *recv* buffer channel for communicating. These channel contains buffer blocks, each of that consists of both message frame and channel pointer for convenience.

Listing 1. Bus Admin structure

```
typedef BA_DEF
{
   byte T_standby; /*t_standby Timer*/
   byte Turn;  /*turn Timer*/
   bit T_find_next; /*t_find_next Timer*/
   bit T_interim; /*t_interim Timer*/
   bit ACT;    /*BA actualized state flag*/
   byte rank;  /*BA sequence number in BA-
       list*/
   byte adr;   /*BA address in memory*/
   chan send = [10] of {FRAME, chan};
      /*BA sender buffer channel*/
   chan recv = [10] of {FRAME, chan};
      /*BA receiver buffer channel*/
}
```

Listing 2. enumeration of BA state

```
mtype =
{ ba_STANDBY_MASTER,
  ba_REGULAR_MASTER,
  ba_END_OF_TURN,
  ba_FIND_NEXT,
  ba_INTERIM_MASTER}
```

Enumeration of BA state consists of all major distinguished states of BA under Mastership Transfer protocol.

Listing 3. message frame structure

```
typedef FRAME
{
   mtype type; /*Frame type*/
   bit  data; /*Frame data*/
   byte from; /*Source BA ID of frame*/
   byte to; /*Target BA ID of frame*/
}
```

Message frame structure defines type, data, and source and target BA ID of messages frames.

Listing 4. enumeration of message frame type

```
mtype =
{ MASTERSHIP_OFFERED,
  MASTERSHIP_RESPONSE,
  STATUS_REQUEST,
  STATUS_RESPONSE,
  REGULAR}
```

Enumeration of message type consists of all major distinguished states of BA under Mastership Transfer protocol.

3.1.2 finite state machine of Bus Administrator

As defined by CFSM in previous section, our model consists of several concurrency running processes, each of that is an instance of process type BA_FSM, which is identified by argument ID. Each process represent an executing Bus Administrator with a member index by same ID in a BA_DEF structure array.

BA_FSM constructs a finite state machine of Bus Administrator. In each state, BA exercise respective operations, receive or sends message frames and transit to other state on conditions.

Listing 5. BA_FSM process structure

```
proctype BA_FSM(byte ID)
{
    STANDBY_MASTER: /*standby state*/
    ...
    /*acts no master operation: if it
        accepts a Mastership Transfer
        Request or if it detect no Bus
        activity during a time greater than
        t_standby, goto REGULAR_MASTER*/
    REGULAR_MASTER: /*master exercise state
        */
    ...
    /*acts master operation: if it detects
        master conflict, goto STANDBY_MASTER
        ; or if it ends its current turn,
        goto END_OF_TURN*/
    END_OF_TURN: /*end of master turn*/
    ...
    /*looks for next BA in BA-list and send
        Status Request; if BA-list exhausts,
         goto REGULAR_MASTER*/
    FIND_NEXT:  /*find next BA to be master
        */
    ...
    /*gets the Status Response: if the BA is
         configured and actualized, then
        offers mastership to it by sending
        Mastership Transfer Request and goto
         INTERIM_MASTER; else if the BA is
        not actualized or time-out without
        response, goto END_OF_TURN*/
    INTERIM_MASTER: /*interim master state*/
    ...
    /*gets the Mastership Transfer Response
        and goto STANDBY_MASTER. Meanwhile,
        if the response is non-acceptance or
         time-out without response, report
        error*/
}
```

3.2 Communication and Timing Modelling

3.2.1 communication mechanism of BusAdmin

Instead of modelling real Bus component, which may introduce more complex concurrency process, we realize communication between BusAdmins by channels. In initial model setting, each BA has sender and receiver channels both with buffer capacity of 10.

asynchronous communication with buffers By positive capacity buffered channel, BAs communicates with each other asynchronously. These messages receiving and sending actions are similar to pulling and posting mails through intermediary.

- when BA receives(pull) message from *recv* channel, it execute

```
BA[ID].recv ? (temp_frame, BA[ID].
    send)
```

  to get message frame into temporal frame to be parsed; meanwhile, get sender's receive channel pointer as send channel of itself, prepared to be used in following sending actions.

- when BA send(post) message to *send* channel, it execute

```
BA[ID].send ! (temp_frame, BA[ID].
    recv)
```

  to put temporal frame into previous channel pointer(another BA's recv channel); meanwhile, send it's recv channel as channel pointer to be received by the target receiver.

In above communication realization, we make channel as part of communication content, reduce amount of channels used in whole model and alleviate state explorations of states caused by channel numbers.

non-blocking communication When channel is empty or full, respectively, receiving or sending processes block at previous execution statement. Obviously, it is inflexible for modelling more complex system execution situation. So we realized non-blocking communication use *full*, *nfull* and *atomic* primitives.

When sender tries to send, it first confirm whether send channel is full or not, and exclusively satisfies either $full$ or $nfull$ guard condition. If send channel is full, sender process skips sending and execute next statement. If not, sender sends message successfully.

```
do
::full(BA[ID].send)->skip;
::nfull(BA[ID].send)->
   BA[ID].send!(temp_frame,BA[ID].recv);
od;
```

Situation is slightly different for receiver process. We encapsulate receiving execution as atomic segment and provides *else* clause besides. When receiver cannot receive message frame from recv channel as the channel is empty, it will chose *else* bypath and will not be blocked.

```
do
::atomic
   {BA[ID].recv?(temp_frame,BA[ID].send)->
      ...
   }
::else->...
od;
```

3.2.2 timing mechanism

In Mastership Transfer protocol, there are many local timer in each process, such as $T\_standby$, $Turn$, etc. As CFSMs semantics is asynchronous models, different timer in process need to be synchronised.

Many modelling language has synchronous channels, which is different from asynchronous channels, the former can be treated as zero-capacity channel that requires sender and receiver must communicated at the same instant.

Based on the synchronous channel structure, we can make timer in different process has same steps. We model another timing manager process to coordinate different timers. Timer is not updated in each process, but be sent to timing manager by each process before updates through synchronous communication. Then timing manage updates all timer counts in atomic segment and synchronously sends timer back to each process. By timing manager, we realize timers in different process to step by same rate.

4 Property Modelling

After we get system model, we need make specification to be verified. In this section, we first introduce properties classification about our model, then for handling troubles of complex property description and gaining benefits of synthesis, we introduce live sequence chart and combine it with previous system model.

4.1 Property Classification

4.1.1 safety property

A safety property states that some bad thing never happens, representing requirements that should be continuously maintained by the system. To our models, we have following safety property to be verified:

- BusAdmin 0 (BA[0]) and BusAdmin 1 (BA[1]) cannot be masters at same time:

$$G\ mutex \tag{2}$$

where

```
#define mutex
(!(ba0_cur==ba_REGULAR_MASTER &&
    ba1_cur==ba_REGULAR_MASTER))
```

- Once BA[0] becomes master, then system must has a master forever:

$$G(\ ba0\_master \rightarrow G\ !nonemaster)) \tag{3}$$

where

```
#define ba0_master
(ba0_cur==ba_REGULAR_MASTER)
#define nonemaster
(ba0_cur==ba_STANDBY_MASTER &&
 ba1_cur==ba_STANDBY_MASTER &&
 ba2_cur==ba_STANDBY_MASTER)
```

4.1.2 liveness property

A liveness property states that some good thing eventually happens, representing requirements whose eventual realization must be ensured. To our models, we have following liveness property to be verified:

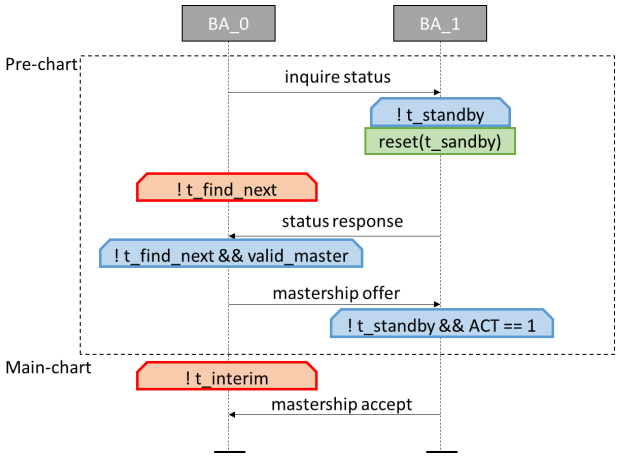

Figure 1. An example of LSC specification: *BA*_0 transfer mas-tership to *BA*_1.

- It is required that BA[0], BA[1] and BA[2] all can infinitely often be the master.

$$GF\ ba0\_master\ \&\&\ GF\ ba1\_master \\ \&\&\ GF\ ba2\_master \tag{4}$$

where $ba1\_master$ and $ba2\_master$ is defined similar as $ba0\_master$.

- After BA[0] becomes the master, it can eventually relieve mastership.

$$G\ (ba0\_master \rightarrow F\ ba0\_standby) \tag{5}$$

where $ba0\_standby$ is defined similar as $ba0\_master$.

4.2 Live sequence charts

Live Sequence Chart (LSC) (Kugler and Segall, 2009; Li et al., 2010) use instance lines, expressions, messages, conditions and updates to describe scenario of interactions among sequence processes. We can iteratively refine spec-ification described by LSCs, that is introduced in initial system design stage and reused for the whole software de-veloping procedures.

Example 1 *In Figure.1, an Live Sequence Chart describes a fragment procedure of mastership transfer from BA_0 to BA_1, which starts from BA_0 send inquire status mes-sage and ends with BA_1 sends mastership accept mes-sage. Red hexagon represents hot condition, which can-not be violated. Blue hexagon represents cool condition, which once be violated, then go back to top and make a new execution.*

Given formal syntax and sematic of LSCs, we can combine normal specification described by LSC with existing formal logics and model checking to verify the properties provided by developer and stakeholder.

Main process of LSC described scenario-based system properties formal description and model checking is that,

1. Use normal LSC to describe process instance interaction scenario in system model, identify the Pre-chart and Main-chart.

2. Translate LSC to Observer Automata *ObsA*. *ObsA* monitors these messages communication, conditions satisfaction and updates consistency proposed by LSC.

3. Combine *ObsA* with original system model $\mathscr{S}$, without introducing side effects in original system operation.

4. Formally, check property

$$G\ (ObsA.l_{min} \rightarrow F\ ObsA.l_{max})$$

where $ObsA.l_{min}$ identifies top of Main-chart, $ObsA.l_{max}$ identities bottom of Main-chart. This property represents that each time the system enters the main chart of LSC, it will eventually reach the bottom of the main chart. Then LSC scenario property is reduced to a classical real-time model checking problem.

4.3 Observer Automata modelling

To translate LSC to observer automata, we need partition LSC into locations, simregions, and cuts firstly. Then a run of observer automata is a successive transitions among states space consisting of cuts and variables valuations.

One requirement for observer automata is that it can monitor concerned information of interactions and configurations in LSC, such as messages. In addition, observer automata need also capture other information such as timers. Meanwhile, observer cannot bring side effects that disturb normal executions of original system model.

We use copy acceptance communication, which pulls a copy message from channel and has no effect on channel information and structure, like

```
BA[ID].recv ? <temp_frame, temp_chan>
```

where syntactic sugar <> means copy message from *recv* to *temp_fram* and *temp_chan*. As mentioned before, timers implement is similar to messages communication, so it is also monitored by observer automata as reference copy.

We define boolean (bit) variables *obsAlmin* and *obsAlmax* as flag denotation for $ObsA.l_{min}$ and $ObsA.l_{max}$ respectively, with initial value of $false(0)$. Based on the above, a monitor process which realizes observer automata *ObsA* and a LSC specification can be both added to our model checking of MVB protocol.

5 Experiments

We implement our approach by explicit states model checking tool SPIN (Holzmann,1997). Its modelling language Promela has all the model elements we proposed previously. To check LSC specification, we implement a tools translate graphic LSC to modelling codes. We run our model checking on 32-bit Window7 platform with 2GB RAM memory limitation. To exhibit the use of our modelling and property setting works

We show the experiments results of MVB protocol model checking against 5 property presented previously in this paper in Table.1.

- First two lines indicates results of first two safety property checking. As safety property is violated by finite prefix of execution, the search depth is equivalent to counterexample depth.

- Lines 3, 4 indicate results of two liveness property checking. Different from above safety property, a counterexample trace that violates liveness property is a infinite suffix of executions, which consists of a lasso structure. Model checking algorithm for search of such lasso is a double-DFS algorithm using stack and has tables. Consequently, these counterexamples depth are less than checking depth reached.

- Last line is result of checking translated LSC property. Obviously, checking a property described by LSC and translated into observer automata is much harder than simple safety and liveness property. It is resulted both from LSC's rich expression and observer automata complex monitoring functions. In this experiment, we can not find counterexample before memory exhausts. Conservatively speaking, the specification described by LSC is satisfied by MVB protocol.

6 Conclusions

Model checking of Multiple Vehicle Bus under mastership transfer protocol shows an industrial verification case study, which combines both device model, communication model and specification model in a unified modelling framework. One benefit of our approach is that, we model Bus administrator as modules, and use channels efficiently. It is an immense improvement on modelling technique compared to (Xia et al., 2013). Another benefit is that we introduce LSCs to make specification of more complex process interaction scenarios. Moreover, with help of translating LSC into observer automata and verifying automata location based liveness property, we can confirm whether LSCs specification is satisfied or not.

We think we have two aspects for future work. One is further improvement of our modelling works and translation from specification to automata. Because the size of models directly affect checking efficiency, we expect smaller models and make possible abstraction. The other extending maybe introduce synthesis technique, which starts from specifications, and seek possible system models that satisfies all the inferred properties.

Table 1. Experiments results of MVB protocol.

Property ID	Transitions	Atomic steps	Memory usage (MB)	Depth reached	Counterexample depth

A Model of a Marine Two-Stroke Diesel Engine with EGR for Low Load Simulation

Xavier Llamas Lars Eriksson

Vehicular Systems, Dept. of Electrical Engineering, Linköping University, Sweden
{xavier.llamas.comellas,lars.eriksson}@liu.se

Abstract

A mean value engine model of a two-stroke marine diesel engine with EGR that is capable of simulating during low load operation is developed. In order to be able to perform low load simulations, a compressor model capable of low speed extrapolation is also investigated and parameterized for two different compressors. Moreover, a parameterization procedure to get good parameters for both stationary and dynamic simulations is described and applied. The model is validated for two engine layouts of the same test engine but with different turbocharger units. The simulation results show a good agreement with the different measured signals, including the oxygen content in the scavenging manifold.

Keywords: modeling, parameterization, simulations, exhaust gas recirculation, combustion engines

1 Introduction

The marine shipping industry is facing increased demands in the reduction of harmful exhaust gas emissions. Stricter emission limits of Sulphur Oxides (SOx) and Nitrogen Oxides (NOx) are imposed in certain Emission Control Areas (ECAs). The emission values to fulfill in these ECAs are set by the IMO Tier III limits (International Maritime Organization, 2013) that came into play in January 2016. One of the available technical solutions to achieve the targeted reduction in NOx emissions is Exhaust Gas Recirculation (EGR). An EGR system recirculates a fraction of the exhaust gas into the scavenging manifold, providing burned gases in the combustion chamber that directly decreases the production of NOx during the combustion.

EGR technologies for two-stroke engines are still at the initial phases of its development. In addition, there are not many available vessels with an EGR system installed and thus performing tests is often difficult. Furthermore, testing any new system in marine two-stroke engines is also very costly mainly due to the fuel cost associated with the sizes of such engines. Hence, in order to improve the performance of the EGR control systems, a fast and accurate simulation model is a very valuable tool.

Mean Value Engine Models (MVEMs), are a very common approach for control oriented modeling of internal combustion engines. In particular, EGR systems have been also modeled using this approach. Many interesting research articles about EGR modeling in automotive applications can be found in the literature, some examples are, (Wahlström and Eriksson, 2011; Nieuwstadt et al., 2000). On the other hand, marine two-stroke engines have not been widely studied. Nevertheless, some research papers focused on MVEMs for two-stroke engines are (Blanke and Anderson, 1985; Theotokatos, 2010; Hansen et al., 2013). In addition, in (Guan et al., 2014) the modeling of the low load operation of a two-stroke engine without EGR is studied.

The work presented here is an extension of the model proposed in (Alegret et al., 2015), which enables the model to simulate low engine loads. The low load operation is very relevant for the EGR control since the Tier III emission limits have to be fulfilled near certain coasts, e.g. harbors, where the vessel is normally operating at low loads. The main new component that needs to be introduced for this low load simulation is the auxiliary electrical blower. Its mission is to ensure that there is enough scavenging pressure at low loads when the turbocharger is not capable to provide it. Moreover, the turbocharger model will be required to simulate at low speeds and pressure ratios. This area is normally not measured in the provided performance maps, so a model that can extrapolate to this area is also required.

The developed model is, as in (Alegret et al., 2015), based on the 4T50ME-X test engine from MAN Diesel & Turbo. It is a two-stroke uniflow diesel engine, turbocharged, with variable valve timing and direct injection. Its maximum rated power is $7080\,kW$ at $123\,rpm$. Also, it is equipped with an EGR system and a Cylinder Bypass Valve (CBV).

2 Experimental data

The targeted test engine is constantly being rebuilt to test new components and new control strategies. This implies that it is difficult to find measurement data from the same engine configuration. Most of the measurement data available is from the same layout as the data used in (Alegret et al., 2015). For layout number 1 the oxygen sensors were not properly calibrated and thus cannot be used for validating the oxygen levels at the manifolds. For the model parameterization 30 different stationary points are extracted from the measurement data and another 24 sta-

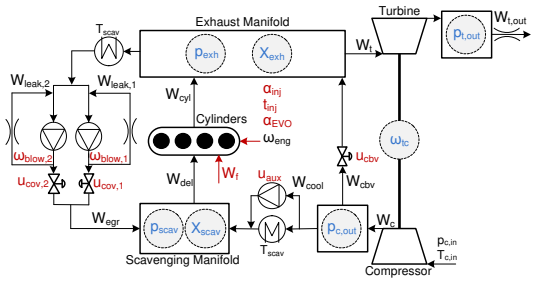

Figure 1. Engine model diagram with states (blue) and control inputs (red).

tionary points are saved for the validation.

Some more data is available from another layout of the engine and will be used for validation of the oxygen level in the scavenging manifold. However, in this layout, number 2, the turbocharger was changed and some sensors where removed. Moreover, there is much less data available, and only 18 stationary points could be extracted for the parameterization and the validation of the model.

3 Modeling

The complete MVEM model consists of thirteen states and nine control inputs. Figure 1 depicts a model diagram. The states are compressor outlet pressure, $p_{c,out}$, scavenging manifold pressure, p_{scav}, exhaust manifold pressure, p_{exh}, turbine outlet pressure, $p_{t,out}$ and turbocharger speed, ω_{tc}. The chemical species mass fractions are states in the scavenging and the exhaust manifolds, X_{scav} and X_{exh}. The species included in the model are oxygen, carbon dioxide, water and sulfur dioxide, $X = [X_{O_2}, X_{CO_2}, X_{H_2O}, X_{SO_2}]$. The dynamic equations are the same for each species so (6) and (7) correspond to eight single ODEs. The dynamic behavior of the modeled states is governed by the following differential equations

$$\frac{d}{dt}\omega_{tc} = \frac{P_t - P_c}{J_t\ \omega_{tc}} \tag{1}$$

$$\frac{d}{dt}p_{c,out} = \frac{R_a\, T_{c,out}}{V_{c,out}}\left(W_c - W_{cool} - W_{cbv}\right) \tag{2}$$

$$\frac{d}{dt}p_{scav} = \frac{R_a T_{scav}}{V_{scav}}\left(W_{cool} + W_{egr} - W_{del}\right) \tag{3}$$

$$\frac{d}{dt}p_{exh} = \frac{R_e\, T_{exh}}{V_{exh}}\left(W_{cyl} - W_{egr} - W_t + W_{cbv}\right) \tag{4}$$

$$\frac{d}{dt}p_{t,out} = \frac{R_e\, T_{t,out}}{V_{t,out}}\left(W_t - W_{t,out}\right) \tag{5}$$

$$\frac{d}{dt}X_{scav} = \frac{R_a T_{scav}}{p_{scav} V_{scav}}\left(X_{exh} - X_{scav}\right) W_{egr} + \frac{R_a T_{scav}}{p_{scav} V_{scav}}\left(X_{amb} - X_{scav}\right) W_{cool} \tag{6}$$

$$\frac{d}{dt}X_{exh} = \frac{R_e T_{exh}}{p_{exh} V_{exh}}\left(X_{cyl} - X_{exh}\right) W_{cyl} \tag{7}$$

The control inputs are EGR blower speeds, $\omega_{blow,1}$ $\omega_{blow,2}$, blower cut-out valves (COV) position, $u_{cov,1}$ $u_{cov,2}$, fuel mass flow, W_f, fuel injection angle α_{inj}, fuel injection time, t_{inj}, exhaust valve closing angle, α_{EVC}, CBV position, u_{cbv}, and auxiliary blower operation u_{aux}. Engine speed, ω_{eng}, and compressor inlet pressure and temperature, $p_{c,in}$ $T_{c,in}$, are considered known inputs to the model.

It is simple to reduce the model to seven states if we are only interested in tracking the oxygen level in the manifolds. Then in (6) and (7), the mass fraction only refers to oxygen, e.g. $X = X_{O_2}$. The model is built using different submodels interconnected. The submodels are mainly control volumes, e.g. scavenging manifold, and flow elements e.g. cylinder bypass valve, compressor, turbine, etc. Since the model is an extension of the one described in (Alegret et al., 2015), only the new or modified submodels are presented here.

3.1 Compressor

In order to properly simulate low loads, a compressor model capable of predicting mass flow and efficiency at low speeds is required. The chosen compressor mass flow model is the one developed in (Leufvén and Eriksson, 2014), which is capable of this extrapolation. In addition, the proposed model is capable of predicting mass flows down to pressure ratios below one and to zero compressor speed. The area where the compressor normally operates during low load is below the slowest measured speed line, which is depicted in Figures 2 and 3.

In the model, each compressor speed line is described by a super ellipse, which mathematically is written as

$$\left(\frac{\bar{W}_c - \bar{W}_{ZS}}{\bar{W}_{Ch} - \bar{W}_{ZS}}\right)^{CUR} + \left(\frac{\Pi_c - \Pi_{Ch}}{\Pi_{ZS} - \Pi_{Ch}}\right)^{CUR} = 1 \tag{8}$$

where $\bar{W}_{ZS}$, $\bar{W}_{Ch}$, Π_{ZS}, Π_{Ch} and CUR are functions of compressor speed. More details about these functions and the model in general can be found in (Leufvén and Eriksson, 2014). Since (8) is invertible, it can be used to predict either pressure ratio given compressor speed and mass flow or mass flow given compressor speed and pressure ratio. The latter case is used in the proposed engine model.

The compressor efficiency is modeled using the ideas from (Martin et al., 2009) for the isentropic efficiency definition. The key for the model is to use the Euler's equation (Dixon and Hall, 2013) applied to the compressor velocity triangles. Using the simplifications from (Martin et al., 2009), the conclusion is that the actual enthalpy rise for a fixed compressor speed can be modeled as a linear function of the mass flow. This simplifies the number of parameters required and since it is based in the physical equations, makes the extrapolation to the low load area more reliable. The proposed compressor model requires 15 parameters for the mass flow submodel and 4 parameters for the efficiency submodel.

The mass flow model together with the efficiency model fitted to the two compressors used in this study is depicted in Figures 2 and 3. The absolute value of the relative errors for both compressors are shown in Table 1.

3.2 Turbine

The Turbine mass flow model is very similar to the one used in (Alegret et al., 2015). However, a modification in the model is required to describe the turbine speed depen-

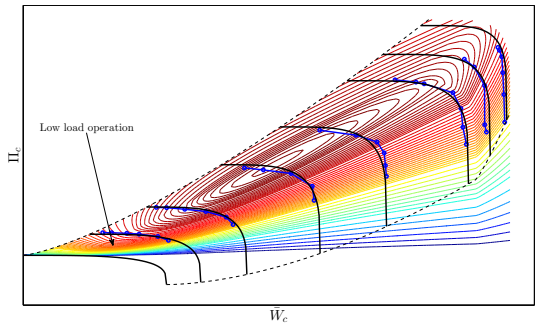

Figure 2. Compressor 1 model, in black, plotted together with the measured map points, in blue dots. The first speed line in the lower left corner represents the stand still characteristics of the compressor. The thinner level lines represent the modeled efficiency extrapolation down to unity pressure ratio.

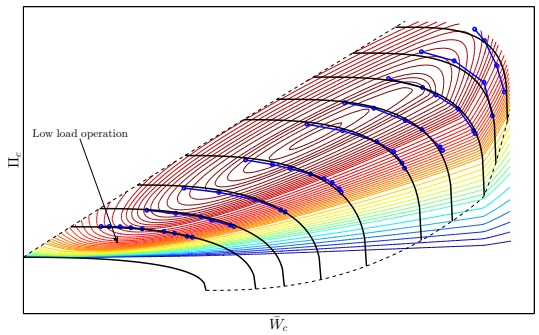

Figure 3. Compressor 2 model, in black, plotted together with the measured map points, in blue dots. The first speed line in the lower left corner represents the stand still characteristics of the compressor. The thinner level lines represent the modeled efficiency extrapolation down to unity pressure ratio.

dence observed for Turbine 2. The mass flow is described by the following function from (Eriksson and Nielsen, 2014)

$$\bar{W}_t = C_t \sqrt{1-(\Pi_t+\Pi_0)^{k_t}} \tag{9}$$

where k_t, Π_0 and C_t are constant parameters to be estimated for Turbine 1. For Turbine 2, k_t and C_t are also constants but Π_0 is modeled using a quadratic polynomial of corrected turbine speed to capture the different speed lines observed in Figure 5. The quadratic polynomial is defined as

$$\Pi_0 = c_{\Pi_0,1}\bar{N}_t^2 + c_{\Pi_0,2}\bar{N}_t + c_{\Pi_0,3} \tag{10}$$

where $c_{\Pi_0,1}$, $c_{\Pi_0,2}$ and $c_{\Pi_0,3}$ are model parameters. The two models fitted to the two turbines are shown on the left side of Figures 4 and 5.

Table 1. Absolute value of the relative errors (%) for both compressors and turbines. Mean indicates the mean value of all errors while Max. is the maximum error computed.

	Compressor 1		**Compressor 2**		**Turbine 1**		**Turbine 2**	
	Mean	Max.	Mean	Max.	Mean	Max.	Mean	Max.
$\bar{W}$	0.86	2.21	0.59	1.87	0.14	0.51	0.56	5.61
η	1.47	4.51	0.74	2.87	0.60	3.32	0.69	6.11

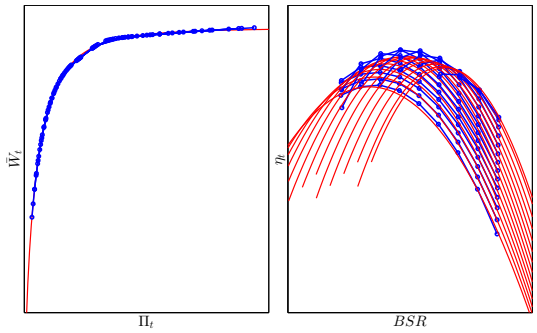

Figure 4. Left: turbine 1 mass flow model, in red, plotted together with the measured map points, in blue dots. Right: turbine 1 efficiency model, in red, plotted with the measured efficiency points, in blue dots.

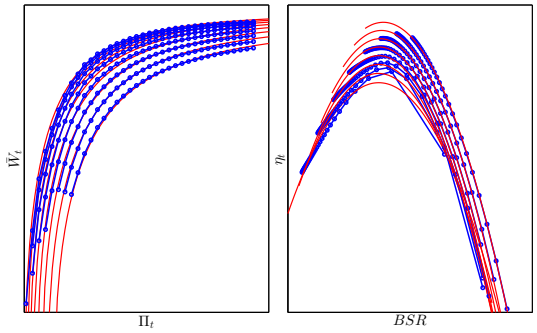

Figure 5. Left: turbine 2 mass flow model, in red, plotted together with the measured map points, in blue dots. Right: turbine 2 efficiency model, in red, plotted with the measured efficiency points, in blue dots.

The turbine efficiency is modeled using the Blade Speed Ratio (BSR), as in (Wahlström and Eriksson, 2011; Alegret et al., 2015). The relation between turbine efficiency and BSR is defined as

$$\eta_t = c_1 BSR^2 + c_2 BSR + c_3 \tag{11}$$

where c_1, c_2 and c_3 are also quadratic functions of turbine corrected speed, and each polynomial is defined as follows

$$c_X = c_{X,1}\bar{N}_t^2 + c_{X,2}\bar{N}_t + c_{X,3} \tag{12}$$

In total the turbine efficiency consists of nine parameters. The modeled and the measured efficiencies for both turbines are depicted in Figures 4 and 5. Furthermore, for both turbines, the absolute value of the relative errors are presented in Table 1.

3.3 EGR Blowers

The EGR blowers are modeled as in (Alegret et al., 2015). The only difference is that there are two equal blowers in parallel. The EGR flow is controlled with the blower speed control inputs, $\omega_{blow,1}$ and $\omega_{blow,2}$, and the cut-out valves are used to open or close the EGR flow. Depending on the engine running mode, there can be only one blower operating or both of them if more EGR flow is required.

3.4 Auxiliary Blower

The pressure increase of an electric blower is often modeled as a quadratic function of the volumetric flow (Guan et al., 2014). Since the blower's pressure increase is available from the system states, the quadratic function is inverted to obtain the volumetric flow. Using the pressure and temperature at the inlet the mass flow provided by the blower is obtained

$$W_{Aux} = \frac{p_{c,out}\left(c_{Aux,1} + c_{Aux,2}\sqrt{c_{Aux,2} - (p_{scav} - p_{c,out})}\right)}{R_a T_{c,out}} \quad (13)$$

where $c_{Aux,1}$, $c_{Aux,2}$ and $c_{Aux,3}$ are tuning parameters estimated with the blower technical specifications.

For the studied test engine, the auxiliary blower is installed in parallel with the air cooler after the compressor. This means that when operating it will pull air mass flow from the compressor outlet control volume to the scavenging manifold. When active, the pressure difference between these two control volumes will reverse. When the auxiliary blower is operated (since there is no restriction valve for reverse flow in the cooler), there is flow recirculation in the air cooler. This issue needs to be modeled in order to capture the measured system behavior. Thus, the flow from the compressor outlet to the scavenging manifold is then modeled using (13) and two incompressible flow restrictions from (Eriksson and Nielsen, 2014)

$$W_{cool} = \begin{cases} W_{Aux} - A_{cool,r}\sqrt{\frac{p_{scav}\left(p_{scav} - p_{c,out}\right)}{T_{scav}}} & \text{if } u_{aux} = 1 \\ A_{cool}\sqrt{\frac{p_{c,out}\left(p_{c,out} - p_{scav}\right)}{T_{c,out}}} & \text{if } u_{aux} = 0 \end{cases} \quad (14)$$

where A_{cool} represents the flow restriction when the blower is inactive and $A_{cool,r}$ models the magnitude of the recirculation when the blower is running. Both are parameters to be estimated.

3.5 Exhaust Back Pressure

An incompressible flow restriction together with a control volume is used to model the back pressure for the turbine, $p_{t,out}$. The pressure dynamics are described by (5). And the exhaust flow $W_{t,out}$ is modeled using the standard incompressible flow restriction from (Eriksson and Nielsen, 2014) where the restriction area is a tuning parameter.

3.6 Combustion Species and Thermodynamic Parameters

The species mass fraction out of the cylinders, X_{cyl}, is calculated using the stoichiometric combustion equation and the air and fuel flows entering the cylinders. Without including the nitrogen explicitly, the combustion equation can be written

$$CH_yS_z + (1 + y/4 + z)O_2 = CO_2 + (y/2)H_2O + zSO_2 \quad (15)$$

where y is the hydrogen to carbon ratio and z the amount of sulfur in the fuel, which are known parameters. In the case of the reduced model with only oxygen mass fraction, X_{cyl} can be computed as in (Alegret et al., 2015; Wahlström and Eriksson, 2011).

Furthermore, the species vector is used to compute the thermodynamic parameters, R, c_p and γ of the working gas. This is done for each different gas composition and computed together with the gas temperature using the Nasa polynomials that can be found in (Goodwin et al., 2014).

4 Parameterization Procedure

The parameterization is done in similar steps as it is described in (Alegret et al., 2015). First the following submodels are parameterized alone: compressor, turbine, ERG blowers and Aux blower. These submodel parameters are kept fixed in the following parameterization steps.

4.1 Complete stationary parameterization

The path to follow would be to estimate the different flow restrictions of the model independently and then do a complete parameterization of the whole model together. However, this is not possible since there is no mass flow measurement available. Hence, the next step in the parameterization is to use the complete model to get the best set of parameters that predict the measured states.

The method followed here differs from the one used previously in (Alegret et al., 2015) where the derivatives of the states are used in the parameterization. Here instead the whole model is simulated at each stationary point and the simulated stationary states are used to compute the relative errors, e_{rel}. Finally, a least-squares problem is formulated with the following objective function

$$V_{stat}(\theta) = \frac{1}{NS}\sum_{i=1}^{S}\sum_{n=1}^{N}(e^i_{rel}[n])^2 \quad (16)$$

where S is the number of different measured signals used to compute the relative errors, in the general case those signals are: $[p_{scav}, p_{exh}, p_{c,out}, p_{t,out}, \omega_{tc}, T_{exh}, P_{eng}, W_{egr}]$. N is the number of stationary points used. The vector θ represents the parameters to be estimated, which in this case are all the static parameters, except of the fixed parameters of the submodels stated in the beginning of Section 4. The stationary simulations are done using a Matlab/Simulink implementation of the model. To reduce the computational time required, the Matlab parallel computing toolbox is used to run simultaneous simulations. Furthermore, a check on the state derivatives is done in order to stop the simulation once the stationary levels are reached.

Different estimation steps are done to ensure that the solver does not get lost with too many parameters. The parameterization is started without EGR, CBV or low load stationary points which are progressively included in the successive steps. Also, the results from each parameterization step are used as initial guess for the following one. Finally, a complete parameterization with all stationary points available is done.

Table 2. Absolute value of the model relative errors (%) for both engine layouts. Low load is with Aux. blower active, Mid load is below 70 % and High load is above 70 %

	Engine Layout 1							
	p_{scav}	p_{exh}	$p_{c,out}$	$p_{t,out}$	ω_{tc}	T_{exh}	$P_{eng,i}$	W_{egr}
Low Load	2.39	2.62	5.13	2.07	2.80	0.80	0.44	11.44
Mid Load	3.51	3.36	6.86	3.37	1.90	0.78	0.36	9.84
High Load	4.74	6.92	2.05	5.29	2.58	1.28	2.52	5.55
	Engine Layout 2							
	p_{scav}	p_{exh}	$p_{c,out}$	$p_{t,out}$	ω_{tc}	T_{exh}	X_{O_2}	-
Low Load	4.75	7.73	4.38	0.17	6.32	1.74	1.93	-
Mid Load	3.75	3.08	4.78	0.18	2.26	1.59	1.03	-
High Load	7.69	10.48	4.42	0.48	2.35	3.48	0.89	-

4.2 Dynamic estimation

Fixing the estimated parameters at the previous steps, the dynamic parameters, J_t, V_{scav}, V_{exh}, $V_{c,out}$, $V_{t,out}$ and τ_{cov}, are tuned using the same procedure as in (Alegret et al., 2015). In this case, 17 different step responses are used, including tree load steps with the auxiliary blowers active.

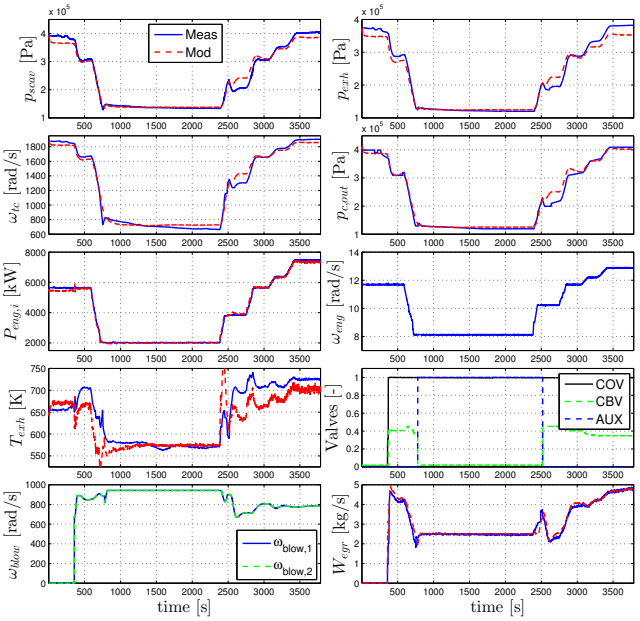

Figure 6. Model simulation vs measurements for Engine Layout 1.

5 Model Validation

Table 2 presents the absolute value of the relative errors separated for different load ranges. For Layout 1, the 24 validation stationary points are used. For Layout 2, since there is few data available, the errors are computed with the same stationary points used in the estimation. For both Layouts, the higher pressure errors are mostly in the high load case, where also the exhaust temperature and indicated engine power errors are higher. This indicates that the model and in particular the Seiliger cycle could be improved in this area. One reason for this could be that at high load is where the engine protection controls limit the maximum pressure in the cylinders, and this might not be totally captured in the model. On the other hand, for the mid and low load ranges the errors are in general of similar magnitude. Note that for the Layout 2, the engine power and the EGR mass flow measurements are not available.

Figure 6 shows the simulation results of Layout 1 compared to the measurements of a dataset not used in the estimation. This simulation has a low load phase where the auxiliary blower is enabled, where it can be seen that the system behavior is captured by the model. In particular the measured pressure and turbocharger speed values are matched by the model. More discrepancy is observed in the modeled exhaust temperature during the transients.

For Layout 2, the simulation results are presented in Figure 7. There is also a low load operation that the model is capable to capture. In this case the turbocharger speed prediction is worse than for the Layout 1 which in turn affects the stationary levels of the pressures. Nevertheless, it is important to mention that it has been parameterized with few data. Oxygen mass fraction validation could not be done due to unreliable measurements for Layout 1 and in the previous investigations from (Alegret et al., 2015). Therefore, the most relevant result from Layout 2 is that the scavenging oxygen level is captured as it can be seen in Table 2 and in Figure 7.

6 Conclusions

An MVEM for a marine two-stroke diesel engine capable of simulating low loads is proposed and validated. A parameterization method to overcome the lack of mass flow measurements is also proposed. The main characteristic is that it uses a Simulink model to integrate the modeled states with stationary inputs and is used to compute the residuals. Two different layouts of the same engine but with different turbochargers are investigated, the results show a good agreement between simulation results and measurements with some room for improvement at high loads. The oxygen prediction capabilities are also validated for the second engine layout since the oxygen measurements are reliable.

Abstract

When modeling technical systems as black-box models, it is crucial to obtain as much and as informative measurement data as possible in the shortest time while employing safety constraints. Methods for an optimized online generation of measurement data are discussed in the field of Active Learning. Safe Active Learning combines the optimization of the query strategy regarding model quality with an exploration scheme in order to maintain user-defined safety constraints. In this paper, the authors apply an approach for Safe Active Learning based on Gaussian process models (GP models) to the high pressure fuel supply system of a gasoline engine. For this purpose, several enhancements of the algorithm are necessary. An online optimization of the GP models' hyperparameters is implemented, where special measures are taken to avoid a safety-relevant overestimation. A proper risk function is chosen and the trajectory to the sample points is taken into account regarding the estimation of the samples feasibility. The algorithm is evaluated in simulation and at a test vehicle.

Keywords: machine learning, system identification, active learning, Gaussian process models, automotive applications

1 Introduction

For calibration purposes, models are used in order to speed up the calibration process, reduce the risk of damages of the system and reduce the time the real system needs to be available. For example, these models can be used in Hardware-in-the-Loop or Software-in-the-Loop environments, or even for automatic model based controller tuning. These models can either be constructed exploiting physical principles (white-box modeling), using data-based modeling techniques (black-box modeling) or a combination of the former (gray-box modeling). White-box models are often hard to generate, as the physical principles and parameters are frequently very complex, hard to model or unknown. Black-box and gray-box modeling overcomes these disadvantages, but strongly depends on informative measurement data. One approach for gathering this measurement data while keeping safety constraints and estimating a black-box model is presented in this paper. We apply the approach to the high pressure fuel supply system (HPFS system) of a gasoline engine.

Active Learning is a subfield of machine learning. Its main idea is to employ a learning algorithm, which chooses queries to be labeled on its own. Labeling data for model learning is often costly, for example due to necessary manpower or expensive test bench time. Thus, it is beneficial to optimize the queries to be labeled in order to minimize the amount of necessary data to achieve a sufficient model quality. In (Settles, 2009) an overview about the Active Learning topic and the corresponding literature is provided.

When taking measurements of a technical system, it is essential to guaranty the integrity of the system. Especially in the case of open-loop measurements, critical system states can occur when choosing improper input signals. For example, when measuring the HPFS system, the maximum allowed rail pressure may not be exceeded.

In many cases, an automation system will avoid threshold violations. Nonetheless, even the attempt to measure unsafe input signals yields side effects: high stress on the test subject, wasted measurement time, and the risk of emergency shutdowns during automated measurement runs. Thus, it is beneficial to avoid critical system inputs in advance.

One possibility to combine the goals of Active Learning, i. e. learning the best model possible using the smallest amount of data, with the goal of avoiding unsafe input queries is presented in (Schreiter et al., 2015). There, a Safe Active Learning algorithm (SAL algorithm) based on GP models is introduced, which finds a set of input samples maximizing the model's entropy, provided that an estimated safety measure is satisfied.

In this paper, the algorithm proposed in (Schreiter et al., 2015) is translated to the real-world application of the HPFS system of a gasoline engine. Compared to the theoretical investigations in (Schreiter et al., 2015), the algorithm is modified in order to meet the requirements of our system. To the best of the authors' knowledge, this is the first time the algorithm is evaluated at a real-world system.

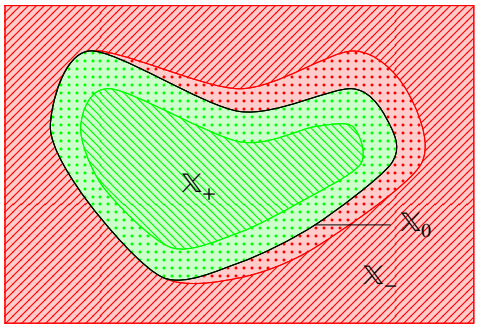

Figure 1. Partition of the input space $\mathbb{X}$ into a safe explorable area $\mathbb{X}_+$ and an unsafe region $\mathbb{X}_-$ separated by the unknown decision boundary $\mathbb{X}_0$. The figure is taken from (Schreiter et al., 2015). There, a discriminative function is learned over the dotted area for recognizing whether the exploration becomes risky.

training data	$y(\boldsymbol{x}_i)$	$h(\boldsymbol{x}_i)$ or $c(\boldsymbol{x}_i)$
SAL's goal	max. model's entropy	satisfy safety constraints

This contribution is organized as follows: First, the fundamentals of the SAL algorithm and the HPFS system are presented. In Section 3, we describe our enhancements of the algorithm and the necessary design decisions. Subsequently, the evaluation in simulation and at a test vehicle is shown.

2 Fundamentals

In this section, we will commemorate the fundamentals of SAL as introduced in (Schreiter et al., 2015) and describe the HPFS system considered in this paper.

2.1 Safe Active Learning

The key goals of SAL according to (Schreiter et al., 2015) are:

1. approximate the system based on sampled data as informative as possible,
2. use a limited budget of measured points, and
3. ensure that critical regions of the considered system are avoided during the measurement process.

A compact and connected input space $\mathbb{X} \subset \mathbb{R}^d$ is defined that is divided into two subspaces $\mathbb{X}_+$ and $\mathbb{X}_-$ in which the system is safe or unsafe, respectively (compare Figure 1). The latter should be avoided with a probability higher than the user defined threshold δ.

In this input space, two GP models are learned. One of the models is a regression of the system output y. For this model, a usual GP is used, which is trained using noisy observations $y = f + \varepsilon$, $\varepsilon \sim \mathcal{N}(0, \sigma^2)$. The second model is a problem specific classifier, used to estimate the boundary $\mathbb{X}_0$. It learns a discriminative function $g : \mathbb{X} \to \mathbb{R}$, mapped to the unit interval to describe the class likelihood for each point. This model is trained with class labels $c(\boldsymbol{x}_i) \in \{-1, +1\}$ or discriminative function values $h(\boldsymbol{x}_i) \in (-1, 1)$, depending on the location of the measured point $\boldsymbol{x}_i$ in $\mathbb{X}$ (compare Figure 1). Thereby it is possible either to only use information whether a point was feasible or not, or to use more detailed data about the grade of its feasibility. Here, the discriminative function value is given by $h = g + \zeta$, where $\zeta \sim \mathcal{N}(0, \tau^2)$ specifies the noise. The mixed kind of training data results in a non-Gaussian model likelihood, hence a Laplace approximation is required, to calculate the model's posterior.

Both GP models use zero mean centered Gaussian priors and squared exponential covariance functions. A major prerequisite is that the hyperparameters of both models need to be known in advance. These are the signal magnitude $\sigma_\bullet^2$, the length-scales $\boldsymbol{\lambda}_\bullet \in \mathbb{R}^d$, and the noise variance σ^2 or τ^2. They are summarized in $\boldsymbol{\theta}_\bullet$. The dot $\bullet$ is a placeholder for the regression and discriminative model, specified by index f or g subsequently. An overview of the two models is given in Table 1.

In SAL, the next measurement point $\boldsymbol{x}_{i+1}$ is selected based on a differential entropy criterion. Thus, $\boldsymbol{x}_{i+1}$ is chosen such that the entropy of the regression model f increases as much as possible. Namely, the variance at $\boldsymbol{x}_{i+1}$ is maximized. In order to ensure safety, the optimization is constrained with a safety criterion depending on the predicted probability of failure from the discriminative model. For more details, we refer to (Schreiter et al., 2015).

2.2 The high pressure fuel supply system

The main components of a HPFS system are the high pressure rail, the high pressure fuel pump, and the ECU (Engine Control Unit; compare Figure 2). The pump is actuated by the crankshaft of the engine. A demand control valve in the pump allows to control the delivered volume per stroke. A pressure-relief valve is also included in the pump, but should never open if possible. Hence, we want to limit the maximum pressure during the whole measurement process. The pump transports the fuel to the rail, which contains the pressure sensor. From there, it is injected into the combustion chambers. See (Robert Bosch GmbH, 2005) for more details.

The system has three inputs and one output. The engine speed ($nmot$) affects the number of strokes per minute of the pump and the engine's fuel consumption. The fuel pump actuation (MSV) gives the fuel volume which is transported with every stroke of the pump. It is applied by opening and closing the demand control valve accordingly during one stroke of the pump. The injection time is a variable calculated by the ECU, which sums up the opening times of the single injectors and is, thus, related to the discharge of fuel from the rail.

A notable difference to the systems considered in

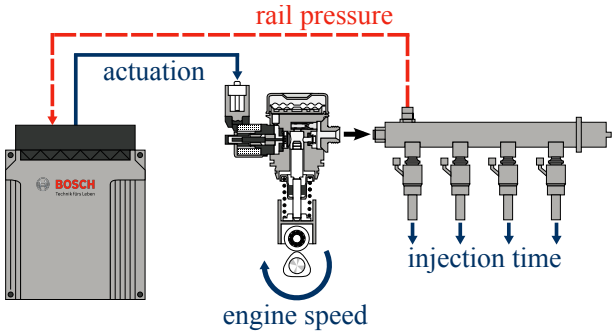

Figure 2. Sketch of the HPFS system's main components, inputs (continuous lines), and output (dashed line). The figure is taken from (Tietze et al., 2014).

(Schreiter et al., 2015) is that the input signals cannot be set directly, but have to be changed continuously. This becomes clear using the example of the engine speed, which cannot change immediately. Another reason for changing the input signals slowly is the system's dynamic behavior. Too fast actions could lead to pressure overshoots which can damage the engine.

If we move from each measurement point on the shortest path to the next one, we would have to assume that $\mathbb{X}_+$ is convex. However, experiments show that this assumption does not hold in the case of the HPFS system. Thus, we always make the detour via a global safe point (GSP), which weakens the precondition on $\mathbb{X}_+$ to star-convexity. This is a sufficient approximation of its real shape if the GSP is chosen correctly. When predicting the feasibility of an input point, the trajectory from the GSP to that point needs to be considered as well.

During the measurement procedure, the injection time is not varied manually but set by the ECU. The permissible times depend on many factors and a wrong choice could extinguish the combustion or even damage components. The engine load would have a major influence on the HPFS system via the injection time, but is omitted to prevent the necessity of a vehicle test bench. In principle, both variables could be additionally considered in the SAL algorithm without major changes of the method.

3 Design and Implementation

The system considered in this paper is defined as follows: the d-dimensional input $\boldsymbol{x} \in \mathbb{X}$ results in a one-dimensional output $y \in \mathbb{R}$ to be modeled. As the input space is divided in a safe and unsafe subspace (compare Section 2.1), we are only interested in measuring the system output $y : \mathbb{X}_+ \to \mathbb{R}$. The safe and unsafe subspace must be distinguishable by supervising the d_z-dimensional additional output $\boldsymbol{z} \in \mathbb{R}^{d_z}$. We assume that all outputs are only observable within $\mathbb{X}_+$. Outside of this subspace, the system cannot be operated safely and thus, no steady state measurements can be taken.

In order to apply the SAL algorithm presented in (Schreiter et al., 2015) to the HPFS system of a real car, three main issues have to be solved:

- learning the hyperparameters $\boldsymbol{\theta}_f$ of the regression model and $\boldsymbol{\theta}_g$ of the discriminative model,
- defining the risk function $\tilde{h} : \boldsymbol{z} \to [-1, 1]$ based on the supervised system output, which is, in combination with measured data, used to calculate the discriminative function value $h = \tilde{h}(\boldsymbol{z})$, and
- implementing the assessment of the feasibility of the trajectory to the next sample.

In the progress of solving these issues, several changes of the algorithm become necessary. This includes:

- implementing an online estimation of the hyperparameters, which requires carefully chosen limits,
- finding a heuristic for an initial set of hyperparameters, and
- replacing the problem specific classifier applied in (Schreiter et al., 2015), which can be trained with labels as well as discriminative function values, by a usual GP regression model.

In the following, these issues are discussed.

3.1 Training of the hyperparameters

In (Schreiter et al., 2015) it is assumed that the hyperparameters of the GP models are given in advance. Thus, when modeling a system from scratch, the hyperparameters need to be determined before the SAL algorithm can be started. The hyperparameters are usually learned by maximizing the marginal likelihood, as shown in (Rasmussen and Williams, 2006). Therefore, already observed data is required. If we assume that we only know one starting point in $\mathbb{X}_+$ in advance, we have almost no idea where the system is in safe operation, so that it is not possible to safely generate measurement data to estimate the hyperparameters.

If we have expert knowledge, which gives us a sufficiently large subspace of $\mathbb{X}_+$, we could generate and measure a space-filling design of experiment (DoE) in this subspace. With the generated data, we could estimate the hyperparameters and subsequently start the SAL algorithm. In Section 4.1, we benchmark this approach against the online hyperparameter training we will develop in the following. A representative subspace of $\mathbb{X}_+$ and a suitably chosen number of predefined measurement points are necessary to obtain a good model with little measurement data. This contrasts the goals of SAL to model the system with little initial knowledge about $\mathbb{X}_+$ and to be content with little measurement data. In industrial practice, a system of similar complexity as the HPFS system would be modeled using about 25 measurement points. Thus, the necessity of previous hyperparameter estimation is a major drawback of the original SAL algorithm.

To overcome this drawback, we estimate the hyperparameters during the SAL. We have to be very careful doing so, as falsely estimated hyperparameters can lead to an overestimation of $\mathbb{X}_+$ and hence to samples in $\mathbb{X}_-$. The estimation is especially error-prone if only a small number of samples is available yet. To reduce this risk, we limit the classifiers length-scales λ_g during the first optimization steps.

According to (Rasmussen and Williams, 2006), the characteristic length-scales λ of a Gaussian process with squared exponential kernel can be interpreted as the distances one has to move in the input space, before the function can change significantly. Thus, large length-scales λ_g of the classifier will result in a fast exploration, because the SAL algorithm assumes little changes in the discriminative function. We do not want the length-scales of the classifier to become too large, as this gives raise to overestimate $\mathbb{X}_+$. To prevent this, λ_g is limited to $\frac{\Delta x}{4}$ until 10 points have been measured and to $\frac{\Delta x}{2}$ until 20 measurement samples have been acquired, where $\boldsymbol{\Delta x} \in \mathbb{R}^d$ is the extent of $\mathbb{X}$ in each input dimension. During the first 5 steps, λ_g is kept constant at $\frac{\Delta x}{4}$, to ensure a good conditioning of the hyperparameter optimization problem. With increasing number of available samples, the estimation of the hyperparameters improves and the limits can be relaxed.

This setup was chosen heuristically and shows good results in the practical application. A motivation for this choice, though no formal derivation, can be given using the expected number of level-zero upcrossings of g in the one-dimensional case. According to (Rasmussen and Williams, 2006), the mean number of level-zero upcrossings in the unit interval for a GP with squared exponential kernel is

$$\mathbb{E}(N_0) = \frac{1}{2\pi\lambda}. \tag{1}$$

As we assume $\mathbb{X}_+$ to be compact and connected and, if $\mathbb{X}_-$ is not empty, we expect the discriminative function h to have $\frac{2}{3}$ level-zero upcrossings in $\mathbb{X}$ on average (compare Figure 3). If we scale $\mathbb{X}$ to the unit interval, this results in a length-scale of

$$\lambda = \frac{\Delta x}{2\pi\mathbb{E}(N_0)} = \frac{\Delta x}{2\pi\frac{2}{3}} \approx \frac{\Delta x}{4}. \tag{2}$$

The other initial hyperparameters of the classifier were set to $\sigma_g^2 = 1$ and $\tau^2 = 0.01$, based on the amplitude and the expected (low) noise level of the discriminative function. Poorly estimated hyperparameters of the regression model f have less severe consequences as those of the classifier g, as they do not result in samples outside $\mathbb{X}_+$. They will lead to a wrong density of the measurement samples' distribution, but this can be corrected by inserting additional samples, once the hyperparameters are well known. Furthermore, the limitations on the length-scales of the classifier will restrict the exploration speed and subsequently enforce a minimum sample density. Thus, no limits on

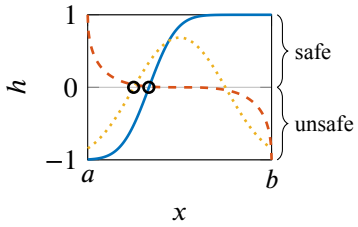

Figure 3. Three representative examples for a discriminative function $h(x)$ without noise in 1D. In this case, $\mathbb{X} = [a, b]$ and $\mathbb{X}_+ = \{x \in \mathbb{X} : h(x) > 0\}$. As one can see, two of the three examples have one zero-level upcrossing, marked with circles, the last one has none.

regression hyperparameters were enforced. The initial hyperparameters until 5 points have been sampled, were chosen as $\lambda_f = \frac{\Delta x}{4}$, $\sigma_f^2 = \left(\frac{\Delta y}{2}\right)^2$, and $\sigma^2 = \left(\frac{\Delta y}{200}\right)^2$, based on similar considerations as in the classifier case. Here, Δy denotes the expected range of the output signal y.

3.2 The discriminative model

Reference (Schreiter et al., 2015) assumes that there is only limited information about the discriminative function when measuring deep within $\mathbb{X}_+$. In contrast, the supervised output z of the HPFS system can be observed within the whole space $\mathbb{X}_+$. Thus, it is reasonable always to use the discriminative function value instead of class labels for learning the discriminative model. Another reason for doing so is hyperparameter training. Using the original algorithm and starting deep inside $\mathbb{X}_+$, it is likely that for the first samples only positive labels are drawn. It is not possible to learn correct hyperparameters from these labels using the standard training method, as shown in (Xiao et al., 2015). Therefore, the hyperparameters of the discriminative function would be estimated wrongly, which may again result in an overestimation of $\mathbb{X}_+$.

Using labels in $\mathbb{X}_-$ has some drawbacks, too. As a label only determines the discriminative function to be positive or negative in a certain point, not to have a specific value, the training algorithm can gain more information from discriminative values than from labels only. Furthermore, the regression model is not updated at all when no output y can be measured. Thus, the optima of the unconstrained part of the optimization problem described in Section 2.1 will not change if a labeled sample from $\mathbb{X}_-$ is added. In combination with the not too strong influence on the discriminative model, this may result in the next sample being generated very close to the preceding sample, as simulations showed.

For these reasons, we use a standard GP regression for the discriminative function instead of the problem specific classifier from (Schreiter et al., 2015). This has the additional advantage that no Laplace approximation for calculating the posterior is necessary. If a sample inside $\mathbb{X}_-$ is drawn, the measurement automation tries to measures at a point near the border, but inside of $\mathbb{X}_+$ instead. At this position, y as well as $\boldsymbol{z}$ can be measured. Since the original sample is usually near the boundary, the replacement sample is not far away.

3.3 The risk function

The risk function is used to encode the supervision of the systems's outputs $\boldsymbol{z}$ into a scalar discriminative function value $\tilde{h}$. This function value should be in the interval $(-1, 1)$, where -1 describes the least permissibility, 1 the highest, and 0 represents the boundary between the allowed and disallowed region.

The shape of the discriminative function h has an influence on the exploring behavior of the SAL algorithm. Comparing the continuous and the dashed line in Figure 3, one can see that the continuous line has a rather well defined zero-crossing, whereas the dashed line has only a small gradient near zero. While the former will result in a faster exploration, but with an increased risk of false positive samples in case of wrongly estimated hyperparameters, the latter will yield a slower exploration, as the discriminative model has to become very certain before samples near the boundary are queried.

By defining the risk function $\tilde{h}(\boldsymbol{z})$ accordingly, we can alter the discriminative function $h(\boldsymbol{x})$ to be learned. A proper choice could further improve the learning and exploring behavior of the algorithm. Unfortunately, $\tilde{h}$ has to be defined before starting the SAL, when the dependency of $\boldsymbol{z}$ regarding $\boldsymbol{x}$ is still unknown. Perhaps, an online optimization of $\tilde{h}$ would be possible, but this is beyond the scope of this contribution. Instead, we define $\tilde{h}$ as a linear function of $\boldsymbol{z}$. In case of the HPFS system with $\boldsymbol{z} = p$ this yields

$$\tilde{h} = 1 - \frac{p(\boldsymbol{x})}{p_{\max}} \tag{3}$$

where p is the current and $p_{\max}$ the highest allowed rail pressure.

3.4 The path to the next sample

As described in Section 2.2, we need to include the path from the GSP to the next sample in the estimation of its feasibility. Therefore, we require the constraint of the optimization problem described in Section 2.1 to be fulfilled not only at the sample point $\boldsymbol{x}_{i+1}$, but also at a number of waypoints between the GSP and $\boldsymbol{x}_{i+1}$. Even though this is only an approximation for the path's feasibility, experiments showed good results, given a sufficiently smooth discriminative function. Furthermore, it can be calculated quite fast and simple. The major drawback of this approach is that the derivative of the probability cannot be calculated analytically anymore, and thus is not available for the optimization algorithm. This results in a slightly reduced rate of convergence of the constrained optimization problem.

3.5 The algorithm

The SAL algorithm is implemented in MATLAB. Listing 1 describes the program flow in pseudocode.

4 Evaluation

4.1 Evaluation in simulation

In the first step, the SAL algorithm is evaluated using a simulated HPFS system with additive zero-mean Gaussian noise. For this purpose, a data-based GP model of the system was generated using measurement data acquired with a space-filling DoE and the ODCM algorithm presented in (Hartmann et al., 2016). ODCM allows to skip some samples based on their estimated feasibility, after a number of points in $\mathbb{X}_-$ has been sampled.

To assess the quality of the classifier, several criteria can be used. In the simulation case, we assess the classifier on a set of 10 000 test points with space-filling distribution. For the interpretation of the results, it is beneficial to consider the relative measures sensitivity and specificity. They describe the fraction of correctly classified test points in $\mathbb{X}_+$ and $\mathbb{X}_-$, respectively.

In order to benchmark the quality of the regression model, we use the root mean square error (RMSE) on m test data samples $y_{\mathrm{t},k}$ and the corresponding model outputs $f_{\mathrm{t},k}$, $k \in \{1, \ldots, m\}$.

In Table 2, a comparison of the SAL algorithm with pre- and online estimated hyperparameters is shown. In the first case, 5 to 20 initial points are sampled in a space covering about 20 % of $\mathbb{X}_+$. This region has to be defined by an expert in advance. In our case it spans about 50 % of the engine speed range and 30 % of the fuel pump actuation range. These points are used for learning the hyperparameters, which are not altered during the following SAL phase. In total, 25 points are sampled and used for modeling. At the end, the hyperparameters are optimized again using all available training data. In case of SAL without predetermined hyperparameters, these are learned online using the

Table 2. Comparison of SAL with pre- and online-learned hyperparameters in simulation after 25 samples

	pre-learned			online-learned
Initial points	5	12	20	0
RMSE	0.5900	0.0383	0.1340	0.0386
Sensitivity	0.7845	0.9928	0.9785	0.9941
Specificity	0.9647	1	1	1
Samples in $\mathbb{X}_-$	14.7	1.2	0.1	0.8

approach described in Section 3.1. All values are averaged over ten runs of the algorithm.

As one can see, 5 initial points are not enough for proper hyperparameter optimization. This leads to a disadvantageous placement of the samples, many samples in $\mathbb{X}_-$, and, subsequently, to a bad model with high RMSE. For the initial hyperparameter estimation, 12 points are a better choice, since this leads to the lowest RMSE of the final model and a small number of samples in $\mathbb{X}_-$. Nonetheless, we can outperform this variant regarding the number of unwanted samples with our online hyperparameter learning approach. The number of unwanted samples can be further reduced using 20 initial points. The remaining 5 points after the initialization are not enough to explore the whole $\mathbb{X}_+$ though, which results in a worse RMSE and reduced sensitivity compared to 12 initial points and the online learning approach.

Despite that, the variants using initial points show another unwanted property, which is not obvious from the data in Table 2: The first points during the SAL phase are often sampled far away from the initial space. In case the initial space is representative for the whole input space, this might indicate a well trained discriminative model which is able to extrapolate. This holds true in case of the HPFS system. Nonetheless, this step induces a high risk of samples in $\mathbb{X}_-$ if the initial space is not exactly representative and the discriminative function increases faster than estimated on the outside. In the online learning case, we do not observe such behavior, but a more steady exploration.

The sensitivity can be seen as a measure for the coverage of $\mathbb{X}_+$. One can see the same pattern as with the other quality parameters: The online learning approach performs best, closely followed by the 12 initial points-case.

With the right number of initial points, using pre-estimated hyperparameters performs almost equally well as the online hyperparameter learning variant. Nevertheless, it shows several drawbacks: The need to define a safe subspace in advance using expert knowledge, the right number of initial points that is hard to choose, and the large steps outside the initial space once the SAL algorithm is started. All of these drawbacks can be overcome using the online hyperparameter learning approach.

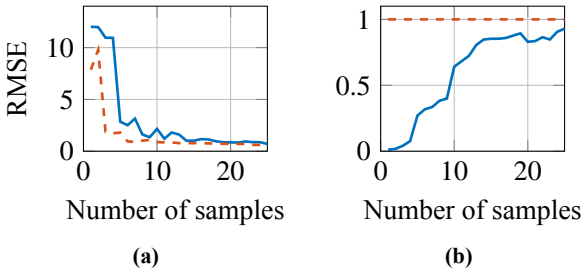

Figure 4. (a) shows the RMSE using SAL (continuous line) and space-filling plans (dashed line) at a test vehicle. The RMSE was calculated using a set of 60 space-fillingly distributed test points in $\mathbb{X}_+$. After 25 measured samples, the SAL approach obtains a RMSE of 0.7045, while a space-filling DoE results in 0.6225. (b) displays sensitivity (continuous line) and specificity (dashed line) using SAL at the test vehicle. The measures were calculated using a set of 129 space-filling test points in $\mathbb{X}$. After 25 samples, the sensitivity reaches 0.9294 and does not change considerably with a further increasing number of samples.

4.2 Evaluation at a test vehicle

After successful test runs in simulation, we apply the SAL algorithm with online hyperparameter estimation to the HPFS system of a real test vehicle. For this purpose, we use a car with 1.4 L four-cylinder gasoline engine. We implemented an automation in MATLAB, which is able to read and write labels from and to the ECU via ETAS INCA MIP, ETAS INCA, and an ETK (an ECU interface).

In Figure 4a, a comparison of the RMSEs achieved by SAL and space-filling designs over the number of training points is given. Our approach performs comparably to the space-filling DoEs. This seems acceptable, as the space-filling DoEs do not consider any limits in the input space and cannot be conducted easily this way. More measurement points do not result in a major improvement of the RMSE. The measured points in input space are shown in Figure 5.

Figure 4b shows sensitivity and specificity for each step of the SAL algorithm averaged over two runs. As one can see, the sensitivity rises rather continuously until most of $\mathbb{X}_+$ is explored. The specificity stays at its maximum value of 1 for the whole time. Note that the number of test points is much smaller compared to the simulation case, which leads to a decreased resolution of sensitivity and specificity. In average over two runs of the SAL algorithm, 0.5 points in $\mathbb{X}_-$ are sampled. As all unwanted points are sampled near the boundary, only little risk for the engine arises from them.

5 Conclusions

The test runs show that the introduced variant of the SAL approach manages to obtain a good model of the HPFS system while correctly estimating the limits of the drivable region $\mathbb{X}_+$. Only very few points are sampled in $\mathbb{X}_-$ and those which are, lie near the boundary. The resulting

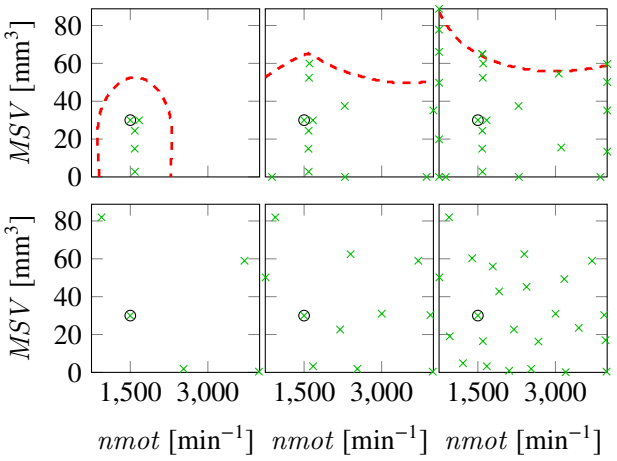

Figure 5. Measured points (crosses) in case of SAL (upper plots) and space-filling DoEs (lower plots). The algorithmic steps and plans are shown for 5, 12, and 25 points, respectively. The GSP is indicated by a circle. In the SAL case, the current estimated boundary $\mathbb{X}_0$ is plotted as dashed line.

model is almost as good as a model learned from space-filling distributed data. It must be pointed out that the latter does not comply with safety constraints or implement an exploration scheme, in contrast to the SAL approach.

Abstract

Recently, the super heavy aircraft A380 started operations between Mexico City and Paris, and it has been announced daily operations in March. In addition, Lufthansa and Emirates are also willing to use the A380 to operate from Frankfurt and Dubai to Mexico, respectively. However, in recent years, Mexico City International Airport has been reporting severe congestion problems and it is a concern whether these problems can be overcome with the current facilities and procedures together with the increasing aircraft demand. In this article, a capacity analysis of the operation performed in the airport is presented using information for a particular high-season day. A model-based approach which allows simulating the daily operation of the A380 is presented. This approach allows incorporating most of the restrictions besides the stochasticity inherent to the system.

Keywords: A380, Mexico City Airport, simulation, performance

1 Introduction

Recently the A380 started operations between Mexico City and Paris. Some operative problems have been reported and it is a concern whether these problems can be overcome with the current facilities. To make the situation even more challenging, Air France will start daily operations in March or April and also Lufthansa and Emirates are willing to use the A380 to operate from Frankfurt and Dubai respectively (CAPA, 2014). The situation represents a challenge for the airport authorities, first accommodating the non-stopping increasing demand and second the change in the aircraft mix will affect the overall airport performance since the A380 has special requirements (Airbus, 2011). In addition, airport authorities have declared the airport congested in different slots in the last years claiming that the traffic is that high that the airport is not able to cope with the demand reported (AICM, 2015).

For assessing the current situation, we developed a stochastic model of the current airport in which the most relevant technical restrictions are incorporated. In addition, it is also implemented the current operation and routes followed by the aircraft in the ground once it lands.

2 The importance of Mexico City Airport

The Mexican air transport system transported in 2015 over 65 million passengers, an increase of 8.5% compared with the previous year. The total number of operations reached more than 1 million in that year, 748,000 of the total corresponded to national flights and 281,000 to international ones (FlightStats, 2015). This growth has supported the employment of 56.6 million people (direct and indirect jobs) and contributed with over 2.2 trillion USD to global GDP. On the other hand, the domestic sector has been growing as fast as the international one; it increased by 10% over the previous year transporting 34 million passengers (60% of the total) while the international increased a 7% moving 22 million passengers (SCT, 2015).

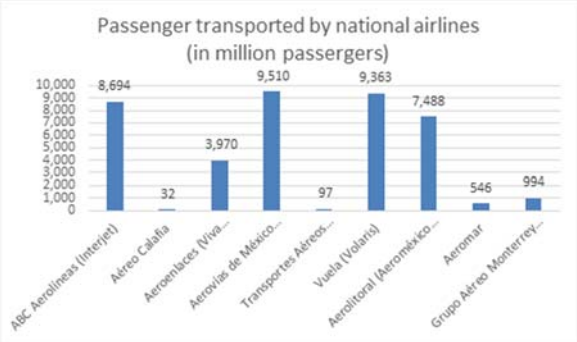

Figure 1. Passengers transported by national airlines in domestic and international routes in 2014.

Figure 1 shows the demand of the 9 regular passenger commercial airlines in México which served domestic and international routes in 2014. It can be noticed that the biggest national airlines in terms of transported passengers are Aeromexico, Volaris, Interjet and Aeromexico-Connect which moved 9.5, 9.3, 8.7 and 7.5 million pax respectively. The rest of passengers (298 000), were transported by 8 charter airlines (SCT, 2015).

Regarding to low-cost carriers (LCC), Viva Aerobus, which started operations in 2006 is growing quite fast and it is forecasted to be one of the leaders in the low-cost sector. In fact, as it can be seen in Figure 2, the low-cost sector has been growing since 2005, and in 2013 it already accounted with 60% of the market. Volaris and Interjet together with Viva Aerobus are categorized as the current Mexican low-cost carriers.

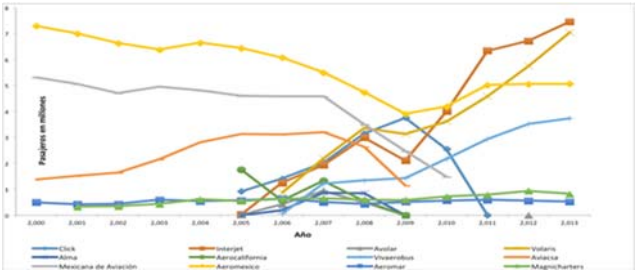

Figure 2. Main development of mexican airlines since 2005.

Table 1 introduces the top 10 domestic routes; from those routes, 47 concentrate 80.2% of the total passengers; while 80% of the international travelers use 94 routes and the 10 most frequent are presented in Table 2.

Table 1. Top 10 Domestic Routes in Mexico.

	Origin	Destination	Transported passengers (thousands)		Growing	Origin-Destination vs. Total %	
			2013	2014	2013/2014	2013	2014
1	Mexico	Cancun	3,295	3,524	7.0%	10.8%	10.7%
2	Monterrey	Mexico	2,460	2,736	11.2%	8.1%	8.3%
3	Mexico	Guadalajara	2,278	2,379	4.4%	7.5%	7.2%
4	Tijuana	Mexico	1,241	1,266	2.0%	4.1%	3.8%
5	Mexico	Merida	1,050	1,131	7.8%	3.4%	3.4%

9	Monterrey	Cancun	673	712	5.9%	2.2%	2.2%
10	Puerto Vallarta	Mexico	527	606	14.9%	1.7%	1.8%

Table 2. Top 10 International Routes in Mexico.

	Origin	Destination	Transported passengers (thousands)		Growing	Origin-Destination vs. Total %	
			2013	2014	2013/2014	2013	2014
1	Mexico	Los Angeles	783	813	3.8%	2.7%	2.5%
2	New York	Cancun	731	803	9.8%	2.5%	2.5%
3	Los Angeles	Guadalajara	746	781	4.7%	2.5%	2.4%
4	New York	Mexico	710	760	7.2%	2.4%	2.4%
5	Cancun	Atlanta	661	704	6.6%	2.2%	2.2%
6	Miami	Mexico	718	694	-3.4%	2.4%	2.2%
7	Mexico	Houston	620	693	11.7%	2.1%	2.1%
8	Dallas	Cancun	630	678	7.7%	2.1%	2.1%
9	Houston	Cancun	561	585	4.3%	1.9%	1.8%
10	Mexico	Bogota	469	572	21.9%	1.6%	1.8%

Mexico counts with 76 airports, 63 of them are international airports and 13 national; in addition there are 1,431 aerodromes registered in the country. This places Mexico as one of the top countries in Latin America with the major airport network. Figure 3 presents the 10 top airports by passenger traffic within Mexico in 2015. It can be noticed, that Mexico City International airport moves the 35% the total domestic traffic of the country, followed by four other airports: Monterrey (10%), Guadalajara (9%), Cancun (8%) and Tijuana (6%), respectively. In the international context, Cancun International airport is a good opponent to Mexico City airport moving 34% and 33% of the total, respectively.

It can be said that the busiest airport in the country is Mexico City International Airport (ICAO code: MMMX), located in Mexico city, and which also conforms, since 2003 the pillar of the Metropolitan Airport system, together with Queretaro, Puebla, Toluca and Cuernavaca.

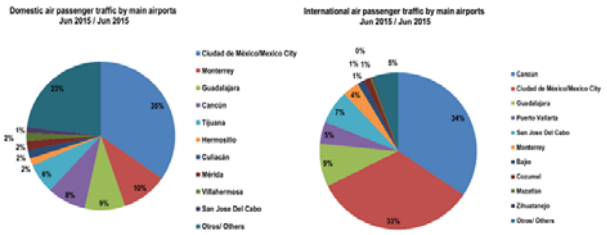

Figure 3. Domestic and International passenger traffic by main airports in Mexico.

Regarding Mexico City Airport, it is considered key for the development of the metropolitan region in Mexico and also for the development of the country. Recently it has been announced the development of the new airport in Mexico City which will have a final capacity of 120 mill pax/yr (Herald On Line, 2014). However the first phase for this airport will not be operative until 2020. In the meantime, Mexico City as a destination is still growing and the country has also gained importance as a tourist and business destination. On the 12th of January 2016, AirFrance started a direct flight from Paris to Mexico City using the mega jumbo A380. At the moment, the flight is only scheduled 3 times a week but it is planned that from March on it will fly on a daily basis (Experience the Skies, 2016). Each flight of the mega Jumbo transports 516 passengers and due to its dimensions and operational requirements some problems have raised in which delays are the most relevant ones.

The flight to and from Paris represents itself a challenge to the airport due to different factors which cause problems to be solved by the airport operator. One problem is that the clearances from the centerline at some taxiways are too narrow for the size of the aircraft which has caused that the aircraft follows a long taxi route to the runway (SENEAMM API, 2015). This operative situation caused that the departure time suffers a delay of 10 to 56 minutes with an average value of 36 minutes (Experience the Skies, 2016). On top of this situation, some years ago the airport authorities

established a limit of 61 ATM/HR as the maximum hour capacity for the airport, hence some slots of the airport have been declared congested. Furthermore, Lufthansa and Emirates have stated that they have intentions to start operating with the A380 from Frankfurt and Dubai to Mexico city respectively. For these reasons is critical to have tools and methodologies that allow the study the current and future operation of the airport. Traditional analytical techniques have proven their lack of power for addressing with accuracy the potential problems of a complex system such as the one of Mexico City airport, that is the reason model-based techniques and in particular stochastic modeling appears as the only one with the capability for analyzing with the proper accuracy the current and future operative situations.

Initial simulation-based approaches have been performed by different authors addressing the problems in MMMX and other airports (Herrera, 2012; Bazargan, 2004; Marelli et al, 1998; Soolaki et al, 2012; Mujica, 2015). In this work, the analysis performed using a validated model of the current operation of the Airport of Mexico City it is presented which allows the understanding of the current potential problems and also the ones that will rise once the daily operation of AirFrance takes place.

3 Model-based Approach

The developed model is a discrete-event-based model which allows including the stochastic characteristics and level of detail that other analytical approaches would not allow. The level of detail is such, that enables the integration of the technical restrictions, the operative restrictions imposed by the airport authority, the rules in place for the different aircraft such as wake-vortex separation and the taxiway routing for landing and takeoff. The elements that compose the complete model are: the two runways, taxi network, terminal buildings, and parking stands of the two terminals. The model focuses only in the airside of the airport and it does not pay attention to the airspace, flow of passengers or vehicles that perform the services within it, so it is bounded to the airside operation only. Figure 4 illustrates the layout of the model that includes the taxiway network, airport stands and runways and it also depicts the different paths that are followed by the traffic within the airside.

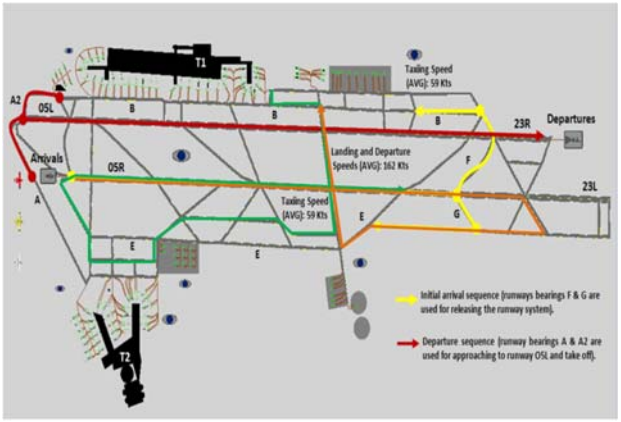

Figure 4. MMMX airport layout with A380.

The yellow path illustrates the normal landing configuration and the red line represents the configuration followed for departing flights. However, the situation of the A380 is slightly different; the A380 follows the orange path and green path for arrival and departure respectively (SCT, 2015).

In order to make the model valid, different characteristics were included in the model besides different assumptions. The most relevant ones are presented in Table 3.

Table 3. Characteristics of the Airside Model.

Parameter	Value
Landing Speed	Min:150 Knot, Max 175 Knot, AVG 162 Knot
Taxiing Speed	Min: 49 Knot, Max: 68 Knot, Avg: 59 Knot
RWY O5L-23R	Length: 3963 m
RWY 05 R-23L	Length: 3985 m
Number of Stands	T1: 50, T2:46
CenterLine Separation	310 m
Turnaround Time	Probability Distributions depending on the type of AC

For the traffic demand generation of the model, information from a representative day was collected. The information was considered (FlightStats, 2015), (Flight Radar24, 2015) and then the performance of the model was compared against the real number of air transport movements of the day.

In order to evaluate the impact of the A380,information from the current operation was collected, the type of information that was included in the model is the following:

- Route of Taxi-In and Taxi-Out of the A380
- Speed of the Taxi-In/out of the A380 in the Airport
- Turnaround time
- Current schedule and gate allocation

The operation of the airport has been modified in order to cope with the challenge of giving space for the A380 to operate. Due to the limitations and restriction in the operation, the route of the aircraft is not the standard one but a modified one so that the aircraft is

able to get to the gates G33 and G34 which were the ones selected for the operation of the A380.

3.1 Experiments and Analysis

The results were obtained running first the case without the A380 in order to make possible to establish a base case for comparison. Once the results were obtained with the base case, modifications to the model were made and attention was paid to some performance indicators.

Scenario 1: Base Case

First the base model was run and the utilization of the gates and the number of operations per hour (ATM/HR) was obtained from the initial replications, Figure 5 illustrates the values of these indicators.

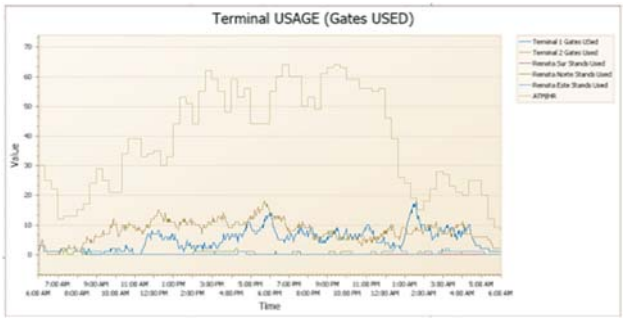

Figure 5. Gate usage and ATM/hr during the day.

Based on the analysis of the base case, it was identified an unbalance in the gates throughout the day. From Figure 5, it can be seen that most of the time the usage of Terminal 2 (brown line) is higher than the usage of Terminal 1 (blue line). It can also be appreciated that, as it has been claimed, during some time of the day, the number of operations has exceeded the declared capacity of the airport (61 Atm/hr), in particular form 1:00 pm until 10:00 pm.

In order to understand the performance capacities of the airport, a statistical analysis of the system was performed and it was evaluated whether the use of the A380 have impacted the operation. For the base case, 30 replications were performed and characteristics of the system were obtained. The most important results are presented in Table 4. From the initial results it can be appreciated that the traffic is apparently unbalanced since the Terminal 2 uses more gates in average than the Terminal 1 during the day. The maximum values represent that at some period of time during the day approximately 21 gates out of the 34 are used. In addition it can also be appreciated that the runway usage is about 69-70% as it can be seen in the green line of Figure 6.

Table 4. Base Model without A380.

Facility	Gate utilization	NO- A380		
	Max Avg	Min	Max	HW
Terminal 1 (36 Gates)	14.4	10	28	1.33
Terminal 2 (34 Gates)	15.2	11	21	0.88
	AVG	Min	Max	HW
Ratio T1Gates/T 2 Gates	0.43	0.34	0.57	0.02
TWY T1 queue	5.5	4	8	0.4
TWY T2, Queue	3.8	2	5	0.33

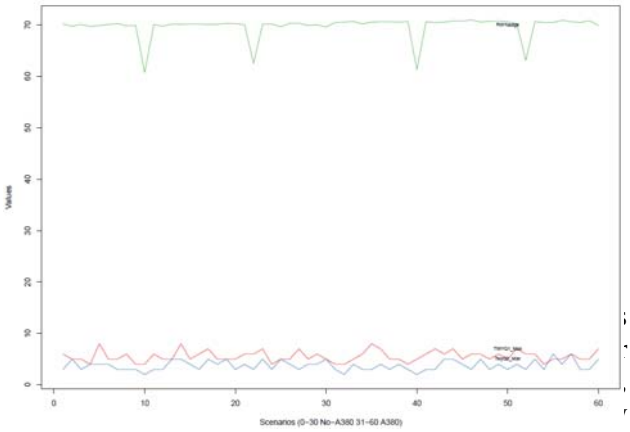

Figure 6. Utilization of runway and gates in the terminals.

This figure suggests that we can identify that the runway is the element of the system that might suffer from the lack of capacity to handle more traffic. Therefore, attention must be paid to that element.

Scenario 2: Disruptive A380

For the scenario that includes the A380, the same flight schedule was used but the flight of AirFrance at 6:40 pm was incorporated using the gates G33-G34 and following the published route for the A380 (SCT, 2015). Table 5 shows the results of scenario 2. For this scenario, 30 replications were run for obtaining the performance of the system under the new conditions.

Table 5. Scenario with A380.

Facility	Gate utilization	With- A380		
	Max Avg	Min	Max	HW
Terminal 1 (36 Gates)	14.16	10	21	0.86
Terminal 2 (34 Gates)	14.86	11	21	0.93
	AVG	Min	Max	HW
Ratio T1Gates/T 2 Gates	0.44	0.34	0.56	0.019
TWY T1 queue	5.6	4	8	0.38
TWY T2, Queue	3.7	2	6	0.39

From these results, it is apparent that in general terms the utilization rate of both terminals is affected since the maximal utilization and also the average values are negatively modified. However, it can also be appreciated that in some replications of the model and due to the variability the usage is as low as 28% and 32% for terminal 1 and terminal 2 respectively.

Impact Analysis

Once the different values and the data of the operation were obtained, *t* tests were performed for evaluating if the impact of the operation is statistically significant. These tests were executed over the following indicators with a level of significance of 0.05:

- Ratio UsageT1/UsageT2
- Effect on Queue of T1
- Effect on Runway usage
- Effect on Queue of T2
- Average T1Gate usage

After running the different tests it was possible only to identify a significant effect over the third performance indicator called *Effect on Runway Usage*. This indicator deals with the level of congestion of the runway. In our study the runway usage went from 69.5% to 70.02 %. Figure 7 illustrates the effect of the indicator once the A380 appears into scene. The dots with the 0 value correspond to the base case and the ones with the 1 value next to the dots represent the scenario with the A380.

In this figure, the effect of the inclusion of the A380 is evident since the trend is similar but just shifted to a high position in the graph due to the increase in saturation of the capacity.

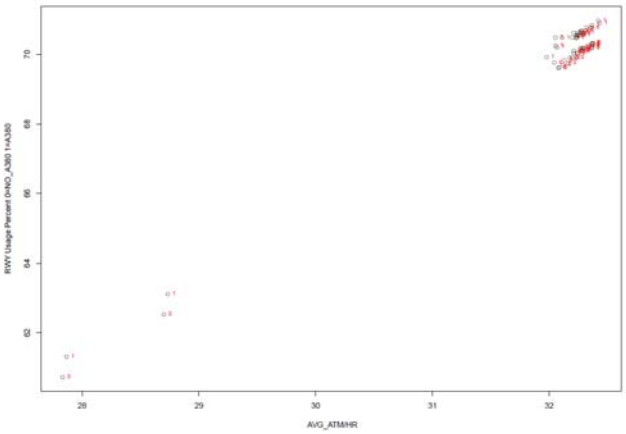

Figure 7. Effect in the RWY of the inclusion of A380.

The next figure also shows the hypothesis test performed for verifying the effect of the A380 in the runway usage. As the reader can appreciate, the shift in the mean is due to the introduction of the A380 as the *p* value confirms.

	Effect on RWY USAGE	
t-Test: Paired Two Sample for Means		
	Variable 1	*Variable 2*
Mean	69.48701814	70.02946
Variance	4.662065343	4.618695
Observations	30	30
Pearson Correlati	0.9966713	
Hypothesized Me	0	
df	29	
t Stat	-16.87623209	
P(T<=t) one-tail	7.74046E-17	
t Critical one-tail	1.699127027	
P(T<=t) two-tail	1.54809E-16	
t Critical two-tail	2.045229642	

Figure 8. Values of the Hypothesis Test.

This result confirms the statement of the airport operator that the runway is the main bottleneck in this system. However, it is also interesting that the system is able to handle this type of aircraft without affecting the operation in the remaining elements of the facility.

4 Conclusions

Airports in the globe are facilities that are very important for the development of a region in any country. Especially international airports have the function as the gateway to economic areas of development.

In the particular case of Mexico, the international airport of Mexico City is a critical infrastructure which works as a catalyst for the development of the region in different aspects that range from tourism to business. In the present article we analyzed through a model-based approach the situation of the operation of the A380 which recently started operations to and from Paris.

We could identify peculiarities of the operation of the airport such as the unbalance of the use of the gates in Terminal 1 and Terminal 2. We run experiments over a couple of scenarios and we could also identify that the operation of the A380 only affected the runway within the system. This result is interesting since it demonstrates that the A380 is not as disruptive as it was initially expected. However, the runway is the most sensitive echelon in the system and the airport should put more focus in the runway management if they want to allow other carriers such as Emirates or Lufthansa fly to Mexico City using A380s.

As a future work, we will study the particular situation of the peak hours of the airport in order to identify the slots that are less sensitive to the operation of a future A380.

A Causal Model for Air Traffic Analysis Considering Induced Collision Scenarios

Marko Radanovic and Miquel Angel Piera Eroles

Department of Telecommunications and Systems Engineering,
Autonomous University of Barcelona, Spain,
{marko.radanovic, miquelangel.piera}@uab.cat

Abstract

Present research on the air traffic management systems is trying to improve an airspace capacity, accessibility and cost-efficiency while maintaining the safety performance indicators. The discretization of the aircraft trajectories in a sequence of the 4D points specifying an agreement between the airspace users and the traffic flow management, in which the aircraft are required to arrive at the certain waypoints in the required time instants, opens a huge scope of applications for the decision support tools. This paper presents the causal model of an induced collision scenario, generated by the Traffic alert and Collision Avoidance System logic, tailored by an impropriate pairwise collision resolutions. It elaborates a unit simulation case and introduces a new modeling approach through the Colored Petri Net formalism. The proposed model provides a better insight on the geometry of collision trajectories which is a baseline for the simulation of new conflict-free resolution strategies that could be automated, and integrated in the further research.

Keywords: causal modeling, hotspot, induced collision, pairwise encounter, resolution advisories

1 Introduction

The constant increase in the air transport demand is generating a continuous pressure on the air traffic control (ATC) system. As a result, more efforts in the ATC modernization have been made to satisfy the main ATM criteria: enhanced capacity, cost-efficiency and safety. Based on the Single European Sky ATM Research (SESAR) initiative (Drogoul *et al*, 2009), there would be necessary to shift from the completely centralized tactical ATC interventions to more efficient, decentralized, collision-avoidance operations. This foresees the important changes in the roles and responsibilities of the overall air traffic management (ATM) system.

At present, an upgraded Traffic Alert and Collision Avoidance System (TCAS II v7.1), has been designed for operations in the traffic densities of 0.3 aircraft per squared nautical mile. The system demonstrates an excellent performance in cases of the pairwise encounters (PEs) but, concurrently shows some performance drawbacks in its logic due to the well reported induced collisions in some traffic scenarios (Jun *et al*, 2014, 2015; Ruiz *et al*, 2013). These drawbacks are also a result of frequent changes in the kinematic trajectory elements (the speed and altitude changes), as well as an ambiguity in the horizontal level crossings and level busts. Thus, one of the goals will be to investigate and implement a new operational framework improving the TCAS functionalities to react at both tactical and operational level as a robust collision avoidance system for different complexities of the traffic scenarios, in which ergonomics and automation interdependencies will be fully considered and aligned with the realistic aircraft performances.

This paper analyzes a pairwise collision scenario as a product of the previously resolved conflicts. From a causal point of view, it illustrates the case in which some inappropriate maneuvers, issued by TCAS to solve one-on-one encounters, can induce a new collision. This effect is known as a downstream effect (i.e. emergent dynamics) of the previous TCAS decisions and can be treated as a surrounding traffic effect, separately from a multi-threat encounter approach. The scenario is then simulated using an open-source conflict detection and resolution (CD&R) toolset *Stratway*, and obtained results are presented. Based on the simulated case, a new approach is introduced through development and validation of a Colored Petri Net (CPN) model. The model presents a baseline for further research on a probabilistic, state-based collision prediction.

The remainder of the paper is organized as follows. Section 2 discusses a conceptual analysis of the hotspot scenario describing both the one-on-one encounters and pairwise induced collisions. A simulated scenario with the obtained results is presented in Section 3, while Section 4 describes the causal modeling approach for the collision prediction. Section 5 validates the presented model, and conclusions are given in Section 6.

2 Conceptual Analysis

A reduction of the separation minima might occur due to many circumstances; in a moment when an air traffic controller issues a resolution directive, in which any change in a desired cruising speed, heading or vertical rate is not appropriate, or when a pilot performs a

maneuver that a controller had not anticipated. The airspace volume that encompasses a subset of trajectories with tight spatiotemporal interdependencies, which can easily lead to reduction of the separation minima, defines a hotspot. This volume is both space- and time-dependent on the aircraft closure rates, in sense that can occupy a couple of flight levels (several thousands of feet's) and a longer horizontal distance (several tens of nautical miles).

An idea of the PE approach lies in fact that an induced collision with the closest points of approach (CPA) of two aircraft cannot dimension the hotspot area, which is not in the case of the multi-threat encounters. Instead, a surrounding traffic aircraft introduce a certain level of uncertainty in the geometry of a resolution trajectories and, thus, very tight spatiotemporal interdependencies between trajectories that can be involved in collision are essential to define the hotspot itself (Billingsley *et al*, 2013). The CPA is an estimated 4D point on the aircraft trajectory, for which a 3D distance between two conflicting aircraft reaches its minimum value.

Even if assumed that integrity levels of the 4D trajectories are fully accomplished (i.e. very small along-track, across-track and vertical path deviations) and the flight parameters (heading, altitude and speed) are progressively maintained, which also imply the constant timestamp changes, it is not possible to predict an induced CPA. Naturally, this question opens many analytical aspects, but the main ones are a limited TCAS logic, based on a certain number of the resolution advisories (RAs), TCAS threshold requirements, and the feasible maneuvering strategies based on the aircraft performance (ICAO, 2006).

Table 1 lists all advisories for TCAS II v 7.1, while Table 2 depicts the TCAS threshold values for different flight levels. The second column in Table 2 refers to the sensitivity level (SL) indexes. This one-digit number features a strength sense of TCAS command.

Table 1. TCAS Advisories.

TCAS II v 7.1			
Type	*Text*	*Meaning*	*Required Action*
TA	Traffic, traffic	Intruder near both horizontally and vertically	Attempt visual contact, and be prepared to maneuver if RA occurs
RA	Climb, climb	Intruder will pass below	Begin climbing at 1500-2000 ft/min
RA	Descend, descend	Intruder will pass above	Begin descending at 1500-2000 ft/min
RA	Increase climb	Intruder will pass just below	Climb at 2500-3000 ft/min
RA	Increase descent	Intruder will pass just above	Descend at 2500-3000 ft/min
RA	Reduce climb	Intruder is probably well below	Climb at slower rate
RA	Reduce descent	Intruder is probably well above	Descend at slower rate
RA	Climb, climb now	Intruder that was passing above, will now pass below	Change from descent to climb[1]
RA	Descend, descend now	Intruder that was passing below, will now pass above	Change from climb to descent[1]
RA	Maintain vertical speed, maintain	Intruder will be avoided if vertical rate is maintained	Maintain current vertical rate
RA	Level off, level off	Intruder considerably away, or weakening of initial RA	Begin to level off
RA	Monitor vertical speed	Intruder ahead in level flight, above or below	Remain in level flight
RA	Crossing	Passing through intruder's level, usually added to any other RA	Proceed according to associated RA
CC	Clear of conflict	Intruder is no longer a threat	Return promptly to previous ATC clearance

[1]This is reversal RA that requires change of 1500 ft/min vertical rate.

Table 2. TCAS Threshold Values.

Own Altitude [ft]	*SL*	*TAU [sec]*		*DMOD [NM]*		*ZTHR [ft]*		*ALIM [ft]*
		TA	*RA*	*TA*	*RA*	*TA*	*RA*	*RA*
1000 - 2350	3	25	15	0.33	0.20	850	600	300

> 42000	7	48	35	1.30	1.10	1200	800	700

2.1 CD&R for One-On-One Encounters

To explain the concept of induced collision, it is first considered an initial state of a non-vectored traffic scenario in the vertical plane, which presents the SESAR concept for a free routing without a level capping. There are four aircraft A/C01, A/C02, A/C03 and A/C04 flying on the trajectories that form two predicted encounters A/C01-A/C02 and A/C03-A/C04 (Figure 1).

A/C01 is cruising on FL160 while A/C02 starts descending at FL180 in the opposite direction from A/C01, which means a direct approch to A/C01 with a loss of height. On the other side, A/C03 starts climbing at FL130, and, with an increase in height, approaching to A/C04, which is crusing at FL153 in opposite direction from A/C01. The sequences of 4D waypoints (WPs) for all four trajectories are assumed to be charaterized by the same absolute timestamps, which confirms the time-based dimension of potential hotspot. It can be noted that a difference in altitude between A/C01 and A/C04 is only 700 feet, and in this case TCAS vertical threshold is still satisfied since the hotspot area belongs to SL6 with an RA activation at the 600-feet difference. Therefore, by concluded that these two aircraft operationally maintain the required vertical separation.

As known, in the normal flight conditions TCAS is incessantly surveying the surrounding airspace by sending queries (interrogations) and receiving responses from the neighbouring aircraft. Therefore, when A/C02 flies into the range of A/C01, the TCAS on-board both aircraft issues traffic advisory (TA) to warn the crew about a possible conflict. In this scenario, the TCAS advises A/C01 and A/C02 in moments t_{TA}^{01} and t_{TA}^{02}, respectively. Naturally, this warning is activated if and only if all three TCAS thresholds for the particular SL are infringed (Table 2). Based on the current flight configuration of both aircraft and approaching closer to each other, at the instances t_{RA1}^{01} and t_{RA}^{02} TCAS issues the RAs requiring that both aircraft perfom an appropriate maneuver (Table 1). Moreover, the RAs are also a subject to the TCAS threshold infringements (Table 2).

The corresponding maneuver depends on the CPA which is determind by speed, heading and position of the aircraft. It is worth mentioning that, due to high level of range-bearing errors in the horizontal plane (Kochenderfer *et al*, 2013), the RAs consider only maneuvers in vertical plane, possibly combined with some turns or heading changes. However, those cases are a measure of the aircraft performances and the crew experiences, and are out of scope of this study. There are four rules in the TCAS logic for the PEs:

1. Two aircraft are alerted by the RAs when the horizontal and vertical threshold distances, DMOD and ZTHR respectively, are violated, or when the time to the CPA (TAU) falls below a specific threshold, with respect to the current aircraft closure rates and a corresponding SL.

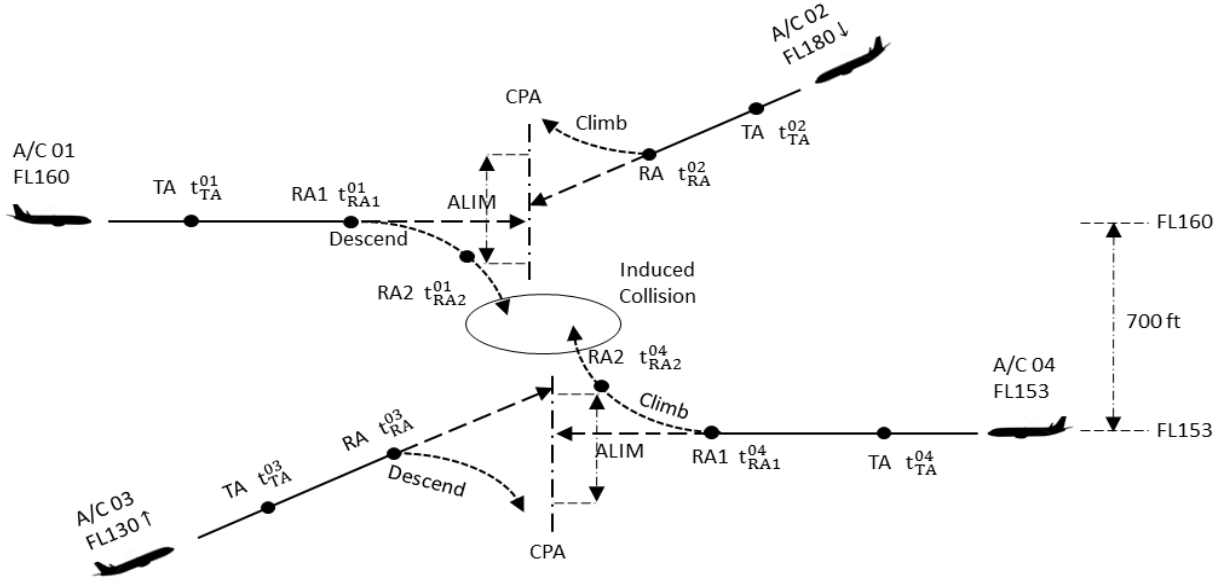

Figure 1. An induced collision scenario.

2. Two RAs are opposite to each other, i.e. they advise an opposite sense for maneuver to the crew (for instance, climb-descend or descend-climb). It is defined as a *reversal* TCAS logic.
3. When the RAs are alerted, an aircraft at a lower altitude performs descending maneuver and the one at a higher altitude complies to a climbing amendment, without consideration of the current flight configuration (cruise, climb or descent); However, the strength sense of the requested manouver will depend on the flight configuration consequently (Table 1).
4. After the RA activation the aircraft following the requested amendments must achieve a vertical separation minima at the CPA, called the altitude limitation (ALIM), as illustrated in Figure 2.

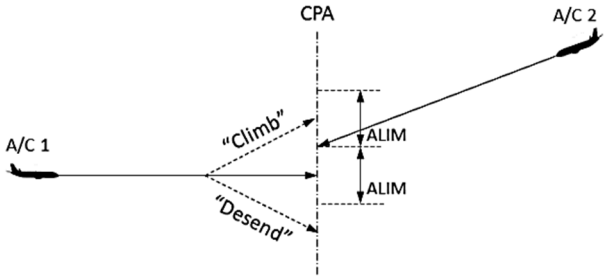

Figure 2. "Descend" RA to achieve ALIM.

TCAS computes TAU as a ratio between the range (an interdistance among the aircraft) and closure rate (or, range rate). Both range and range rate in horizontal plane are obtained from the TCAS interrogations, usually with one-second update, and they apply to aircraft in crusing configuration. In vertical plane, the time to co-altitude (vertical TAU) is computed as a vertical separation divided by a vertical closure rate (Jun *et al*, 2015).

It can be observed from Figure 1 that A/C01 at moment t_{RA1}^{01}, from the crusing phase, starts descending while A/C02 changes from descending to climbing manouver at t_{RA}^{02}, both achieving required separation minima at the CPA. Another PE, A/C03-A/C04, results in a similar way. The TAs in the moments t_{TA}^{03} and t_{TA}^{04} warn A/C03 and A/C04 about a potential conflict. At t_{RA}^{03} and t_{RA1}^{04}, the RAs are activated and both aircraft start performing the advised maneuvers. A/C03 is passing to the descending and A/C04 to the climbing amendment. In practice, it could happen that any of the Ras is not properly applied due to some unpredictable factor(s) (a meteo situation – a wind component, lack of the requested aircraft performance, or any technical error on-board the aircraft). In this case, the ALIM might be infringed and the conflict evolves into a collision.

2.2 Induced collision scenario

The previous subsection has led to the conflict resolutions of two neighbouring encounters. However, the main question is whether these amending trajectories could possibly generate a new conflict. This induced conflict can be elaborated though the emergent dynamics concept. Based on the dimensioned hotspot, it can be observed that A/C02 and A/C03 leave the area on their new conflict-free paths. In other words, they achieve their clear of conflict (CC) points (Table 1).

Concurrently, by following the previous RAs A/C01 and A/C04 induce a conflict. This state could be ambiguous. If the hotspot encompasses several flight levels and a larger horizon this encounter would become an induced conflict and might remain a conflict-based with enough time for the new RAs activation. However, if there is no sufficient time, the induced collision occurs. The analyzed scenario points out to that state. As a collision avoidance layer activates in less than 60 seconds and the RAs are issued in less than 35 seconds before the CPA reachability, once resolved conflicts produce very high uncertainty in guidance over the resolution amendments. Since the original trajectories of A/C01 and A/C04 have been vertically separated only by 700 ft and, by performing their resolution manouvers, the aircraft triggered the new TCAS alerts, the vertical thershold has been considerably violated. A/C01 and A/C04 were automatically alerted by the succeeding RAs, at the timestamps t_{RA2}^{01} and t_{RA2}^{04}, respectively. Due to insufficient time for the appropriate maneuvers, the aircraft came to the induced collision.

TCAS is operating in vertical plane which comprises a set of the vertical RAs only. Therefore, a collision event is predominantly affected by the upstream and downstream traffic flows.

3 Scenario Simulation – Unit Case

This section describes the simulation platform for CD&R algorithm and provides the scenario results for unit case. Results are presented both graphically (within integrated Graphical User Interface – GUI) and textually (in form of the log messages).

3.1 Simulation Platform for CD&R algorithm

For simulation of our scenario we have used the Stratway tool. It is the algorithm for a strategic, intent-based, CD&R, developed by the NASA Langley Research Center. Stratway is an open source software tool, implemented both in Java and C++ environment, and can be called from other programs through an Application Program Interface (API) and also excuted from a command line. The main features are as follows:

- work with the complete 4D flight plans as inputs (three spatial geographic coordiantes + time);

- generation of the conflict resolution in the form of conflict-free paths for the ownship aircraft (a reference trajectory) in presence of the multiple traffic aircarft (intruders), if feasible;
- use of a set of the heuristic search strategies for the conflict resolution;
- output of the message errors and warnings, as well as the textually-based solutions;
- considerably based on the real aircraft performances and use of a large set of the navigation parameters, that are user-configurable;
- implementation of a set of maneuvering strategies (*vertical*, *track*, *speed*, or *side-step*) which are 3D-oriented (Figures 3, 4 and 5);
- iterative tests of all involved trajectories, and output of all possible combinations for the trajectory resolutions;
- no current support to testing the induced collision scenarios; however, there are possibilities for making the upgrades with the new functionalities and strategies.

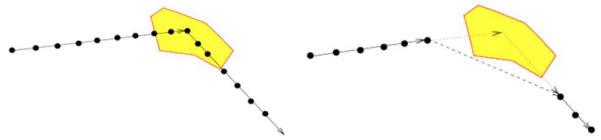

Figure 3. Track search strategy.

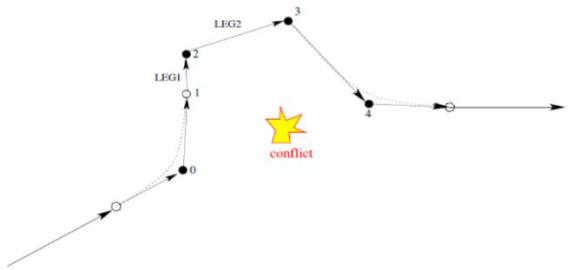

Figure 4. Vertical search strategy.

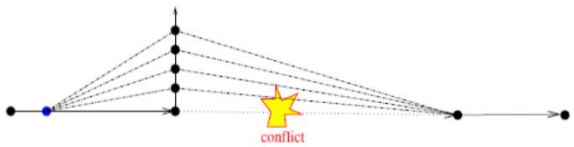

Figure 5. Side-step search strategy.

Figures above illustrate three types of maneuvering strategies. The first type is a *track* strategy (Figure 3) which is based on a heading change. The goal is to avoid a hotspot by isolating the WPs, positioned inside the hotspot, and to directly re-route to the first available WP outside the hotspot. Nevertheless, this strategy can be treated as a *fly-by-waypoint* procedure, where this WP is an imaginary center of the hotspot area. The second type is a *vertical* strategy (Figure 4). It seeks to resolve the conflict through a sequence of climbs or descents without changing the current heading of the trajectory. The strategy starts from the WP in vicinity of the hotspot using the same isolation method as the track strategy. From this WP, an aircraft increases the climb amendment (or descent, in the opposite case) in order to overtop a potential intruder. The amending trajectory leg is usually shaped as a polygon consisting of the shorter segments. A *side-step* strategy (Figure 5) is the third type, and is not considered so flight-efficient as the track strategy, but sometimes can provide the comparable solutions. It resolves a conflict by only removing a WP right before the conflict. The strategy is very effective for the trajectories containing longer segments. It inserts a *lead-in* WP (blue-colored point) in advance of the current aircraft position, from which the aircraft starts with an amending leg, and then continues with a resuming leg to the original trajectory. A deviation from the original trajectory, or the point at which amending leg terminates and the resuming leg starts, depends on the geometries of the conflicting trajectories and the closure rates.

3.2 Unit Case Simulation and Results Validation

For simulation of two PEs, it has been implemented a unit case scenario within the Dortmund enroute airspace (51°30′53″ N, 7°27′57″ E), between 13000 and 18000 ft (FL130 – FL180). Each of four trajectories has been generated in a sequence of 10 WPs with the constant time-based segments (15 seconds of the time interval) in order to facilitate the encounters prediction. Closure rates, i.e. the true airspeed (TAS) in cruising and vertical speed - rate of climb/descent (ROC/D) - are assumed to be constant as well, and by default set to TAS = 330 knot and ROC/D = 1500 ft/min. Nevertheless, these values can be changed as per user preferences, or adopted to a specific SL. Table 3 illustrates a sample of the sequences of the 4D WPs for all four trajectories used as an input. *OWN* in the table denotes the ownship aircraft, while *TRAF* with the given index corresponds the traffic aircraft.

Table 3. Input Data.

Name	*Latitude [deg]*	*Longitude [deg]*	*Altitude [deg]*	*Time [sec]*
OWN	51.51389	7.53075	16000	2400
OWN	51.51389	7.55370	16000	2415
TRAF1	51.51649	7.61961	18000	2400
TRAF1	51.51604	7.61894	17625	2415
TRAF2	51.48779	7.68225	13000	2400
TRAF2	51.48824	7.68292	13375	2415
TRAF3	51.49155	7.80565	15000	2400
TRAF3	51.49155	7.78405	15000	2415

In order to graphically present the simulated results, a graphical user interface (GUI) has been developed as a part of the Stratway algorithm. The Stratway GUI is

composed of 6 views illustrating the interdependencies between 4D coordinates:

- latitude-longitude,
- altitude-longitude,
- altitude-latitude,
- altitude-time,
- latitude-time,
- longitude-time.

By default, latitude and longitude are expressed in degrees [deg], altitude in feets [ft] and time in seconds [sec]. The simulation of the Dortmund scenario in Stratway has validated that the present resolution algorithm cannot find a conflict-free path within an induced collision (Figure 6). None of four aircraft, set iteratively as the ownship, could avoid induced collision as it has occurred on the central segments of their trajectories. The Stratway also generates also the graphical output of the pairwise conflicts without a possibility for any aircraft approaching to the induced collision state to perform an appropriate RA maneuver (Figure 7).

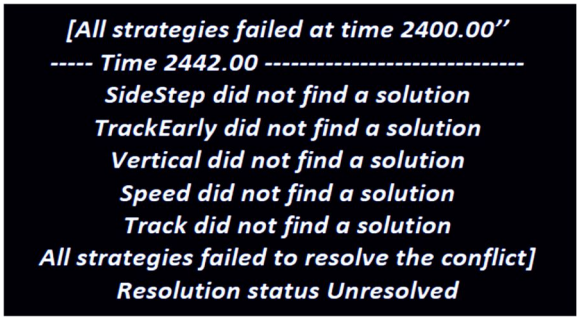

Figure 6. Log message output.

4 Causal Model for Collision Prediction

4.1 CPN Formalism

The main CPN characteristics that present very applicable formalism for a description of the discrete event-oriented simulation models are:

- all events that could appear according to a certain system state can be easily determined by a reachability graph;
- all events that can set off the *firing* of a specific event can be detected visually. CPNs are considered as a graphical modeling tool with a few syntactic rules.

The main CPN components that meet the modeling requirements are: the *places*, represented by the circles, and specifying the system states; the *transitions*, depicted by the rectangles and expressing the system events; the *input arc expressions* and *guards*, indicating the types of tokens used to fire a transition; the *output arc expressions* indicating the system state change that appears as a result of firing the transition; the *color sets*, the entity attributes which determine types, operations and functions that can be used by the elements of the CPN model; a *state vector,* the smallest piece of information for prediction of the events that could appear. This vector denotes the number of tokens in each place and the colors in each token. The color sets allow specification of the entity attributes, and the output arc expressions define what actions should be coded in the event routines linked to each event.

4.2 CPN Modeling Approach for Pairwise Collision Prediction

This subsection proposes a new causal modeling approach for the right discretization of conflict/collision

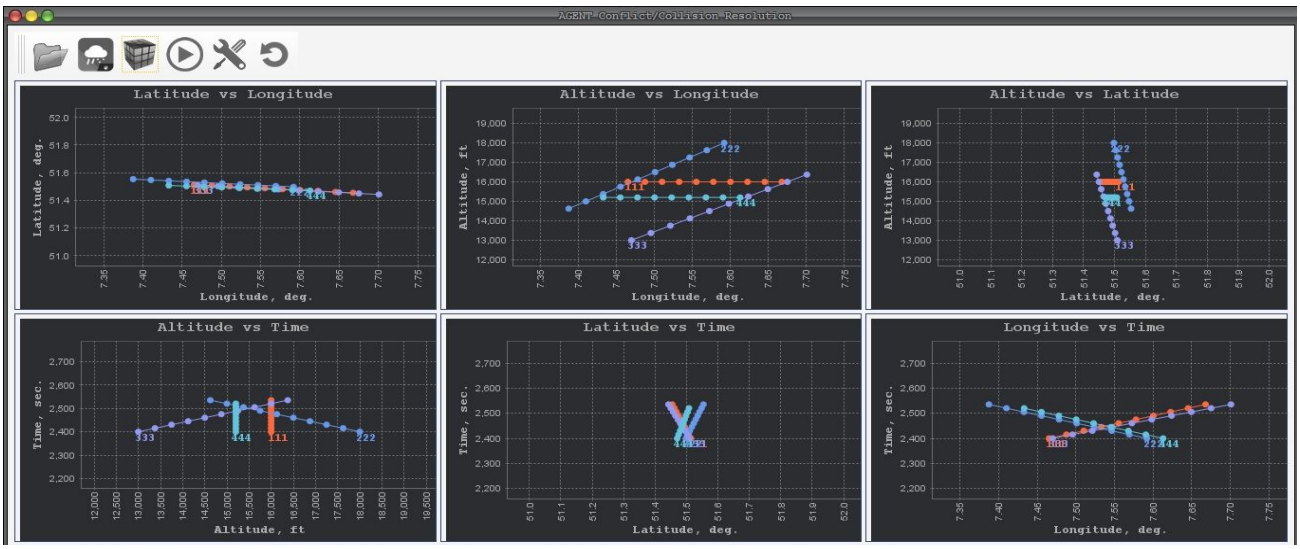

Figure 7. Stratway GUI Output.

events (Munoz *et al*, 2013) considering a larger time horizon in form of a *look-ahead* time (LAT), which is decomposed into a sequence of shorter time intervals for the control actions. For the simulated induced collision scenario, it is proposed the LAT of 300 seconds. Since, the simulation case assumes the ideal case – the constant closure rates and timestamps - the CPA will occur after 150 seconds. In real cases, i.e. the flown trajectories that include the trajectory prediction states, the CPA presents a fluctuating point, so it may occur in less or more than 150 seconds. The LAT could be sequenced in different time intervals. In this scenario, an update rate of 30 seconds has been used, meaning that the system has been considered in the discrete moments: 120, 90 and 60 seconds before the CPA. The elapsed time in less than 60 seconds denotes the TCAS convergence area based on the TAU thresholds (the TA and RA activations). The model is based on the following pre-conditions:

- The LAT provides a prediction of collision event and a way on how to avoid the hotspot at all.
- A pre-decision process (a multi-trajectory selection) is given advantage over a decision process (RA maneuver) with respect to the aircraft performance (feasibility criteria);
- With a continuous decrease in distance to the CPA less number of the potential conflict-free trajectories is achievable.

The proposed model relies on one basic concept – protected volumes. They take a shape of the imaginary cones, ground-in horizontally, with the peaks presenting the starting points of the 300-seconds time horizon. The shortest distance within these cones is the LAT distance along x-axis. These protected volumes have been considered to denote the aircraft capability to fly in a limited airspace. The limitation reflects both laterally and vertically, in the following way:

- The maximum heading change in the horizontal plane is 30 degrees. For an easier model representation, it is used the term *gradient*, presenting a coefficient of a gradual increase of the horizontal divergence measured from the x-axis, with the beginning at an identified LAT WP;
- The maximum vertical gradients from the LAT WP, i.e. ROC/D are ±5000 ft/min.

With the shortest distance and specified gradients, it is possible to define a base of the cone computing the LAT distance. After this distance, both gradients form a base with two radiuses. This imaginary base takes a shape of an ellipse. The simulation model computes all the aircraft cones together with its proximity and/or intersections defining the hotspot volumes. The intersection volumes are defined by the aircraft cones that mutually intersect in some segments of their trajectories. The shape of these volumes depends on the trajectories geometry, and considerably on the four-time colors: an entrance time of first aircraft (*time-in*, t_{1i}) and its exit time (*time-out*, t_{1o}), as well as an entrance time of second aircraft (t_{2i}) and its exit time (t_{2o}).

Once a hotspot volume has been computed and projected, the simulation model searches for the collision states by applying the TCAS RA thresholds within the intersection volumes. Therefore, any aircraft flying within its cone, but outside the intersection area, is supposed to be in a CC state. This search also includes the neighboring aircraft trajectories for the induced collision cases. If a collision state is identified/predicted the proper RAs are issued, and the aircraft perform requested maneuvers inside their imaginary cones. The model records the pairwise collisions only. It is graphically described in Figure 8.

The elements of the model are structured as follows:

- **T1** – the first transition denoting the protected volumes construction with its guard function **GU1**; **T2** - second transition defining the intersection volumes with the guard function **GU2**; **T3** – third transition that checks out the number of collision events controlled by the guard function **GU3**;

- **P1** – the place expressing the vertical gradients; **P2** – the place expressing the lateral gradient (the heading change); **P3** – the place containing 300-seconds time window; **P4** – the place that stores the along-track distances; **P5** – the control place 1 assuring that input values are satisfied; **P6** – the place linking the transitions T1 and T2, and marking the protected volumes state; **P7** – place denoting the time matrix values; **P8** – the control place 2 checking that extracted time values are satisfied; **P9** – the place that depicts the intersection volumes; **P10** – the place containing the 4D trajectory data; **P11** – the place containing the RA thresholds; **P12** – the place that stores the pairwise checks within a set of aircraft; **P13** – the place storing the pairwise induced collisions.

5 Validation and Evaluation

Presented CPN model is deployed as an essential approach to the quantitative state space analysis of the events in which the potential conflicts can likely result in collisions. At present, the causal model has been validated with some stakeholders by means of:

- *Model Purposiveness*: the conceptual model has been validated by means of a unit test (mainly though the extreme scenarios), and all detected bugs have been removed. As a result of the meeting with the experts, some modifications to the conceptual model has been added to extend the simulation/tests targets.
- *Model Plausibility*: the level of plausibility, or the expert opinion, basically referes to two features of the model. The first considers a question of whether the model *looks logical*. This answer on this question

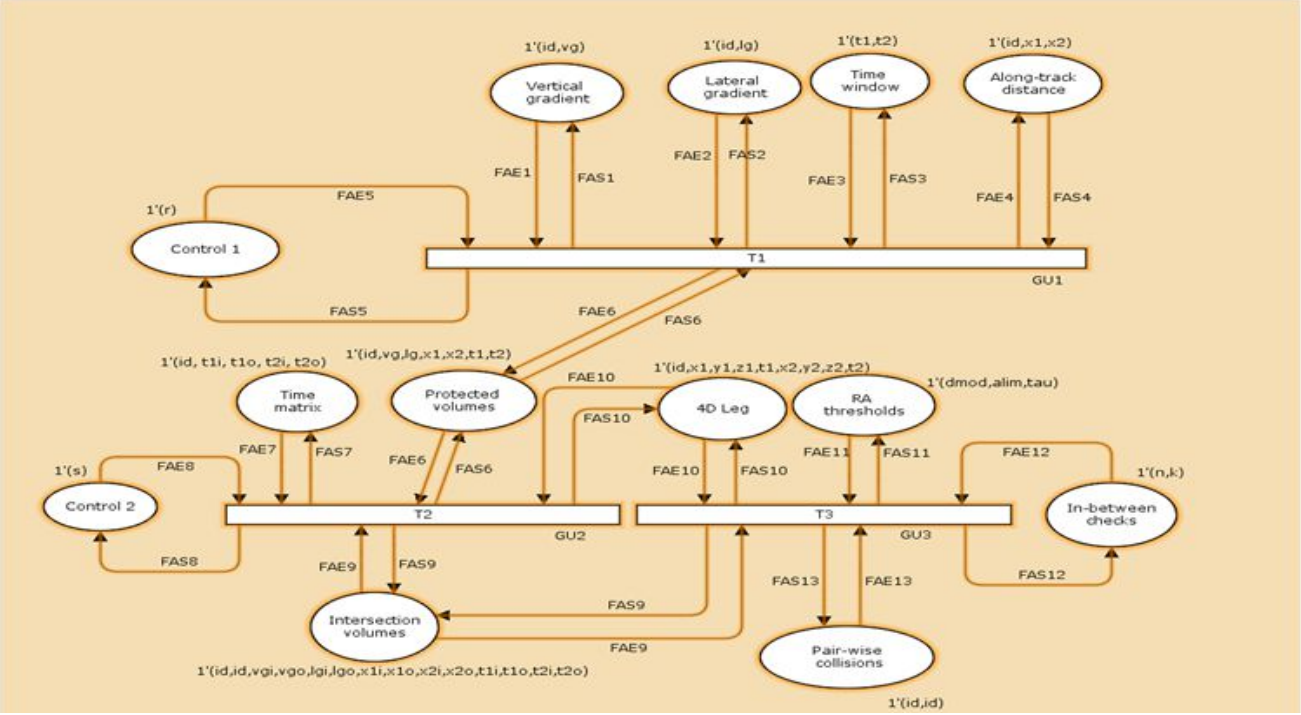

Figure 8. CPN model for pairwise collision prediction.

gives the characteristics of the model structure (the rules and hypothesis) and its parameters. The second is related to the question of whether the model *behaves logically*. This part provides an assessment of the reaction of the model outputs to the typical events (scenarios) on the inputs.

The aircraft state information, such as position and velocity, coming from the analyzed non-vectored scenario have been fed the Stratway simulation tool, and the obtained outputs – conflict segments in a form of the 4D points – have been used as an intial marking, or zero conditions, for generaion and execution of the CPN model. In addition, defined metrics, such as vertical and lateral gradients, conflict time intervals and constants (RA values) had provided a better insight of the spatiotemporal interdeoendencies in the potential collsion scenario, and creation of the intersection volumes as a qualitative solution. Finally, several simulation runs, performed in Stratway, had provided different initial markings, that are further used for computation of the final solution state in the CPN model. The intial markings pointed out to the different geometries of the conflict segments.

The follow-up validation steps will consider the state space analysis of a conflict scenario for detection of the sequence of maneuvres, that could lead to an induced collision. The generated data will be fed to InCAS (the simulation tool developed by EUROCONTROL) to validate the trajectories computed by the causal model. It will be also used *TimSpat* (Baruwa *et al*, 2015) to perform the computation of all states that can be reached from initial configuration, as illustrated in Figure 9.

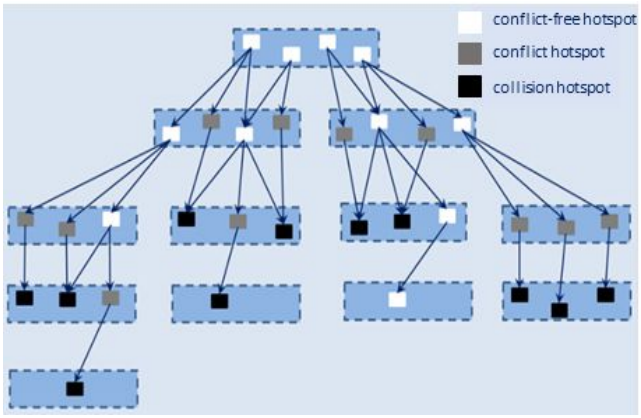

Figure 9. Reachability graph for collision events.

Each node in the graph represents a feasible marking and each arc the transition or event which allows the system evolution from the initial state to a new one. The reachability graph is structured in four levels and composed of nodes of the hotspot areas that are classified in three categories: conflict-free (white-coloured), conflict (grey-coloured) and collision (black-coloured) hotspots. There is only one node in the final level obtaining one collision hotspot. Still, the third level reaches also a node with a conflict-free hotspot.

6 Conclusions

This paper analyses the induced collision scenario in the en-route airspace as a product of the previously resolved pairwise conflicts. Based on the TCAS shortages, it tries

to identify the dynamic structures of the 4D trajectories involved in collision through simulation of their tracks and implementation of the appropriate feasible strategies. The paper further focuses on causal modeling trying to generate a new approach that will provide a higher awareness of the collision hotspot and a better decision-making process.

Multi-Sourcing and Quantity Allocation under Transportation Policies

Aicha Aguezzoul

Lorraine University, UFR ESM-IAE, Metz, France, aicha.aguezzoul@univ-lorraine.fr

Abstract

Multi-sourcing, inventory, and transportation management are among the major levers of a supply chain. In this paper, we study the case of multi-sourcing problem by considering the transportation policies used between suppliers and a buyer. Thus, we propose a programming model that determines the optimal order quantities to allocate to the suppliers used, according to the direct or indirect shipment. The objective to minimize in the model is the total logistics cost which is composed of purchasing, inventory, and transportation costs. The constraints related to suppliers and buyer are considered. The model is illustrated with a comprehensive example.

Keywords: nonlinear programming, multi-sourcing, quantity allocation, transportation, simulation

1 Introduction

Transportation and sourcing from suppliers are among the main activities for a supply chain management and optimization. Indeed, the costs of raw materials and components account for 40 to 60% of production costs for most US manufacturers (Wadhwa and Ravindran, 2007), while the transportation cost accounts a large part of the total logistics cost. The literature is very abundant on the sourcing and supplier selection studies in terms of criteria, methods for measuring their performance, and strategies on mono versus multi-sourcing.

This paper also caters these issues, and studies the impact of transportation on the multi-sourcing process. Indeed, in that process, splitting orders across multiple suppliers will lead to smaller transportation quantities which will likely imply larger transportation cost. Moreover, transportation and inventory elements are highly interrelated and contribute mostly to the total logistics cost. Finally, transportation takes a great place in the current context of sustainable development.

The remainder of this paper is organized as follows. Section 2 presents relevant literature on the sourcing strategy. In Section 3, the mathematical model is described. Section 4 reports the results of computational experiments, based on simulations. The last section contains some concluding remarks.

2 Literature review

Sourcing strategy is one of the most critical activities in purchasing process. This strategy further includes the supplier selection problem, which is widely studied in the literature. It's a very complex process because it involves various conflicting criteria such as cost, quality, delivery, reputation, flexibility, production capacity, geographical location, relationship, etc.

Dickson (1966) was the first one to address this issue and has identified 23 different criteria by which purchasing managers have selected suppliers in various procurement environments. The problem is how to select suppliers that perform satisfactorily on the desired criteria. Based on a review of 74 papers published since 1966, Weber et al. (1991) have found that vendor selection is a multi-criteria decision making (MCDM). To solve that MCDM problem, the authors showed that the proposed approaches might be grouped into three categories, which are: linear weighting methods, mathematical programming models, and statistical/probabilistic approaches. Since that time, other methods in various research contexts such as supply chain design/management, agile manufacturing, and dynamic alliances appeared in the literature. For instance: Expert system (Zhao and Yu, 2011; Amindoust et al., 2012), multi-objective programming (Aguezzoul and Ladet, 2007; Amid et al., 2009; Jadidi et al., 2014), Data Envelopment Analysis (DEA) (Sevkli et al., 2003), Analytic Network Process (ANP) (Dargi et al., 2014), hybrid approach (Demirtas and Üstün, 2009; Haldar et al., 2012; Karsak and Dursun, 2014), etc. An analysis of these methods can be found in (Aguezzoul and Ladet, 2006; Ho et al., 2010; Chai et al., 2013; Aguezzoul, 2014).

As mentioned in (Aguezzoul, 2015), in these various approaches, the criteria relating to transportation like shipment cost, geographical location of supplier, etc. are considered in the outsourcing process only in an implicit manner. Moreover, the stocks in the entire transportation network linking buyer to suppliers is not evaluated. Finally, in the current context of sustainable development, environmental dimensions such as external transport costs that are related to air pollution, noise, congestion, accidents, etc., are rarely considered.

In this paper, we refer to the work cited in (Aguezzoul, 2015) by considering the particular case of transit via a single terminal. In addition, we study the case of several scenarios depending on whether or not the suppliers use the transit via the given terminal. The detail of the model is given in the following paragraph.

3 Model development

In this article, we consider the total logistics cost as the relevant criterion to minimize in the case of sourcing from several suppliers. Such suppliers have to establish a green supply chain. The total cost is the sum of purchasing, transportation, external shipment, and inventory costs, while capacity and quality of suppliers, and buyer's demand are formulated as constraints. The model aims to deduce the order quantity for each supplier, taking into account the transportation policies to put in place between each supplier and the buyer. The following notation and formulations to model this problem are:

n: number of suppliers,

D: buyer demand per unit time, assumed constant,

Q: ordered quantity to all suppliers in each period,

Q_i: ordered quantity to i^{th} supplier in each period,

A_i: ordering cost of i^{th} supplier per order, in each period,

P_i: unit purchase price of i^{th} supplier,

C_i: production capacity of i^{th} supplier,

q_i: rate of quality of i^{th} supplier

q_a: minimum rate of quality accepted by the buyer

r: inventory holding cost rate

d_i: distance between the i^{th} supplier and the buyer,

Cf_i: shipping cost per distance between the i^{th} supplier and the buyer,

Cv_i: shipping cost per load between the i^{th} supplier and the buyer.

Cex_i: external shipping cost between the i^{th} supplier and the buyer.

The decision variables for the model are:

- X_i: fraction of Q assigned to i^{th} supplier
- $Y_i = \begin{cases} 1 \; if \; X_i > 0 \; (i^{th} \; supplier \; is \; used) \\ 0 \; if \; X_i = 0 \end{cases}$

In addition, D/Q is the number of periods during the time considered. The total cost has the following form:

$$TC = \sum_{i=1}^{n} [DX_i P_i] + \left[D/Q \begin{pmatrix} d_i Y_i (Cf_i + Cex_i) \\ +QX_i Cv_i \end{pmatrix} \right] + [rP_i Q X_i^2] \quad (1)$$

- The first term in this function is the total purchasing cost. $X_i D$ is the part of demand to assign to i^{th} supplier,
- The second term represents the total transportation cost. Cf is a fixed shipping cost which is independent of a load and includes cost of stop and cost per unit distance. Cv is a cost per load and it's independent of the distance covered. Cex is the external cost of transportation,
- The last term in the function is the total inventory cost. In a transportation network, total inventory includes loads that are waiting to be shipped from each supplier, and loads that are waiting to be used by the buyer. That supposes that each supplier produce items at a constant rate and the production planning is synchronized with that of transportation. The average time required to i^{th} supplier to produce a shipment of size Q_i is Q_i/D. Each item in the load waits on average half of this time before being shipped $Q_i/2D$. After arriving, each item waits on average $Q_i/2D$ before being used. Thus, the average time spend by an item from i^{th} supplier to buyer is: Q_i/D.

Here, we use the Economic Order Quantity (EOQ) model which is widely used to calculate the optimal lot size to reduce the total logistics cost. EOQ is the value that cancels the derivation of TC:

$$EOQ = \sqrt{\frac{D \sum_{i=1}^{n} Y_i \, d_i (Cf_i + Cex_i)}{r \sum_{i=1}^{n} P_i X_i^2}} \quad (2)$$

Thus, by replacing Q by EOQ in (1), the final expression of the total cost is:

$$TC = \sum_{i=1}^{n} DX_i (P_i + Cv_i) + 2 \sqrt{Dr \left(\sum_{i=1}^{n} d_i Y_i (Cf_i + Cex_i) \right) \left(\sum_{i=1}^{n} P_i X_i^2 \right)} \quad (3)$$

The mathematical formulation of the nonlinear programming model is given as follow:

$$Min(TC) = \sum_{i=1}^{n} DX_i (P_i + Cv_i) + 2 \sqrt{Dr \left(\sum_{i=1}^{n} d_i Y_i (Cf_i + Cex_i) \right) \left(\sum_{i=1}^{n} P_i X_i^2 \right)} \quad (4)$$

The mathematical formulation of the nonlinear programming model is given as follow:

$$Min(TC) = \sum_{i=1}^{n} DX_i(P_i + Cv_i) + 2\sqrt{Dr\left(\sum_{i=1}^{n} d_i Y_i(Cf_i + Cex_i)\right)\left(\sum_{i=1}^{n} P_i X_i^2\right)} \quad (5)$$

S.T.

$$\begin{cases} X_i D \le C_i & i = 1,n \quad (6) \\ \sum_{i=1}^{n} q_i X_i \ge q_a \quad (7) \\ \sum_{i=1}^{n} X_i = 1 \quad (8) \\ \epsilon Y_i \le X_i \le 1 & i = 1,n \quad (9) \\ Y_i = 0,1 & i = 1,n \quad (10) \end{cases}$$

- Equation (5) represents the total cost TC to minimize and whose expression is given by (4).
- Constraint (6) represents the capacity restriction for each supplier.
- Constraint (7) is an aggregate performance measure for quality for all suppliers.
- Constraint (8) indicates that demand is placed with the set of n suppliers.
- Constraint (9) requires that an order be placed with a supplier if only it's used; ε is a positive number, slightly greater than zero.
- Constraint (10) imposes binary requirements on the decision variables Y_i.

4 Numerical example

4.1 Problem Data

In this section, we present a case study of three suppliers, denoted S1, S2 and S3, who have capacities limited. Two types of shipment are used: a TruckLoad (TL) and a Less than TruckLoad (LTL), characterized respectively by the shipping cost per load of 0€ and 0.05€, the shipping cost per distance of 1.32€/mile and 0.15€/mile, and the external cost per distance of 1.11€ and 1.07€. The demand of the buyer is 1000 per week, r=20%, and the minimum accepted rate of quality is 95%. Table 1 below contains other information on the suppliers. In these experiments, we take ε = 0.001 by supposing that 0.1% is the minimum percentage of the demand that the buyer will order to a supplier.

Table 1. Suppliers' information.

Suppliers	*S1*	*S2*	*S3*
Capacity	700	800	600
Rate of quality (%)	97	95	93
Unit purchase price (€)	9	7	5
Distance to buyer (miles)	100	150	200
Distance from suppliers to terminal (miles)	50	70	100

To solve the model, simulations are used. Each one corresponds to a scenario, which depends on the mode of transport (Tl or LTL) used between each supplier and the buyer. We then have the following eight scenarios:

- Scenario 1: Each supplier uses a TL.
- Scenario 2: S1 uses a LTL while each of S2 and S3 uses a TL.
- Scenario 3: S2 uses a LTL while each of S1 and S3 uses a TL.
- Scenario 4: S3 uses a LTL while each of S1 and S2 uses a TL.
- Scenario 5: each of S1 and S2 uses a LTL while S3 uses a TL.
- Scenario 6: each of S1 and S3 uses a LTL while S2 uses a TL.
- Scenario 7: each of S2 and S3 uses a LTL while S1 uses a TL.
- Scenario 8: Each supplier uses a LTL.

4.2 Computational Results

The results presented in table 2 bellow are generated on a personal Acer computer (Intel Core, 2.10 GHz) using Matlab software version 6.1.

Table 2. Computational results.

Scenario	*% of order quantities*			*Total cost (€)*
	X_1	X_2	X_3	
1	28	37	35	7964,14
2	30	34	36	7895,71
3	22	56	22	8088,12
4	28	42	30	8320,93
5	20	55	25	8081,67
6	29	37	34	7847,01
7	23	58	19	8169,99
8	26	54	20	8030,18

From these results, we can deduce the following remarks:

- This table gives the quantity allocation for the suppliers, and the total logistics cost, according to the transportation policy considered.

- The quantities to order to each of the three suppliers depend much of the scenario used, and therefore of the considered transport policy.
- Over 50% of the quantity is allocated to the supplier within scenarios 3, 5, 7 and 8. In these cases, transportation between S2 and buyer is done by a LTL.
- In all scenarios, the total cost is minimum (= 7847, 01) for scenario 6. In this case, each of S1 and S3 uses a LTL while S2 uses a TL. The order quantities in % for suppliers are respectively 29, 37, and 34.

5 Conclusions

Multi-sourcing strategy is one of the most critical activities of purchasing management in a supply chain. A review of literature on that field shows that there has been very little work that comprehensively examines the role of the transportation in this decision.

In this paper, a nonlinear programming approach is developed to determine the order quantities to allocate to the suppliers considered, taking into account the type of transportation, LTL or TL. To solve the model, simulations are used; each one corresponds to a given scenario related to a transportation policy used to carry the products bought from the suppliers to the buyer with an aim of minimizing total logistics cost. Thus, the buyer will have available several scenarios to make its procurement decisions.

One of the prospects for this work is to integrate the case where goods can be transhipped through intermodal freight transportation. In this case, the goods undergo at least three changes of the means of transportation between their origin and their destination. For example, in a road-rail combined transport, a shipment is first transported by truck to a given terminal. Then, it is transhipped from truck to train. At the other end of the transport chain, the shipment is transhipped from train to truck and delivered by truck to the receiver.

A Variogram-Based Tool for Variable Selection in a Wastewater Treatment Effluent Prediction

Markku Ohenoja Jani Tomperi

Control Engineering, University of Oulu, Finland, forename.surname@oulu.fi

Abstract

In this study, a variogram method was utilized as a variable selection tool for finding the optimal subsets of variables for developing predictive models for the quality of wastewater treatment effluent. The quality of effluent was here assessed by biological and chemical oxygen demand and suspended solids in biologically treated wastewater. The dataset included, in addition to traditional process measurements, results of a novel optical monitoring device which was used for imaging an activated sludge process in-situ during a period of over one year. The study showed that the variogram based method has potential in fast and computationally easy variable selection. The developed models can be used for proactive monitoring and estimating the quality of effluent in several stages hours before in comparison to laboratory analysis taken from treated wastewater.

Keywords: activated sludge process, BOD, COD, cross-validation, modeling, optical monitoring, suspended solids, variogram

1 Introduction

While the amount of produced wastewater is increasing, the regulations for the quality of discharges by authorities are constantly tightening, and the operating costs are necessary to be minimized. Wastewaters are commonly treated in biological activated sludge processes (ASP), which are sensitive to external and internal disturbances, such as changing temperature, and varying quality and quantity of wastewater. Disturbances affect the bacterial balance of biomass and the optimum operating conditions, which are in a key role for a high pollution removal rate, low suspended solids in the effluent and a good settling properties of the sludge. Disturbances in the bacterial balance may have serious environmental and economic effects as they often produce dysfunctional flocculation and settling. The most common problem in ASP is filamentous bulking, which is caused when the secondary settler is unable to efficiently remove the suspended biomass from the wastewater. Recovery from the occurred disturbances is slow and the effects on process operation and purification result are long-lasting. (Tchobanoglous *et al*, 2003; Amaral, Ferreira, 2005; Mesquita *et al*, 2009)

On this account, an accurate operating of the wastewater purification process is required. The performance of a wastewater treatment process can be assessed analyzing the quality parameters of treated wastewater, such as biological and chemical oxygen demand (BOD, COD), suspended solids (SS), and sludge volume index (SVI). However, these parameters only show the poor quality of effluent when it already occurs and the corrective operations are inevitably late. Thus, there is a demand for new real-time monitoring tools and methods to be used in process control in parallel with the traditional offline analysis of wastewater samples and expert knowledge. The novel on-line optical monitoring method gives fast, objective information about the state of the wastewater treatment process, reveals some of the reasons for settling problems, and combined to a predictive model, shows the quality of effluent in advance (Koivuranta *et al*, 2015; Tomperi *et al*, 2017). In this study, a variogram method is utilized for finding the optimal subset of variables to develop predictive models for BOD, COD, and SS in biologically treated wastewater. The dataset from a period over one year included the results of the in-situ optical monitoring of an ASP, and the offline process measurements.

2 Material and methods

2.1 Wastewater Treatment Plant

The data used in this study was collected from the largest wastewater treatment plant (WWTP) in Finland, located in Helsinki. Viikinmäki WWTP processes daily 270,000 m^3 of wastewater from over 800,000 inhabitants around the Helsinki region. Part of the total flow (15%) come from industrial sources. This WWTP is a three-phased activated sludge process that utilizes the simultaneous precipitation method for phosphorus removal. Wastewater is processed in nine activated sludge process lines. In addition to mechanical, biological, and chemical treatment, a biological filter has been added to improve nitrogen removal. The unit operations of the process are intake, screening, grit, and grease removal, preliminary settling, aeration, degassing, secondary settling, biological de-nitrification filtration, and discharge (Figure 1). Screening removes the large solids from the water. Grit and grease removal separates rapidly settling, very coarse solids, as well as, greasy and oily substances that are lighter than water. In

the preliminary settling phase, easily settling material is separated from the water. The biological treatment is conducted by means of a de-nitrification-nitrification process in an aeration tank which is used to grow activated sludge. At the head of the aeration tank, there is a separate mixing area, where new wastewater entering the tank is reseeded with returned activated sludge from the secondary settling tank, and recycled sludge from the end of the aeration tank. Activated sludge, biomass which contains organic matter and nutrients, is separated from the treated wastewater by settling in the secondary settling tank and returned to the aeration tank. Part of the activated sludge is removed daily to maintain a suitable sludge age and sludge concentration in the aeration tank. After the secondary settling phase, wastewater is led to filtration based on bacterial action to enhance de-nitrification of the wastewater. (HSY, 2016)

2.2 Optical Monitoring and Image Analysis

To replace the slow, irregular, and subjective manual microscopic analysis of wastewater samples, a small-scale optical monitoring device and an image analysis method were developed (Koivuranta *et al*, 2013) and proved functional for monitoring the floc morphology reliably in-situ in full-scale municipal ASP (Koivuranta *et al*, 2015). The device consists of an imaging unit, a sample handling unit, and a control PC with an electronics unit. Wastewater samples were taken from one activated sludge line in the aeration tank, diluted, and pumped through a cuvette, which was imaged with a high-resolution charge-coupled device (CCD) camera. At normal flow, the delay between optical monitoring measurement and the output of the WWTP was about 13 hours. The optical monitoring device measured several morphological features of the flocs and filaments: in addition to the size parameters such as mean equivalent diameter, floc area, and filament length, the calculated shape parameters included, for example, fractal dimension, form factor, and roundness. The parameters were calculated as an average of the values for individual objects over a single image. The detailed description of the device and mathematical formulas of the calculated parameters are presented in (Koivuranta *et al*, 2013).

2.3 Variable Selection Using Variogram

Modern plants produce large amounts of data which often include irrelevant variables for a specific purpose, for instance modeling. Only significant input variables should be selected for model development. The greater number of variables does not necessary mean better prediction results because correlated, noisy and uninformative input variables increase the computational complexity, make the training of the model more difficult and worsen the prediction result. Over-fitting may occur if the model contains too many variables which are fitted not only to the data but also to the random noise. Additionally, the sampling rates of different input variables may differ significantly, therefore describing the process dynamics in different precisions.

In this work, a variogram-based method is utilized as a variable selection method in order to find the optimal subsets for modeling the suspended solids content, BOD, and COD in biologically treated wastewater. The idea of utilizing variogram for variable selection comes from the fact that a variogram of particular measurement holds the information about the relative error levels of the sampling and analysis of that measurement. Variogram is a fundamental tool within Theory of Sampling (Gy, 2004) and has already been considered in drift estimation (Paakkunainen *et al*, 2007), temporal uncertainty propagation (Jalbert *et al*, 2011), fault diagnosis (Kouadri *et al*, 2012), statistical process control (Minnit, Pitard, 2008), and as a process stability measure (Bisgaard, Kulachi, 2005).

Variogram is calculated from a set of systemically collected data. In this work, it is assumed that the data is systemically sampled and that the flow rate, or sample weight, is constant. Hence, the heterogeneity of the data can be interpreted as:

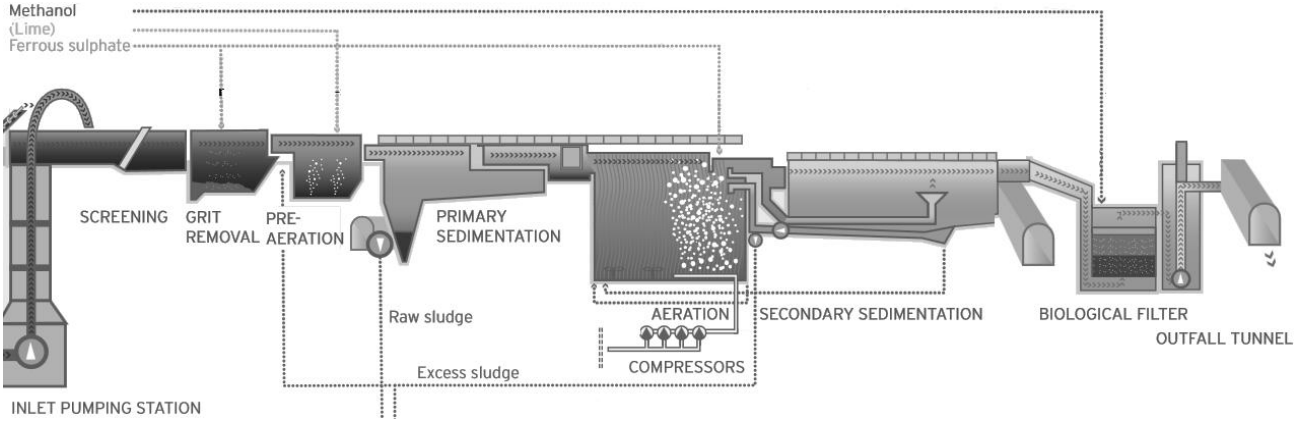

Figure 1. The wastewater treatment process at Viikinmäki. Modified from (HSY, 2016).

$$h_i = \frac{x_i - \bar{x}}{\bar{x}} \quad (1)$$

where h_i and x_i are the heterogeneity and the measurement result for sample i, respectively and $\bar{x}$ is the average of measurements x_i. The semi-variogram is calculated as:

$$v(j) = \frac{1}{2(N - j)} \sum_{i=1}^{N/2} (h_{i+j} - h_j)^2 \quad (2)$$

where $v(j)$ is the relative standard error between samples collected with lag j and N is the number of samples in the data set. The intercept $v(0)$ is estimated based on a linear extrapolation of the first $N/10$ (floored) points of the variogram. The index describing the relative information content of the measurement and thus the criterion for variable selection is calculated as relation between the estimated sampling error $v(1)$ and process variability s_P:

$$I = \frac{v(1)}{s_P} \quad (3)$$

A low value of the index I indicates that a single sample of that measurement can describe the present process variability with good accuracy. On the other hand, high value for I indicate that the relative information content of the measurement is low either due to higher sampling error or lower variability in the process.

2.4 Modeling

A k-fold cross-validation is a typical resampling method for predicting the fit of a model for a validation set, when dataset is small, and the split to separate training and validation subsets is not possible without a significant loss of data. Efficient training and validation require long and representative subset of data for both. In environmental related processes, the source dataset for model training should also encompass at least one full year of measured data because the temperature and rainfall, for instance, change depending on the season of the year and affect the process. In k-fold cross-validation, the original dataset is randomly partitioned into k subsets of equal size. One subset is used as a validation data for testing the model and the remaining k–1 subsamples are used as training data. The cross-validation process is repeated k times and each of the subsets is used only once as the validation data. A single estimation is then produced by combining these k results of the folds. Optimal k is often reported being between five and ten folds because statistical performance does not increase notably for larger values of k, and averaging over less than ten splits is computationally feasible. In this study, five-fold cross-validation was used. Multivariable linear regression (MLR) was used to predict an output variable as a linear combination of selected input variables as:

$$Y = b_0 + b_1 X_1 + b_2 X_2 + ... + b_n X_n + e \quad (4)$$

where b_o is a constant value, $b_1 \ldots b_n$ are the n regression coefficients, $X_1 \ldots X_n$ independent variables and e is the error. The performance of the model was evaluated by using Root Mean Square Error (RMSE) and coefficient of determination (R^2), which can be used to compare the relative performance of the models. (Rao *et al*, 2008; Arlot, Celisse 2010)

3 Results and Discussion

The dataset used in this work consisted of optical monitoring results and wastewater treatment process measurements from a period of over one year. On-line optical monitoring measurements were carried out at least once a day, but the laboratory measurements, on the other hand, were done only two to three times a week. During the process maintenance stoppages or occasional problems with the device, the optical measurements could not be performed. The missing laboratory and on-line data was not interpolated in this study. Thus, the total number of data points was 94 observations for 50 variables. Measurement data was scaled to range [-2, 2] before variable selection as in (Tomperi *et al*, 2017). Only variables that are useful and reliable to measure were selected. The variables from as early stage of the process as possible were preferred in order to establish models which could give proactive information of the quality of biologically treated wastewater.

Table 1. Variable selection using variogram.

Variable	Value of criterion
Fractal dimension[1]	0.17
Aspect ratio[2]	0.18
Temperature[3]	0.22
Median area of objects[4]	0.25
Filament length[5]	0.27
Roundness[6]	0.30
Sludge age[7]	0.31
Amount of filaments	0.32
Suspended solids	0.33
Number of small objects	0.34

In this study, variogram was utilized as a variable selection tool for searching the optimal subset of variables for model development. The variogram-derived indices and ten first selected variables are presented in Table 1. As seen, the most of the variables are on-line optical monitoring variables and only three of ten variables are process measurements. In comparison, five other variable selection methods tested

in (Tomperi *et al*, 2017), resulted as a suspended solids model with only one on-line optical monitoring variable (fractal dimension) and six process measurements (influent total nitrogen and sulphate, mechanically treated wastewater iron and nitrate nitrogen, temperature and anoxic proportion). Plausible reason is the lower variance of the optical monitoring variables, which shows in variogram as lower error-estimate and lower value of criterion. The earlier data analysis also showed that the quality parameters of biologically treated wastewater (BOD, COD, SS) have high mutual correlation and follow the changes of the temperature: the quality of treated wastewater was good in summer time when wastewater was warmer. The optical monitoring parameters also have several mutual correlations. For example, at summer time the amount and length of filaments was low, flocs were larger, the roundness of flocs was higher and the number of objects was lower (Tomperi *et al*, 2017). Hence, several variables in Table 1 have high mutual correlations which affect the results of model validation.

Seven input variables (n=7, 1-7 in Table 1) were selected for developing linear models for suspended solids, BOD and COD in biologically treated wastewater. The fitness of the models was predicted using 5-fold cross-validation. The results of modeling, the R^2 and RMSE values, and the regression coefficients of each developed model, are presented in Table 2. The results presented here can be considered satisfactory although in (Tomperi *et al*, 2017) the R^2 values of the SS model were between 0.79 (received using the genetic algorithm subset variable selection) and 0.71 (received using the correlation based variable selection), and the RMSE values were between 0.47 and 0.55. In the same study, the R^2 values of the BOD model were between 0.55 and 0.45, and R^2 values of the COD model were between 0.56 and 0.45.

The performance of variogram-based model for suspended solids in biologically treated wastewater is presented in Figure 2, together with the correlation-based model from the earlier study (Tomperi *et al*, 2017). All models developed using input variables selected by the variogram method have the most difference to the measured value of BOD, COD and SS at the same point: between 10-20 data point and around 40 and 75 data point. The visual interpretation also indicates that the modeling results with the variogram based variable selection contains less fast fluctuations.

The results of this study show that the variogram based tool has potential in selecting input variables for developing predictive models of treated wastewater quality even though the performance of the models was not as high as in the earlier study. Expert knowledge is required to improve the performance of the models. However, it should also be noted that the computational effort of variogram-based variable selection was minimal (less than 0.5 sec.) and implementation of the method was considerably easier than for example with genetic algorithm and successive projections algorithm, whose computational time was tens of minutes. Although the variogram-based variable selection has limited performance in the tested dataset, the method is seen interesting as it could also be developed into a recursive variable selection method due to its computational performance.

Table 2. The modeling results and the regression coefficients of input variables

Variable	R^2	RMSE	b_0	b_1	b_2	b_3	b_4	b_5	b_6	b_7
BOD	0.45	0.71	-0.64	0.47	0.67	0.09	-0.08	0.60	0.12	-0.11
COD	0.37	0.75	-0.35	-0.43	0.39	0.22	0.02	0.37	0.49	-0.13
SS	0.60	0.64	-0.61	-0.47	0.33	-0.25	0.15	0.52	0.67	-0.20

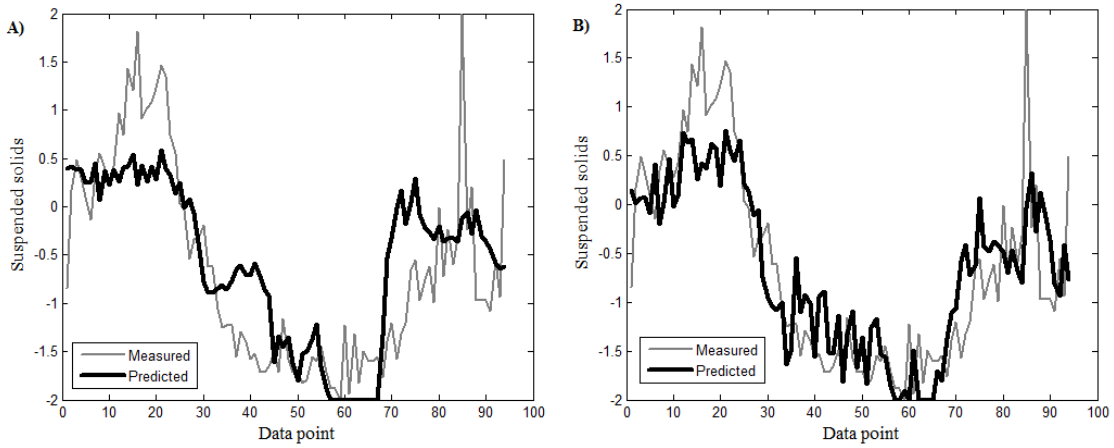

Figure 2. Measured and predicted suspended solids in biologically treated wastewater as scaled values, A) variogram based selected variables, B) correlation based selected variables (Tomperi *et al*, 2017).

4 Conclusions

In this study, a variogram method was utilized as a variable selection tool. Selected variables were used as input variables in predictive models of BOD, COD and suspended solids, which are important and critical quality parameters of the wastewater treatment process efficiency. Dataset included process measurements and the results of a novel optical monitoring method from a period of one year. Five-fold cross-validation was used to evaluate the performance of the developed models.

The presented results of variable selection show that the variogram based tool has potential in selecting input variables for developing predictive models of treated wastewater quality even though the fitness of the developed models was not as high as in the earlier study. The variogram method is, however, easier to implement and faster to use than some traditional variable selection methods. Nevertheless, the results can be considered satisfactory and the developed models can be used for proactive monitoring and estimating the quality of treated wastewater in several stages hours before in comparison to laboratory analysis taken from the treated water.

Abstract

In wastewater treatment, the dewatering of sludge is one of the most important steps, because it affects largely in both the process economics and the costs of sludge disposal. To optimize the dewatering processes, it would be beneficial to be aware of the different water types present in the sludge. In addition to free water, generally there are also mechanically, physically and chemically bound water within the sludge. All these water types behave differently when the sludge is dried, and they all require a different amount of energy when being removed. In this study, the Independent Component Analysis (ICA) method has been applied to an analysis of NMR (Nuclear Magnetic Resonance) relaxation data obtained from the measurement of wastewater sludge samples with a known moisture content. The results strongly suggest that the ICA method can be used for determining the amount of different water types within the wastewater sludge without a priori knowledge on their shares.

Keywords: independent component analysis, water content, nuclear magnetic resonance, sludge, relaxation decay

1 Introduction

Sludge is a semi-solid by-product remaining after wastewater treatment, industrial or refining processes. It is a separated solid suspended in a liquid, characteristically comprising large quantities of interstitial water between its solid particles (Global Water Community, 2015). This material can be dried to reduce its volume and to remove most of the moisture content of the solids within the sludge (Global Water Community, 2015). In wastewater treatment, the dewatering of sludge is one of the most important steps, because it affects largely both the process economics and the costs of sludge disposal.

It is suggested by several authors that the moisture in activated sludge can be classified to the following four categories (Kopp & Dichtl, 2000; Vesilind 1994; Tsang & Vesiling, 1990; Vesilind & Hsu, 1997; Smith & Vesiling, 1995):

- **Free** water: water which is not bound to the particles, including void water not affected by the capillary force.
- **Interstitial** water: water bound by capillary forces inside crevices and interstitial spaces of flocs.
- **Surface** water: water bound to the surface of solid particles by adhesive forces.
- **Bound** intracellular water.

This is a widely accepted classification and can be used as the reference in determining the main water types of sludge.

Another classification of water types in sludge is to divide it in three groups, i.e. 1) free water, 2) mechanically bound water, and 3) physically or chemically bound water. The free water in sludge can be easily removed by mechanical means, whereas the bound water is held firmly within the floc, bound to the sludge or trapped between the sludge particles, and thus cannot be easily removed (Jin *et al.*, 2004). The bound water can be further divided into chemically or physically bound water which is removable only by thermal drying, and mechanically bound water which is bound by weaker capillary forces (Colin & Gazbar, 1995).

In summary, it has to be emphasized that determining the water types is not straightforward, and based on the literature it is difficult to reach an unambiguous interpretation on the distribution of water within activated sludge (Vaxelaire & Cézac, 2004). Furthermore, there seem to be no studies concentrating on the analysis of water types in sludge without a priori knowledge of the shares of different water types.

Time domain nuclear magnetic resonance method (TD- NMR) is also becoming highly attractive for industrial applications due to relatively low price, mobility, easy operating, and simple sample preparation procedure. The most successful applications of TD-NMR confirmed by international standards are solid fat content determination in food and water (ISO 8292) and oil content in oilseeds (ISO 10565). They are based on the difference of NMR parameters of water and lipids and a low exchange degree between these two fractions.

A possibility to use the same principle for analysis of lipid content in microalgae (Gao *et al.*, 2008), for analysis of oil content of olive mill wastes and municipal wastewater sludge (Willson *et al.*, 2010) was demonstrated. Effects of flocculation on the bound water in sludge as measured by the NMR spectroscopy has been studied by Carberry and Prestowitz (1985).

Moreover, the international standard for hydrogen content determination in aviation fuels (ASTM D7171 – 05, 2011) has been developed recently. Metal ions, particularly paramagnetic ions, can also change significantly relaxation times in water and biological samples (Yilmaz *et al.*, 1999; Grunin *et al.*, 2013) which can be applicable when controlling wastewater treatment. Time domain NMR data have also been used in analyzing the water contents of wood and peat based fuels (Nikolskaya *et al.*, 2011) and monitoring the precipitation of metals in mine waters (Nikolskaya *et al.*, 2015).

Independent component analysis (ICA) is a statistical method that has been successfully applied to a variety of problems in signal processing (Hyvärinen *et al.*, 2001). For example, the method has been applied to a variety of problems in several fields such as brain imaging (Pulkkinen *et al.*, 2005; Calhoun *et al.*, 2002), vision research (Zhang & Mei, 2003; Ameen & Szu, 1999), telecommunications (Ristaniemi & Joutsensalo, 1999) and financial research (Kiviluoto & Oja, 1998; Back & Weigend, 1997). ICA is a method for extracting underlying, fundamental factors or components from multivariate data. It is designed so that it searches for components that are both statistically independent and non-Gaussian (Hyvärinen *et al.*, 2001), which makes it a distinguished method among the other techniques.

The complexity of spectral information can be approached by assuming that the obtained spectra are statistically independent. Principal component analysis (PCA) is the standard approach to analyze spectral data (Hyvärinen *et al.*, 2001). PCA is based on second-order statistics, which is applicable in the analysis of Gaussian distributed data. However, spectral data can comprise interesting information having a non-Gaussian distribution that can potentially be analyzed with ICA.

In the present study, the ICA method has been applied to an analysis of NMR relaxation data obtained from the measurement of wastewater sludge samples with a known moisture content.

2 Materials and methods

2.1 NMR measurements

The seven sludge samples (See Table 1) were obtained from an industrial waste water treatment plant. The samples were gathered after the dewatering stage of the process. The water contents of samples were measured using the standard oven drying method.

Relaxation times measurements were done using a mobile NMR device with a 1H resonance frequency of 25.7 MHz (Resonance Systems Ltd). The device has been modified for online measurements in industrial conditions. The permanent magnet of 0.6 T has dimension of 140x190x150 mm weighting 19 kg. The diameter of sensor hole was 10 mm. CPMG (Carr-Parcell-Meiboom-Gill) pulse sequence for spin-spin relaxation time T2 measurements was used.

Table 1. Description of sludge samples

Sample ID	Water content [%]
Sample 1	54
Sample 2	68
Sample 3	75
Sample 4	79
Sample 5	83
Sample 6	85
Sample 7	89

2.2 Independent Component Analysis

It is assumed here that there are n observed signals (i.e., types of water), WS_1, WS_2, ..., WS_n in the data, which are linear combinations of m independent components, IC_1, IC_2, ..., IC_m. The equation for IC_i can be written as:

$$WS_i = a_{i1}IC_1 + a_{i2}IC_2 + \cdots + a_{im}IC_m = \sum_{j=1}^{m} a_{ij}IC_j \quad (1)$$

where i = 1, 2, ..., n and the a_{ij} are real coefficients (contributions of ICs). The independent components, IC_j, and also the corresponding coefficients, a_{ij}, are unknown.

The statistical model in Eq. (1) is called the independent component analysis model (Hyvärinen *et al.*, 2001). The ICA model is a generative model that describes how the observed data are generated by a process of mixing the components IC_i. Both IC_i and a_{ij} need to be estimated using the observed data. The starting point for ICA is the assumption that the components IC_i are statistically independent, which can be concluded from non-gaussianity (Hyvärinen *et al.*, 2001). Here, a fixed-point algorithm (Fast-ICA) was used as an implementation of ICA (Hyvärinen *et al.*, 2001). The analysis was performed using the Fast-ICA toolbox under the Matlab software platform (Mathworks, Natick, MA, USA).

After the analysis, the relative shares of each component can be calculated using the following formula:

$$a_{ij,rel} = \frac{a_{ij}}{\sum_{j=1}^{m} a_{ij}} \times 100 \quad (2)$$

3 Results

The original NMR measurement signals can be seen in Fig. 1. It can be seen that there is a clear dependency between the amplitude of the signal and the moisture content of sludge samples. The gained NMR relaxation data were then analyzed by the ICA method based on the Hyvärinen's fixed-point algorithm (Hyvärinen *et al.*, 2001). Several numbers of ICs were tested, and three ICs were eventually used, because this setting was found to yield the most consistent and stable results. The three independent components (IC) can be seen in Fig. 2. It can be seen that all three ICs have their own, independent behavior.

According to theory, the share of bound water from the total amount of water remains stable in the sludge when the water content is increased from 0 on to a certain point (See Fig. 3, above). After this point, other types of water start to accumulate. When moisture content is 100%, all water is considered to be in a free form, but when the sludge is dried, the share of free water decreases dramatically, and the share of bound water increases. The share of the so called interstitial water (bound by weaker capillary forces) reaches its highest value at around 70 – 90 % moisture content.

In Fig. 3 (below), the calculated relative shares of different water types as a function of the total water content of the samples can be seen. It can be seen that the measured and analyzed values roughly follow the theoretic values and thus support them.

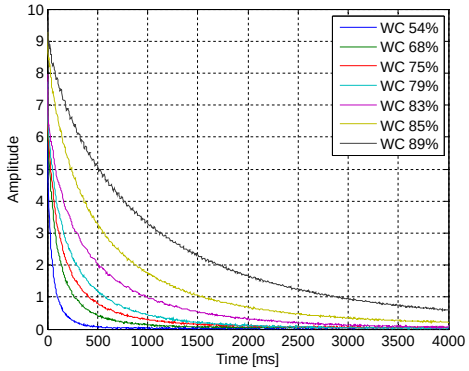

Figure 1. The observed NMR measurement signals (WS) from the 7 samples. WC = the water content of sample.

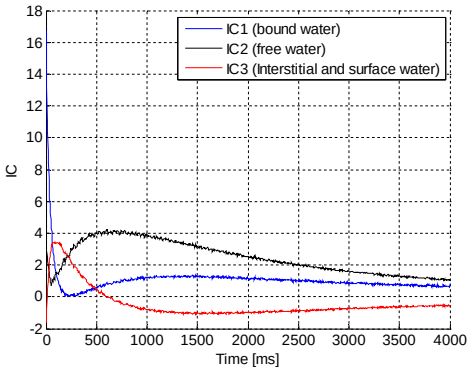

Figure 2. The three independent components (IC) computed from the NMR relaxation data.

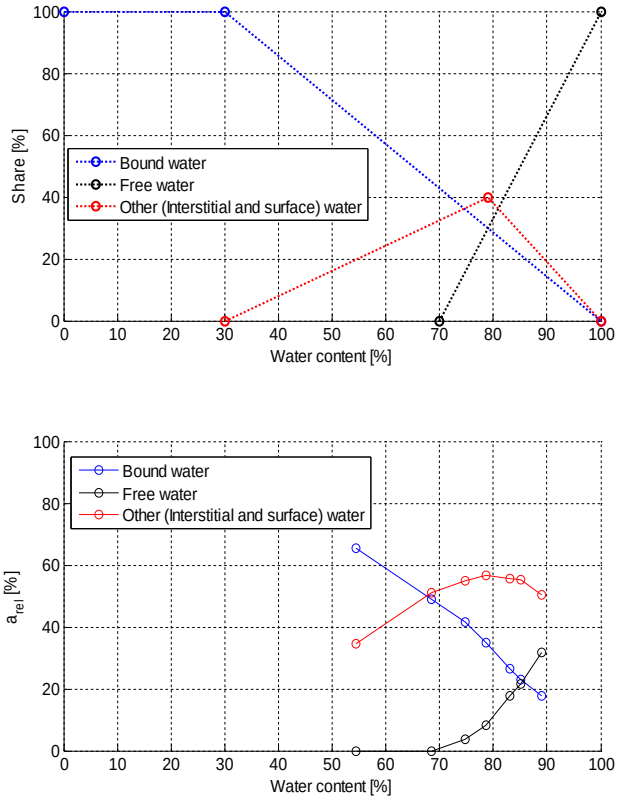

Figure 3. Theoretic (above) and calculated (below) relative shares of different water types as a function of the total water content of the samples.

4 Discussion

Measurement of the different water types in sludge is an exceptionally challenging problem, and to our knowledge this has not been tried before. In this respect, the results are extremely promising.

ICA is a universal statistical technique in which observed data are linearly transformed into components that are maximally independent from each other. A key issue in using the ICA method is to decide the number of ICs to be estimated. For the data set used, only the physically meaningful components were chosen. Our results support the use of three independent components in this case. This suggests that there are three types of signals in this data.

There is no universal truth on how many water types are present in sludge. The four water types including free, interstitial, surface and bound water, are widely accepted, but also other viewpoints exist. In this particular case three independent components could be most easily extracted from the NMR relaxation data. This suggests that there are three signals that are maximally and statistically independent when it comes to their spectra, but this does not mean that there could be more water types present as well.

Based on the results it seems that the combination of time-domain NMR and ICA can be used for determining the amount of different water types within the

wastewater sludge. It is also beneficial that the ICA method does not require a priori knowledge on the water types and their shares in the sludge. This makes it very specific and a promising approach to optimize the dewatering processes of sludge.

5 Conclusions

Based on the results it can be concluded that incorporating ICA into data analysis allows for decomposition of independent, systematically occurring patterns in NMR relaxation data. This new information can be used for guiding further study and may lead to a way of extracting the shares of different water types in wastewater sludge. This would help in making the sludge dewatering more economical and in reducing the costs of sludge disposal.

Firing Accuracy Analysis of Electromagnetic Railgun Exterior Trajectory Based on Sobol's Method

Dongxing Qi, Ping Ma*, Yuchen Zhou

Control and Simulation Center, Harbin Institute of Technology, Harbin, P.R. China
QiDongxing01@163.com, PingMa@hit.edu.cn, ZhouYuchen-01@163.com

Abstract

Firing accuracy is an important index in the performance evaluation of electromagnetic railgun (EMRG). Based on a Six-DOF (degree of freedom) computer model of exterior trajectory, Sobol's method, a global sensitivity analysis approach, is utilized to analyse the influence of multiply model inputs with uncertainty on the strike accuracy of EMRG projectile. The method utilizes the firing data error and the dispersion error as the firing accuracy assessment factors of the projectile, and the input data are sampled based on Latin Hypercube Sampling (LHS). Furthermore, an example is provided, in which Sobol's method is applied in the analysis and calculation of the exterior trajectory. First-order sensitivity and total sensitivity of each factor are obtained, and then we identify the impact mechanism and interaction of different input parameters having on firing accuracy. Finally the results verify that the method is feasible and effective in the process of performance analysis of EMRG exterior trajectory.

Keywords: Sobol's method, firing accuracy, sensitivity analysis, EMRG

1 Introduction

Electromagnetic railgun (EMRG) is a typical representative of the electromagnetic emission weapons. As a new concept of weapon-system, EMRG has the advantages of quick response, hypersonic speed, and high damage efficiency for remote ground target strike mission (Fair, 2009; Ma, 2007) compared with conventional guns. And firing accuracy is an extremely important indicator to measure the operational performance of the EMRG. Nowadays, especially with the rapid development of science and technology, the accurate attack of railguns is strongly stressed by each country's military personnel (Fair, 2005). It's extremely necessary and urgent to analyze the shooting accuracy of the EMRG accurately.

Currently, the domestic and foreign research on the analysis of firing accuracy of EMRG is still in infancy. Shared research about EMRG system firing accuracy analysis is limited. Most of the studies concentrated on the analysis of guns system problems. Guo had in-depth research in detail in artillery weapons system. Reference (Guo, 2001) described the calculation method of gun's firing accuracy and the influence of various factors on the firing accuracy. But for the EMRG system, there are few complete solutions to analyze its firing accuracy precisely. Therefore, figuring out how to analyze the EMRG firing accuracy exactly is essential.

As an important tool for modeling, sensitivity analysis can let the modeler know the influence of the model parameters and inputs to the model outputs. It can be utilized effectively in modeling, model testing, and model calibration. There are a lot of classification methods about the sensitivity analysis, among which the basic idea of Sobol's global sensitivity analysis method is to study the effect of variance of the inputs parameters to the variance of outputs, using integration to describe the sum of progressive increase items factorized by system functions, then calculate ratios of the total variance to each partial variance to get the accuracy after sampling (Sobol, 2013). Compared to other methods of sensitivity analysis, Sobol's method can calculate different order sensitivity more efficiently and accurately, and it can also get the impact index, named total sensitivity which reflects the interaction of all factors. Thereby we can analyze the influence of each factor having on EMRG firing accuracy.

Sobol's method is widely applied in the field of economy, environment and climate (Yu, 2004). In this paper, we analyze the firing accuracy of electromagnetic railgun exterior trajectory by Sobol's method. Taking six factors as the research objects, such as the quality, muzzle and velocity, the first-order sensitivity and total sensitivity of each factor are calculated by the method. In the end, the influence mechanism of various factors on firing accuracy and the interaction among them is gained. The process verifies that Sobol's method is feasible in the process of accurate analysis and provides a foundation for optimizing EMRG's performance.

2 Exterior Trajectory Simulation of Electromagnetic Railgun

The model of EMRG exterior trajectory describes the process of projectiles' movement after leaving the railgun with a high speed in the atmosphere (Keshmiri,

2004; Keshmiri, 2007). It is the foundation of exterior trajectory simulation and the characteristic analysis of trajectory. The paper considers EMRG's shooting range, high altitude flight, the variation of the earth curvature and gravitational acceleration. The Six-DOF model of projectiles is built in the paper. In the model, the projectile of the EMRG is considered as a particle, and Six-DOF motion equations are established. Those are dynamic equations of projectile's centroid, dynamic equations around the centroid, kinematics equations of the centroid, kinematics equations around the centroid and the relevant initial parameters. Run the simulation program, corresponding EMRG exterior trajectory simulation results can be got.

2.1 Simulation Framework

The diagram of the simulation process is shown in Figure 1. By setting the initial projectile conditions and flight termination conditions to limit projectiles flight process, the projectile's flying state in each simulation step is determined by calculating atmospheric parameters and flight parameters of the projectile. After confirming EMRG exterior trajectory simulation process, the MATLAB programming language is utilized to achieve it.

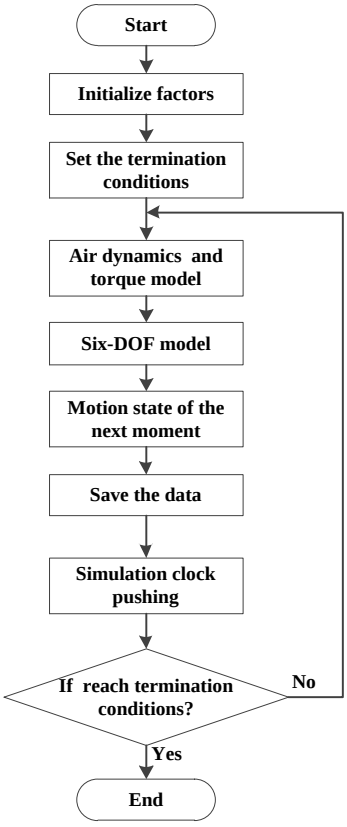

Figure 1. Electromagnetic railgun exterior trajectory simulation process.

2.2 The Experimental Design Method

In order to ensure the reliability of the projectile firing accuracy analysis which is based on the Six-DOF model, reasonable experimental design method should be chosen. Latin Hypercube Sampling (Deng, 2012) is employed in the paper. The method has great one-dimensional projection and stratified distribution characteristics, which can cover upper and lower limits of the probability distribution uniformly and distribute random number to each interval evenly. In this way, sampling frequency declines and the result remains stable. A lot of duplicate sampling work can be avoided, which improves efficiency of sampling (Ding, 2013; Zhong, 2009). The basic steps of LHS are as follows.

Set the objective function

$$y = f(x) \tag{1}$$

where y is a output variable, f is a definite function model, $x = \{x_1, x_2, \cdots, x_k\}^T$ is input variable, k is the number of input variable. Each input variable $x = \{x_1, x_2, \cdots, x_k\}^T$ subjects to a known probability distribution function $F_i(x_i)$. First of all, the input variable x_i should be sampled randomly. When random sampling, M random numbers should be generated between 0 and 1 firstly, and then transform them using the equation as follows

$$U_m = U/M + (m-1)/M \tag{2}$$

where $m = 1, 2, \cdots, M$, U is a random number between 0 and 1. U_m are the random numbers in the m'th interval.

Depending on equation(2), obviously, there is only one generated number in each interval. Because

$$(m-1)/M < U_m < m/M \tag{3}$$

where $(m-1)/M$ and m/M are the lower bound and upper bound of the m'th interval.

LHS strictly ensures the entire area was uniformly sampled, and it is almost impossible to sample repeatedly. Therefore, the method can convergence to a smaller sample size.

3 The Analysis of Electromagnetic Railgun Firing Accuracy

Electromagnetic railgun firing accuracy is influenced by multiple factors, and the influence of various factors is not identical. Meanwhile, there may be a certain coupling relationship between different factors. Thus, it is significant to analyze the impact of various factors on projectiles' firing range and direction, confirm the main factors. This section introduces the definition of firing accuracy, and gives the overall process of electromagnetic railgun firing accuracy analysis.

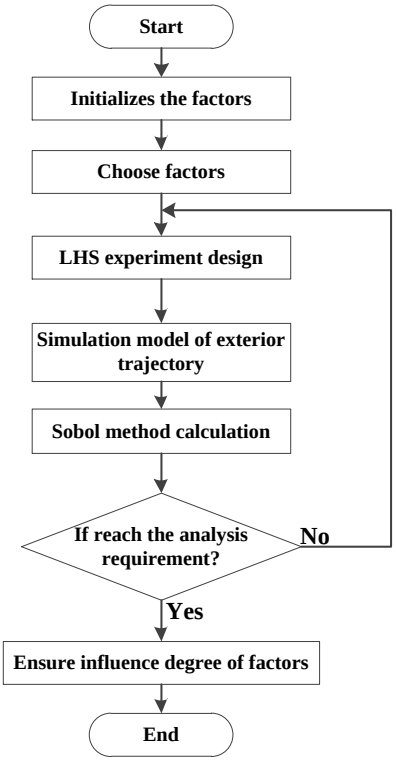

Figure 2. Process of electromagnetic railgun firing accuracy analysis.

3.1 Firing accuracy

In order to facilitate the research of the electromagnetic railgun firing accuracy, suppose that the shooting target of the electromagnetic railgun is on the ground, which is shown in Figure 3.

Assuming that the origin O is the shooting center, the deviation between projectiles average placement and shooting center is $\overline{\Delta}$, the coordinates relative to the shooting center are $(\overline{X},\overline{Z})$. The deviation between each projectile placement and shooting center is Δ, the coordinates relative to the shooting center are (x,z). The deviation of between each projectile placement and their average placement is Δ_r. For each projectile, the deviation between each projectile placement and shooting center Δ can be expressed

$$\Delta = \overline{\Delta} + \Delta_r \tag{4}$$

where Δ is the firing error, $\overline{\Delta}$ is the dispersion error, Δ_r is the firing data error. They can be written as

$$\Delta = \left[x, z\right]^T \tag{5}$$

$$\overline{\Delta} = \left[\overline{x}, \overline{z}\right]^T \tag{6}$$

$$\Delta_r = \Delta - \overline{\Delta} = \left[x_r, z_r\right]^T \tag{7}$$

where x and z are the components of the firing error in x axis and z axis; $\overline{x}$ and $\overline{z}$ are the components of the dispersion error in x axis and z axis; x_r and z_r are the components of the firing data error in x axis and z axis.

In the paper, the firing accuracy of projectiles is described by the components of the firing data error in x axis and z axis Δ_x, Δ_z and the components of the dispersion error in x axis and z axis E_x, E_z.

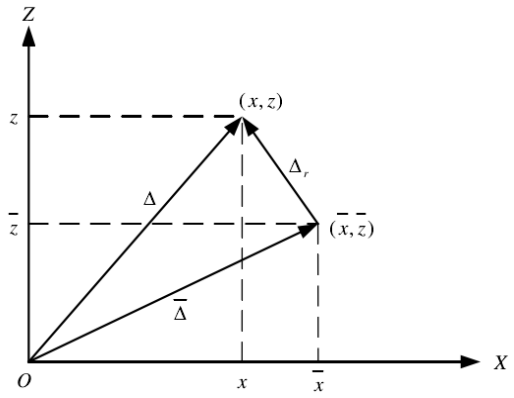

Figure 3. Projectile's firing error.

3.2 Sobol's Method

Sobol's method is based on the idea of model decomposition, 1, 2 times and higher sensitivity can be got through it (Sobol, 2013). Usually first-order sensitivity reflects the main influence parameters, and second order and higher sensitivity reflect the sensitivity among the parameters. To describe Sobol's method, firstly, one k dimension unit Ω^k should be defined as the spatial domain of input parameters (Saltelli, 2012). The main idea of Sobol's method is dividing the function $f(x)$ into some progressive increase items.

$$f(x_1,x_2,\cdots,x_k) = f_0 + \sum_{i=1}^{k} f_i(x_i) + \sum_{1\le i<j\le k} f_{i,j}(x_i,x_j) + \cdots + f_{1,2,\cdots,k}(x_1,x_2,\cdots,x_k) \tag{8}$$

where f(x) can be divided by multiple integral. In equation (8), f_0 is a constant. So we have

$$\int_0^1 f_{i_1,\cdots i_s}(x_{i_1},x_{i_2},\cdots,x_{i_s})\,\mathrm{d}\,x_{i_k} = 0 \tag{9}$$

From equation(8) and equation(9), each item is orthogonal, that is if $(i_1,i_2,\cdots,i_s) \neq (j_1,j_2,\cdots,j_l)$, then

$$\int_{\Omega^k} f_{i_1,i_2,\cdots,i_s} f_{j_1,j_2,\cdots j_l}\,dx = 0 \tag{10}$$

Thus

$$f_0 = \int_{\Omega^k} f(x)\,dx \tag{11}$$

The decomposition of equation(8) is unique, and each item can be got from multiple integral

$$f_i(x_i) = -f_0 + \int_0^1\cdots\int_0^1 f(x)\,dx{\sim}(i) \tag{12}$$

$$f_{i,j}(x_i,x_j) = -f_0 - f_i(x_i) - f_j(x_j) + \int_0^1\cdots\int_0^1 f(x)\,dx{\sim}(ij) \tag{13}$$

where $x{\sim}i$, $x{\sim}(ij)$ are the variables, except x_i and variables except x_i and x_j, respectively.

The total square deviation of f(x) is D

$$D = \int_{\Omega^k} f^2(x)dx - f_0^2 \quad (14)$$

The partial variance can be got though each items in equation (8).

$$D_{i_1,i_2,\cdots,i_s} = \int_0^1 \cdots \int_0^1 f_{i_1,i_2,\cdots,i_s}^2 \left(x_{i_1}, x_{i_2}, \cdots, x_{i_s}\right) dx_{i_1} \cdots dx_{i_s} \quad (15)$$

where $1 \le i_1 < \cdots < i_s \le k$ and $s = 1,2,\cdots,k$ .Calculate the integral of equation (15) squared in the region of Ω^k and from equation, we obtain

$$D = \sum_{i=1}^{k} D_i + \sum_{1 \le i < j \le k} D_{i,j} + \cdots + D_{1,2,\cdots,k} \quad (16)$$

Thus, sensitivity $S_{i_1,i_2,\cdots,i_s}$ can be described as

$$S_{i_1,i_2,\cdots,i_s} = D_{i_1,i_2,\cdots,i_s} / D, \left(1 \le i_1 < \cdots < i_s \le k\right) \quad (17)$$

Therefore, S_i is called the first-order sensitivity, $S_{i,j}$ is the second-order sensitivity, By that analogy total sensitivity S_{Ti} is

$$S_{Ti} = S_i + \sum_{i \ne j_1} S_{i,j_1} + \sum_{\substack{i \ne j_1 \\ i \ne j_2 \\ j_1 \ne j_2}} S_{i,j_1,j_2} + \cdots + S_{1,2,\cdots,k} \quad (18)$$

In the process of applying Sobol's method, to calculate the first-order sensitivity coefficient and total sensitivity coefficient of factors (Tarantola, 2012), assuming the gained sample $A_{N\times r}$, $B_{N\times r}$ from LHS, where N is sample size, k is the factor number, some equations are given like that

$$f_0 \approx \frac{1}{N} \sum_{j=1}^{N} f(A)_j \quad (19)$$

$$V + f_0^2 \approx \frac{1}{N} \sum_{j=1}^{N} f^2(A)_j \quad (20)$$

$$V_i + f_0^2 \approx \frac{1}{N} \sum_{j=1}^{N} f(A)_j f\left(B_A^{(i)}\right)_j \quad (21)$$

$$V_{-i} + f_0^2 \approx \frac{1}{N} \sum_{j=1}^{N} f(A)_j f\left(A_B^{(i)}\right)_j \quad (22)$$

where under the condition of A is unchangeable, change the i'th column of B into A to get $A_B^{(i)}$, and the same method to get $B_A^{(i)}$ .Thus the first-order sensitivity coefficient S_i and total sensitivity coefficient S_{Ti} of the parameter i can be written as

$$S_i = V_i / V \quad (23)$$

$$S_{Ti} = 1 - V_{-i} / V \quad (24)$$

4 Case study

In order to verify the effectiveness of the Sobol's method for the analysis of firing accuracy, in this section, the Sobol's method is applied in EMRG exterior trajectory sensitivity analysis. And the influence of each input factor on the firing accuracy is obtained. With the purpose of researching the influence of model output (ballistic range, m) according to the uncertain input factor of the model, six factors, which are mass, initial velocity, initial shooting angle, initial drift angle, y rotational angular velocities, and z rotational angular velocities may have an impact on ballistic range are extracted based on the prior knowledge, which is shown in Table 1.

Since a large number of interference parameters, in order to simulate the real environment, random wind along the positive direction of the Z axis is added to the model. After that 500 groups of testing conditions are designed by LHS. Take the series of testing conditions into the EMRG ballistic model, this series of processes are completed by simulation in MATLAB, scatter diagram is shown in Figure 1.

Table 1. Scope of Each Factor.

No.	Name of factor	symbol	units	value range
1	mass	m	kg	[9.9,10.1]
2	initial velocity	v	m/s	[1990,2010]
3	initial shooting angle	α	rad	[0.8373,0.9769]
4	initial drift angle	β	rad	[-0.001,0.001]
5	y rotational angular velocities	w_y	rad/s	[-0.001,0.001]
6	z rotational angular velocities	w_z	rad/s	[-0.001,0.001]

Table 2. Experimental Result of Longitudinal Dispersion.

Factor Names	m	v	α	β	w_y	w_z
First-order Sensitivity	0.2197	0.5851	0.5016	0.1359	0.1460	0.1440
Total Sensitivity	0.1931	0.2762	0.4432	-10^{-5}	-0.0014	0.0111

Table 3. Experimental Result of Lateral Dispersion.

Factor Names	m	v	α	β	w_y	w_z
First-order Sensitivity	-0.013	-0.012	-0.014	0.9935	-0.013	-0.014
Total Sensitivity	-0.001	0.0046	0.0013	1.0101	0.0013	10^{-5}

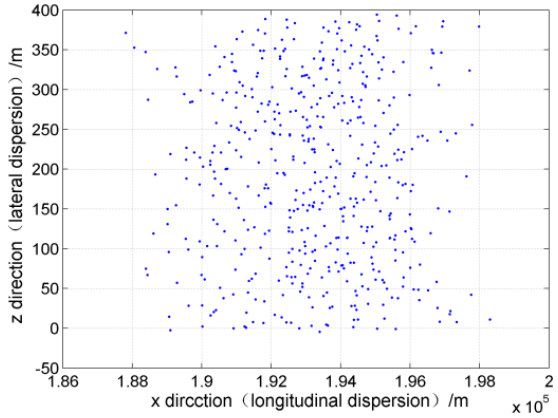

Figure 4. Scatter diagram of experiment.

The influence of each factor on the firing accuracy in two directions cannot be got from the simple scatter diagram. So we need the calculation of Sobol's method. The simulation in MATLAB needs to be run $(6\times2+1)\times500$ times. Analyze longitudinal dispersion and lateral dispersion, respectively. The experimental results are shown in and Table 3.

Transform the tables into histograms, as shown in Figures 5 and 6. From Table 2 and Figure 5, we can draw the conclusion that each factor has influence on the longitudinal dispersion and the influence degree is different. First-order sensitivity and total sensitivity of initial velocity, initial shooting angle and mass are large. Though comparing the first-order sensitivity and total sensitivity, it is explicit that influence of velocity on longitudinal dispersion decreases obviously under the comprehensive effect of multiple factors. On the contrary, the influence caused by the initial shooting angle and mass is mainly not affected by other factors. Furthermore, the sensitivity of the latter three factors is close and small. And there is poorly impact on longitudinal dispersion after they interact with other factors. In conclusion, there are three main influencing factors, initial velocity, initial shooting angle and mass under the designed experimental condition.

It is clear from Table 3 and Figure 6 that the first-order sensitivity and total sensitivity of initial drift angle all are largest (close to 1), and the sensitivity of other factors is very little (close to 0). It turns out that for the lateral dispersion, the impact of the initial drift angle is extremely significant and basically there is no effect on other factors. So in the process of testing the firing accuracy on lateral dispersion, initial drift angle should be taken into account particularly.

The first-order sensitivity in the table reflects the individual effect of each factor and the total sensitivity reflects the interaction among factors. It describes the effect of one factor on the firing accuracy under the interaction of other factors. Furthermore, the first-order sensitivity and the total sensitivity of each factor are different, which shows the interaction between the six factors is disparate.

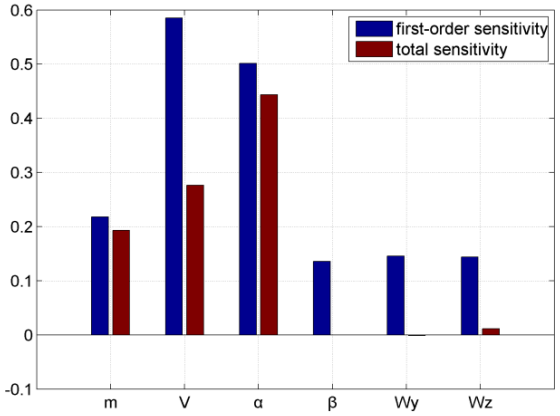

Figure 5. Result of longitudinal dispersion.

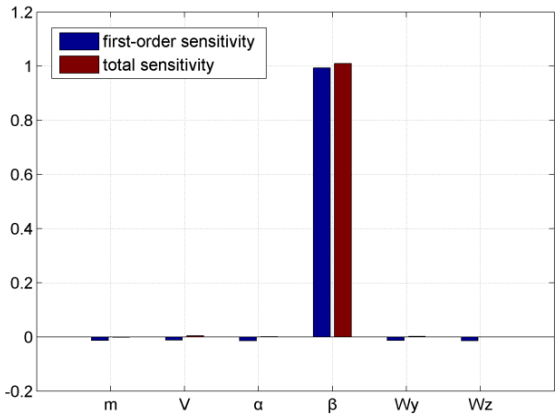

Figure 6. Result of lateral dispersion.

5 Conclusions

In this paper, the Sobol's method, a global sensitivity analysis approach, is applied to analysis of EMRG exterior trajectory firing accuracy. Single influence and interaction among each factor can be analyzed using the method, especially in the analysis which has much uncertain impact factors, a wide range of design parameters and obvious interactions between each factor. Simulation analysis results using Sobol's method show that various factors have different impact on firing accuracy of EMRG exterior trajectory, which verifies that Sobol's method is feasible and effective for firing accuracy of it. Finally the impact mechanism of each input factor on the firing accuracy and the interaction among them is obtained. In this paper, the simulation of EMRG exterior trajectory, data collection and application of Sobol's method are all implemented in MATLAB. It is easy to achieve, but the simulation needs to take a long time. In order to improve it and make firing accuracy analysis faster and more accurate, EMRG exterior trajectory simulation and data analysis tools based on C++ and Visual Studio 2010 will be designed and achieved in the future.

Abstract

A simulation model of a paraglider flight is presented in this paper. The dynamics of the paraglider trajectory, as well as its twist angle are governed by a complex interplay between gravity and drag force. Differential equations describing this dynamical behaviour are developed by balancing all the forces and torques acting on the system. The developed model allows to compare different flight situations and find out optimal values of the parameters, which may be used in further steps for example optimization of the towing process. Simulation results of the paraglider launch process using a vehicle unreeling winch and subsequent gliding under different wind conditions are compared with real data.
Keywords: paraglider, gliding flight, towing process, aerodynamics, simulation, modelling

1 Introduction

In the 1960s, a hype about paragliding started in Europe. The performance of gliders increased significantly and the crafts were easier to control due to advanced designs. This was a major step towards making the flight safer (Currer, 2011). However, the development of modern paragliders, the ones we know today, needed a long time. There are some competitions in different disciplines as well, whereby aerial acrobatics like spiral dives or full stalls are often performed (Whittall, 2010). Most pilots drive to big mountains like the Alps to enjoy paragliding.

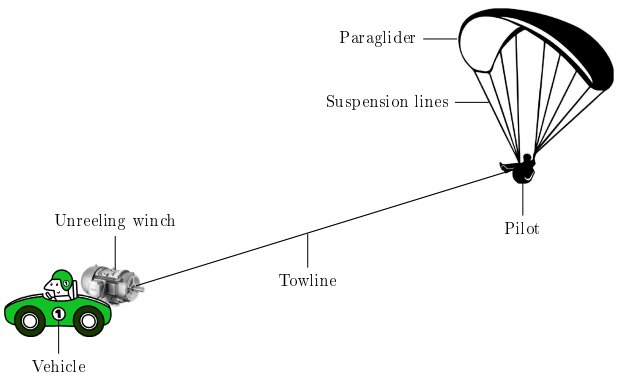

Figure 1. Winch tow launch.

Potential energy or a start altitude is transformed into kinetic energy to bridge distances as long as possible. This process is called "gliding flight". But there is an alternative method for paragliding as well. The so called winch tow launch can also be used in lowlands (see Figure 1). With the help of an unreeling winch mounted on the back of a vehicle the pilot is pulled into the air. Various parameters can be influenced during this process to reach the best possible outcome. A simulation model of the towing procedure can be helpful for optimisation of the process.

The standard reference written by Janssen et al. (2013) for paragliders and hang gliders provides guidelines about different security measures to prevent hazard situations. Consequently, it is an ideal guide for trainee pilots as well as experienced gliders. Whittall (1995) introduced basic flying techniques and presented additional information about equipment, weather and soaring. Over the years, the aerodynamics and flight mechanics of paragliders improved continuously and the fundamentals of fluid mechanics as well as the involved physical processes are nowadays well understood (Oertel, 2005). A detailed description of the effective forces acting on the paraglider and the pilot during a gliding flight can be visualised with the help of a free body diagram (Voigt, 2003). This free body diagram can be augmented in order to describe the so-called towing process (see Figure 1), whereby the pilot starts from the ground and is lifted into the air (Fahr, 1992). A polar curve, also named as Lilienthal Curve (Karbstein, 1996), describes the ratio of sink velocity to air speed in x-direction for a specific glider under different operating conditions. It allows, as a decisive advantage, to predict the glider's performance (Currer, 2011).

In spite of all the improvements and understanding of physical phenomenon and parameters, there is no complete model available, which could be employed to simulate the dynamical behaviour of the system. The aim of this contribution is to derive such a mathematical model. It could be used to simulate the system behaviour in towing and gliding states. This could lead on one hand to analyse the performance, safety and stability of paragliders and to optimise the towing process on the other hand. This paper is organised as follows. A complete mathematical model of the system is derived in section 2. How this model can be parametrised, is discussed in section 3. Sec-

tion 4 presents some simulation results, while conclusions and a brief outlook are given in section 5.

2 Modelling

In order to develop the model a simplified free body diagram of the whole system is drawn in Figure 4. The mass of the paraglider m_g and the mass of the pilot M_p are assumed to be connected to each other rigidly. The aim is to derive differential equations describing translational and rotational dynamics of the system. A coordinate system "CS" is displayed next to the figures to define the positive axes and angles.

2.1 Centre of Gravity

The centre of gravity G is the point at which the sum of all torques due to gravitational forces equals zero. The two torques involved are the torque due to the weight of the pilot and the torque due to the weight of the paraglider. Consequently, the distance l_{MG} can be determined (see equation (2)). With this information, l_{Gm} is calculable with the help of the length of the suspension lines l_{line} as well (equation (3)). The line length is known from the data sheet provided by a paraglider manufacturer which is used as a reference glider in the simulation.

$$M_p \cdot g \cdot l_{MG} = m_g \cdot g \cdot (l_{line} - l_{MG}) \tag{1}$$

$$\Leftrightarrow l_{MG} = \frac{m_g \cdot l_{line}}{M_p + m_g} = \frac{m_g \cdot l_{line}}{m_t} \tag{2}$$

$$l_{Gm} = l_{line} - l_{MG} \tag{3}$$

2.2 Aerodynamic Forces

Aerodynamics deal with forces caused by air flow around an object. Typical forces and angles of a paraglider in static conditions are shown in Figure 2. The notational symbols are explained in Table 1. The weight $F_{W,t}$ points

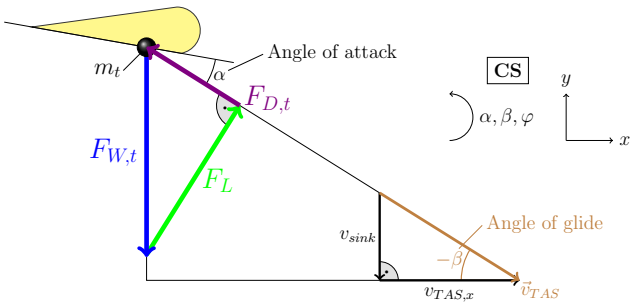

Figure 2. Aerodynamic forces.

vertically downwards and is compensated by the total aerodynamic force which is the resultant of the lift force F_L and the drag force $F_{D,t}$. They are perpendicular to each other whereby F_L creates the lift to glide through the air. The drag force $F_{D,t}$ is directed contrary to the direction of movement. Drag is caused by friction between paraglider and air and converts a part of the energy into losses. The

Table 1. Notations.

Symbol	Description
$F_{D,t}$	Drag force
F_L	Lift force
$F_{W,t}$	Weight
$T_{D,g}$	Paraglider torque caused by drag force
$T_{D,p}$	Pilot torque caused by drag force
T_L	Torque caused by lift force
T_{res}	Resultant torque clockwise
T_{start}	Start torque

half density of the air $\frac{\rho_{air}}{2}$ multiplied by the squared true air velocity $(v_{TAS})^2$ yields the dynamic pressure $p_{dynamic}$ of the air. The total drag force of a paraglider $F_{D,t}$ is equal to the dynamic pressure $p_{dynamic}$ multiplied by the projected area $A_{project}$ and the drag coefficient $c_{d,g}$ of the paraglider (Anderson, 2005).

$$F_{D,t} = c_{d,g} \cdot A_{project} \cdot \underbrace{\frac{\rho_{air}}{2} \cdot (v_{TAS})^2}_{p_{dynamic}} \tag{4}$$

Figure 2 displays how the total drag force $F_{D,t}$, under the assumption of static conditions, alternatively can be determined. It means that no acceleration force has an affect on the system. The drag force $F_{D,t}$ equals the total weight $F_{W,t}$ multiplied by the sine of the negative angle of glide $\sin(-\beta)$, which in turn is the sink velocity v_{sink} divided by the true air speed v_{TAS}.

$$F_{D,t} = F_{W,t} \cdot \sin(-\beta) = F_{W,t} \cdot \frac{v_{sink}}{v_{TAS}} \tag{5}$$

Equating equation (4) with equation (5)

$$c_{d,g} \cdot \frac{\rho_{air}}{2} \cdot A_{project} \cdot (v_{TAS})^2 = F_{W,t} \cdot \frac{v_{sink}}{v_{TAS}} \tag{6}$$

$$\Leftrightarrow c_{d,g} = \frac{F_{W,t} \cdot 2}{A_{project} \cdot \rho_{air}} \cdot \frac{v_{sink}}{(v_{TAS})^3} \tag{7}$$

The lift force F_L follows the same rule as the drag force (Anderson, 2005). The dynamic pressure $p_{dynamic}$ multiplied by the projected square $A_{project}$ and the lift coefficient c_l is equal to the lift force.

$$F_L = c_l \cdot A_{project} \cdot \underbrace{\frac{\rho_{air}}{2} \cdot (v_{TAS})^2}_{p_{dynamic}} \tag{8}$$

It is clear from Figure 2 that the lifting force F_L equals the total weight $F_{W,t}$ multiplied by the cosine of the negative angle of glide $\cos(-\beta)$ which is equal to the ratio of the horizontal velocity $v_{TAS,x}$ and the true air speed v_{TAS}.

$$F_L = F_{W,t} \cdot \cos(-\beta) = F_{W,t} \cdot \frac{v_{TAS,x}}{v_{TAS}} \tag{9}$$

Equating equation (8) with equation (9)

$$c_l \cdot \frac{\rho_{air}}{2} \cdot A_{project} \cdot (v_{TAS})^2 = F_{W,t} \cdot \frac{v_{TAS,x}}{v_{TAS}} \quad (10)$$

$$\Leftrightarrow c_l = \frac{F_{W,t} \cdot 2}{A_{project} \cdot \rho_{air}} \cdot \frac{v_{TAS,x}}{(v_{TAS})^3} \quad (11)$$

2.3 Definition of Angles

The tangent of the glide angle β, located between horizontal line and direction of movement v_{TAS} (see Figure 3), is calculated by the ratio of the air speed in y-direction to the air speed in x-direction (equation (12)).

$$\beta = \arctan\left(\frac{v_{TAS,y}}{v_{TAS,x}}\right) \quad (12)$$

The angle of attack α is the angle at which the airflow meets the wing (Currer, 2011) and is defined between the chord line and the direction of flight (see Figure 3). This angle influences the pendulum torque around the pitch axis mandatorily and can be controlled by the pilot via the brakes. The negative angle of glide $-\beta$ equals the angle

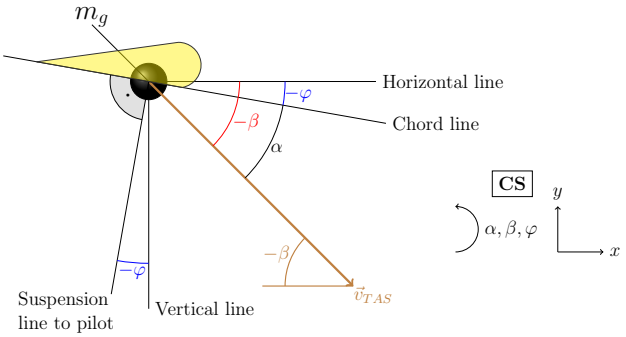

Figure 3. Definition of angles.

of attack α minus the angle of twist φ. Consequently, the angle of attack α is the difference of the angle of twist φ and the angle of glide β (see Figure 3).

$$-\beta = \alpha - \varphi \quad (13)$$

$$\alpha = \varphi - \beta \quad (14)$$

The negative angle of twist $-\varphi$ can also be found between the vertical line and the suspension line to the pilot. This information helps to determine the lever arms needed for the torque calculations (see section 2.4).

2.4 Lever Arms

As a next step the lever arms of the pendulum system have to be determined. Figure 4 clarifies the relationship between the angles of a paraglider (section 2.3) and the corresponding lever arms (section 2.4). The distances l_{Gm} and l_{MG} result from the position of the gravity point G which

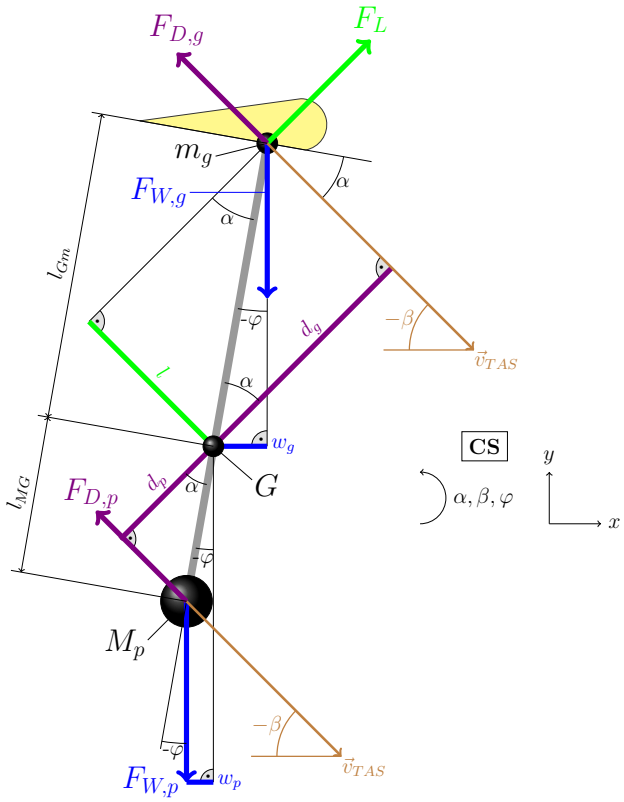

Figure 4. Lever arms.

has been calculated before in section 2.1.

$$w_g = l_{Gm} \cdot \sin(-\varphi) \quad (15)$$

$$d_g = l_{Gm} \cdot \cos(\alpha) \quad (16)$$

$$l = l_{Gm} \cdot \sin(\alpha) \quad (17)$$

$$d_p = l_{MG} \cdot \cos(\alpha) \quad (18)$$

$$w_p = l_{MG} \cdot \sin(-\varphi) \quad (19)$$

With the help of the lever arms the torques around the gravity point G can be determined (see section 2.6).

2.5 Catenary

If the pilot starts from the ground and is pulled into the air with the help of the towline, the situation slightly changes.

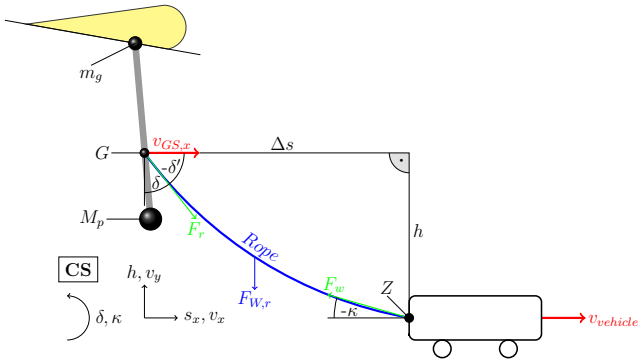

Figure 5. Catenary.

The weight $F_{W,r}$ of the rope causes a sag and results in a curved line, which directly affects the rope angles δ and κ (see Figure 5). The angles δ and κ are calculated recursively with the help of the catenary. The pilot starts from the ground and thus, the angle κ is at the beginning of the towing process zero ($\kappa_{initial} = 0°$). The catenary can be approximated by the following equation (Dankert and Dankert, 2009)

$$y(x) = C_2 \cdot x^2 + C_1 \cdot x + C_0 \tag{20}$$

where

$$C_2 = \frac{0.5 \cdot q_0}{F_w \cdot \cos(-\kappa)}. \tag{21}$$

The unknown parameters C_0 and C_1 are determined with the help of Figure 5. The height of the catenary at the position $x = 0$ equals

$$y(0\,\mathrm{m}) = C_0 = h \tag{22}$$

and at the position $x = \Delta s$

$$y(\Delta s) = C_2 \cdot \Delta s^2 + C_1 \cdot \Delta s + C_0 = 0 \tag{23}$$

$$\Leftrightarrow C_1 = \frac{-C_0}{\Delta s} - C_2 \cdot \Delta s. \tag{24}$$

Consequently the parameters C_1 and C_2 are defined. With the parameters C_0, C_1 and C_2 the rope angles δ and κ can be calculated. By differentiating equation (20) with respect to x results

$$\frac{\mathrm{d}y(x)}{\mathrm{d}x} = 2 \cdot C_2 \cdot x + C_1. \tag{25}$$

Figure 5 also displays the derivation at the position $x = 0$

$$\left.\frac{\mathrm{d}y(x)}{\mathrm{d}x}\right|_{x=0} = C_1 = \tan(\delta') \tag{26}$$

with $\delta' = \delta - \frac{\pi}{2}$ follows

$$\delta = \tan^{-1}(C_1) + \frac{\pi}{2} \tag{27}$$

as well as at the position $x = \Delta s$

$$\left.\frac{\mathrm{d}y(x)}{\mathrm{d}x}\right|_{x=\Delta s} = 2 \cdot C_2 \cdot \Delta s + C_1 = \tan(-\kappa) \tag{28}$$

$$\Leftrightarrow \kappa = -\tan(2 \cdot C_2 \cdot \Delta s + C_1). \tag{29}$$

By balancing the forces in x-direction (see Figure 5) results the rope force F_r which is needed for the following section 2.6.

$$F_r = F_w \cdot \frac{\cos(-\kappa)}{\sin(\delta)} \tag{30}$$

Until an altitude of 50 metres the constant winch force F_w is reduced to prevent large angles of attack α which could otherwise lead to dangerous flying situations. Safety is very important and gets top priority.

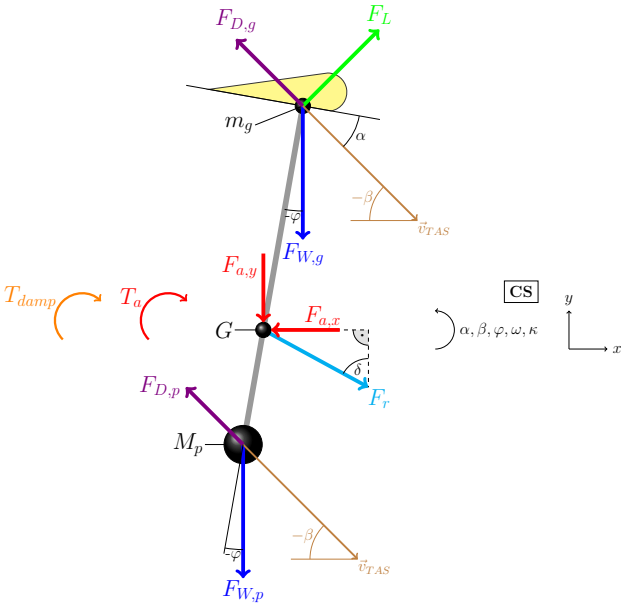

Figure 6. Balance of forces whilst towing.

2.6 Equations of Motion

Figure 6 displays the flight system whilst towing. For a gliding flight the rope force F_{rope} is zero. The algebraic sum of all forces in x-direction is zero. The acceleration force in x-direction equals the total mass m_t multiplied by the time derivative of the ground speed in x-direction $\dot{v}_{GS,x}$.

$$\begin{aligned} m_t \cdot \dot{v}_{GS,x} = &- F_{D,g} \cdot \cos(-\beta) - F_{D,p} \cdot \cos(-\beta) \\ &+ F_L \cdot \sin(-\beta) + F_r \cdot \sin(\delta) \end{aligned} \tag{31}$$

Balancing the forces in y-direction results in the following differential equation.

$$\begin{aligned} m_t \cdot \dot{v}_{GS,y} = &- F_{W,p} - F_{W,g} + F_{D,g} \cdot \sin(-\beta) \\ &+ F_{D,p} \cdot \sin(-\beta) + F_L \cdot \cos(-\beta) \\ &- F_r \cdot \cos(\delta) \end{aligned} \tag{32}$$

The algebraic sum of all torques around the gravity point G is zero. The lever arms have already been calculated in section 2.4 and are now used in equation (33). The accelerating torque around the gravity point G equals the total moment of inertia I_t multiplied by the time derivative of the angular velocity $\dot{\omega}$.

$$\begin{aligned} I_t \cdot \dot{\omega} = &+ F_{W,p} \cdot w_p - F_{W,g} \cdot w_g - F_{D,p} \cdot d_p \\ &+ F_{D,g} \cdot d_g - F_L \cdot l - T_{damp} \end{aligned} \tag{33}$$

The damping torque T_{damp} caused by the movement of the paraglider in the air equals the damping coefficient d multiplied by the angular velocity ω.

$$T_{damp} = d \cdot \omega \tag{34}$$

2.7 Velocities

The true air speed v_{TAS} is crucial to calculate the aerodynamic forces. It is the velocity of the airflow in relation to the aerofoil. In addition, the ground speed v_{GS} can be calculated with the true airspeed and the wind speed (Currer, 2011). The true air speed in x-direction $v_{TAS,x}$ is equal to the ground speed in x-direction $v_{GS,x}$ minus the headwind speed $v_{wind,x}$ (equation (35)). The true air speed in y-direction $v_{TAS,y}$ is equivalent to the ground speed in y-direction $v_{GS,y}$ minus the upwind speed $v_{wind,y}$ (equation (36)).

$$v_{TAS,x} = v_{GS,x} - v_{wind,x} \tag{35}$$
$$v_{TAS,y} = v_{GS,y} - v_{wind,y} \tag{36}$$

2.8 Self Stabilisation

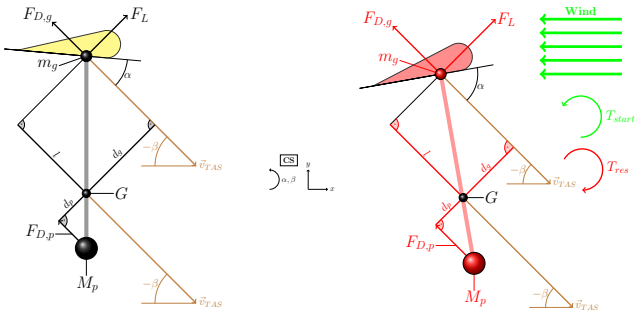

Figure 7. Self stabilisation.

A paraglider is sometimes exposed to turbulence conditions during a flight for example a sudden appearance of contrary wind (see Figure 7). The wind situation at higher altitudes is often different from the situation at ground. It is important to mention in this context that the torques due to weights cancel each other out if the paragliding system starts to swing (see equation (1)). Consequently, the weights $F_{W,g}$ and $F_{W,p}$ are not drawn in Figure 7. It displays a "standard" flight situation on the left and the reaction of the system due to headwind on the right side. This wind causes a counterclockwise torque T_{start}, which leads to an increase the angle of attack α. This affects lift and drag coefficients which are getting larger (see Figure 8). As a result, F_L and $F_{D,g}$ are also getting larger and the lever arms d_g and d_p shorter (see section 2.4). The only increased lever arm is l, which leads to an increase of T_L. This causes a self-aligning moment T_{res} trying to compensate the start torque. Consequently, the paraglider stabilises on its own and the pilot often does not have to intervene.

2.9 Complete Model

Now we summarize our discussion of previous sections and write the complete model of the system. The dynamics of six state variables of the system can be described by the following state equations.

$$\dot{s}_x = v_x \tag{37}$$
$$\dot{v}_x = \frac{1}{m_t} \cdot [-F_{D,g} \cdot \cos(-\beta) - F_{D,p} \cdot \cos(-\beta) + F_L \cdot \sin(-\beta) + F_r \cdot \sin(\delta)] \tag{38}$$
$$\dot{s}_y = v_y \tag{39}$$
$$\dot{v}_y = \frac{1}{m_t} \cdot [-F_{W,p} - F_{W,g} + F_{D,g} \cdot \sin(-\beta) + F_{D,p} \cdot \sin(-\beta) + F_L \cdot \cos(-\beta) - F_r \cdot \cos(\delta)] \tag{40}$$
$$\dot{\varphi} = \omega \tag{41}$$
$$\dot{\omega} = \frac{1}{I_t} \cdot [+F_{W,p} \cdot w_p - F_{W,g} \cdot w_g - F_{D,p} \cdot d_p + F_{D,g} \cdot d_g - F_L \cdot l - d \cdot \omega] \tag{42}$$

With

$$F_L = c_l \cdot A_{project} \cdot \frac{\rho_{air}}{2} \cdot (v_{TAS})^2 \tag{43}$$
$$F_{D,g} = c_{d,g} \cdot A_{project} \cdot \frac{\rho_{air}}{2} \cdot (v_{TAS})^2 \tag{44}$$
$$F_{D,p} = c_{d,p} \cdot A_{pilot} \cdot \frac{\rho_{air}}{2} \cdot (v_{TAS})^2 \tag{45}$$
$$F_{W,g} = m_g \cdot g \text{ and } F_{W,p} = M_p \cdot g \tag{46}$$
$$F_{D,p} = c_{d,p} \cdot A_{project} \cdot \frac{\rho_{air}}{2} \cdot (v_{TAS})^2 \tag{47}$$
$$v_{TAS,x} = v_{GS,x} - v_{wind,x} \tag{48}$$
$$v_{TAS,y} = v_{GS,y} - v_{wind,y} \tag{49}$$
$$\beta = \arctan\left(\frac{v_{TAS,y}}{v_{TAS,x}}\right) \tag{50}$$
$$\alpha = \varphi - \beta \tag{51}$$
$$\delta = \tan^{-1}(C_1) + \frac{\pi}{2} \tag{52}$$

3 Model Parameters

In this section we want to summarize important parameters used in this model. Values of some of the parameters are provided by the manufacturer or calculated analytically. Other parameters are tuned experimentally, for instant the damping coefficient d, to get a good image of the reality.

$\rho_{air} = 1.27\,\frac{\text{kg}}{\text{m}^3}$	$m_g = 6\,\text{kg}$
$M_p = 100\,\text{kg}$	$l_{line} = 6.97\,\text{m}$
$A_{projected} = 24.26\,\text{m}^2$	$A_{pilot} = 1.0\,\text{m}^2$
$l_{MG} = 0.395\,\text{m}$	$l_{Gm} = 6.575\,\text{m}$
$d = 10000\,\frac{\text{Nms}}{\text{rad}}$	$c_{d,p} = 0.33$

The aerodynamic coefficients c_l and $c_{d,g}$ are assumed to be functions of the angle of attack α. These dependencies are shown in Figure 8 graphically.

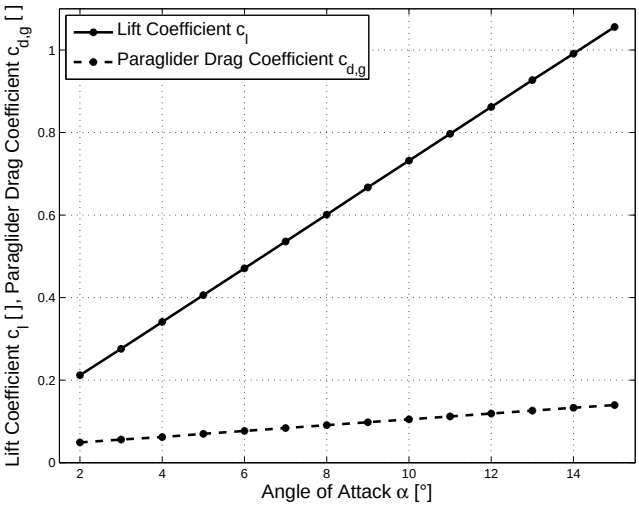

Figure 8. Aerodynamic coefficients as functions of α.

4 Simulation Results

The model is implemented in Matlab/Simulink. Two different flight situations are simulated. The first one is a gliding flight, where the pilot begins to fly at a certain height. The second one extends the first model by a winch launch to enable the pilot to gain altitude.

4.1 Gliding Flight

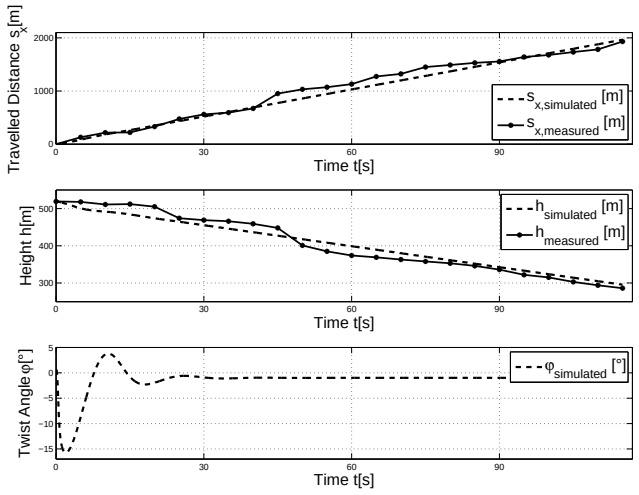

Figure 9. Gliding flight.

The three plots seen on Figure 9 show the translational motion of the system over the time. The angle of glide β is constant during the whole flight. With a start height h of 500 metres, a flight distance in x-direction s_x of 1930 m is reached on the expense of a 230 m loss in altitude. The third plot illustrates the dynamics of the twist angle φ with a settling time of about 30 s. The deviation between the simulated and measured results may be due to different wind situations. The wind affects the system behaviour significantly (see Figure 10). At the beginning,

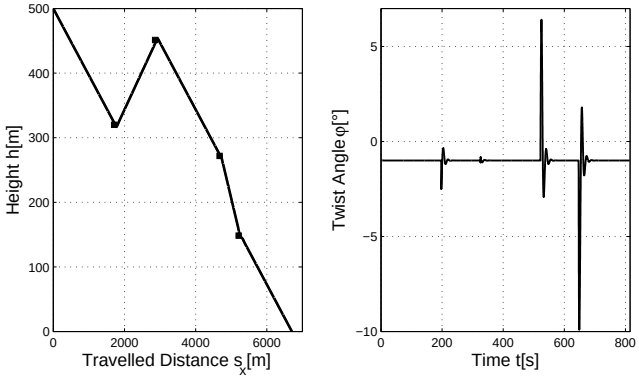

Figure 10. Gliding flight with wind impact.

the pilot glides down and is slowly reducing altitude. Subsequently, the pilot enters an updraft region (first black square) and, as a result, the pilot gains altitude and rises up to 450 m (second black square), where the helpful wind stops. The pilot glides down to the third black square, where headwind prevails. Consequently, the ground speed v_{GS} reduces and the angle of glide β increases. Therefore, height is lost more quickly than before and, as a result, the travelled flight distance s_x gets shorter. At a height of 150 m (fourth black square), the headwind levels off and the paraglider flies again with trim speed. The reaction of the twist angle φ in relation to the changing conditions is displayed on the right side of Figure 10. If the ground speed v_{GS} changes due to the impact of the wind, the angle of twist φ is disturbed from its steady-state value and after short time it is settled again. The disturbance caused by horizontal wind is stronger than the vertical wind, because headwind or tailwind directly creates a torque around the gravity point G and deflects the system from the rest position.

4.2 Towing Process

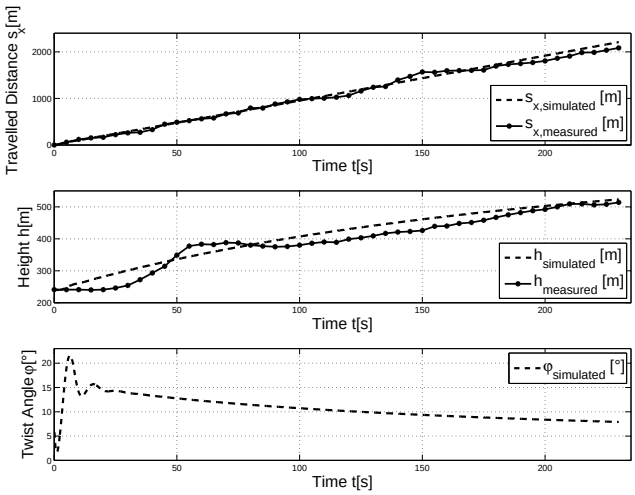

Figure 11. Towing process.

The first diagram of Figure 11 shows the travelled distance of the paraglider in x-direction s_x over the time. It is easy to recognize that the movement is linear due to the constant slope of the graph. The second plot shows the height h, whereas the transient response of the twist angle φ is drawn in the last diagram of Figure 11. A comparison of measured and simulated results reveals that the simulation model provides a fair reflection of the reality.

5 Conclusions

A simulation model for a paraglider is derived and implemented in Matlab/Simulink. The parameters are adjusted in order to simulate the behaviour of a certain paraglider. With the help of the model two different flight situations, i.e. gliding flight and towing process, are simulated. Simulation results are compared with data of a real flight. The model provides a good approximation of the dynamical behaviour of the real system. It allows to compare different parameter settings, determine their influence on the system as well as to optimise the towing process. However, as already mentioned, paragliding is under constant change and this model has to be adjusted accordingly.

Abstract

Objects having a flattened geometry, such as those encountered in heritage, have always been difficult to be analysed with conventional X-ray tomography methods due to their anisotropic morphology. To overcome the limitations of classical tomography for such samples, we envisage a new imaging modality based on Compton scattering. While Compton effect is usually considered as noise in tomography, in Compton scattering tomography the conditions are set such that this becomes the imaging agent of the image formation process. Our interests are, firstly, to avoid the relative rotation between the object, the source and the detector, and secondly, to be able to obtain in-depth data even when the sample is supported by some deep or dense material by exploiting only back-scattered photons. To replace the information provided by multiple projections angles in classical tomography, we make use of the relation between the energy loss of the scattered photons and its scattering angle, the Compton equation. Modelling of this new modality, image formation and object reconstruction through a filtered back-projection algorithm of a Radon transform on a half-space is presented. The feasibility of this concept is supported by numerical simulations.

Keywords: Radon transform, Compton scattering tomography, image reconstruction

1 Introduction

1.1 Context

Analysis of flat objects has remained particularly challenging with X-ray imaging methods. X-ray imaging has the strong advantage of providing non-invasive/non-destructive probing of the material and enables 2D two-dimensional (2D) imaging of the sample which is often mandatory when analysing heritage samples. However, a large set of those samples has a complex flattened geometry, *i.e.*, a large ratio between the front area and its thickness and the high differential light path in distinct directions prohibits the relative rotations of the sample to perform a three-dimensional reconstruction as would be done in regular tomography, using either absorption or phase contrast modality. Such samples could be encountered in conservation/restoration studies of easel painting requiring the characterisation of the stratigraphical assemblage of pigments often over a very dense background layer (Figure 1), *e.g.* made of white lead. Another type of samples falling in this set is encountered in palaeontology with the Lagerstätten fossils (Gueriau et al., 2014) which are mechanically flattened during the fossilisation process and stand on one side of a thick sedimental slab which can not be thinned for the study (Figure 2). In both cases the volume of interest forms a layer on top of a material matrix which is opaque to X-ray either due to its density or its thickness.

In both cases scientists left with one of two choices : either to perform a stratigraphical section of the sample which is an invasive method, or perform a 2D analysis, for example with synchrotron X-ray fluorescence spectral raster-scanning (Gueriau et al., 2014) while an in-depth reconstruction is still desired. Furthermore, because of the opaque supporting material, transmission and forward scattering data, with a scattering angle inferior of $\frac{\pi}{2}$, are impossible to collect. This leads us to propose a modality tapping on back-scattered data, that is, data collected with a scattering angle comprised between $\frac{\pi}{2}$ and π, as shown in Figure 3.

Using the approximation that all electrons of the material are both free and at rest, the Compton equation establishes in (1) a diffeomorphism between the scattering angle and the scattered energy, provided that the incident beam is monochromatic, *i.e.* a single value E_0 of an incident energy is illuminating the object. In such circumstances the Compton scattering image formation process corresponds to a Radon transform over either one branch of a V-line or equivalently over lines in a half-space (Morvidone et al., 2010; Truong and Nguyen, 2011, 2015) when the scene is purely 2-dimensional, or over the surface of a cone (Nguyen et al., 2005; Cebeiro et al., 2015) when a 3-dimensional scene is considered.

1.2 Compton scattering tomography (CST)

Three basic photon-matter interaction phenomena are considered in classical X-ray imaging and hence tomography : Photoelectric absorption, Rayleigh scattering which is both elastic and coherent, and Compton scattering which conversely is both inelastic and incoherent. In this last one, an incident photon of energy E_0 is absorbed by a target electron, who re-emits a secondary photon scattered by an angle ω relative to the direction of the original photon. The scattered photon has then an energy E_ω which is related to the scattering angle ω by (1), the Compton equation, when the target electron is both free and at rest.

In classical X-ray imaging and tomography, Compton scattered signal is considered as noise added to photoelectric absorption and coherent scattered data. This is because X-ray transmission signal is dominated by the photoelectric absorption whilst coherent scattering may produce significant amplitude variations at low scattering angles thanks to constructive and destructive interference effects due to the coherent nature of this scattering. However, depending on the material, if the incident radiation has an energy superior of $40-50$ keV, Compton scattering is becoming the dominant phenomenon in the process, even more when detection is performed far from the transmission geometry ($\omega = 0$).

Classical tomographic imaging modalities, developed and used in most all applications in the last half century include : Transmission Computed Tomography (CT), Single Photon Emission Tomography (SPECT) and Positron Emission Tomography (PET). All of them regard primary radiation and perform a 3D mapping leaning on relative rotations between the object and the imaging setup. In such framework the Compton scattering is adding a non-uniform background to the observation, a systematic bias which leads to artefacts in the reconstruction if it is not accounted for. As the relative importance of the Compton scattering over the other two processes mentioned above is increasing with an increase on incident energy, its effect is even more important when using higher energy γ-ray imaging and tomography.

The idea of exploiting scattered radiation by Compton effect in imaging techniques has been introduced and studied simultaneously and it has given birth to CST (Norton, 1994; Nguyen et al., 2005; Morvidone et al., 2010; Cebeiro et al., 2015; Truong and Nguyen, 2011, 2015), which focuses to reconstruct the electron density map of the object.

To replace the information provided by multiple projections angles in classical transmission or emission tomography, CST exploits the energy loss of the scattered photons. This energy loss encodes the scattering angle information thanks to the Compton equation given by

$$E_\omega = \frac{E_0}{1+\frac{E_0}{m_e c^2}(1-\cos\omega)}, \tag{1}$$

where $m_e c^2 = 511$ keV is the rest mass energy of the electron.

The first CST scanner was proposed in 1994 (Norton, 1994) through a Radon transform over arc of circles starting at a γ-ray source and ending at the detecting point. Radon transforms over V-lines and its analytic inversion formula as well as a filtered back-projection reconstruction was proposed in (Morvidone et al., 2010), three different types of these V-line transforms with fixed axis direction are studied in (Truong and Nguyen, 2011) and new properties and applications including a Radon transform on a half-space were presented recently in (Truong and Nguyen, 2015). Radon transforms over conical surfaces having fixed axis directions and variable opening angle are studied in (Nguyen et al., 2005) where an analytic inversion formula is proposed, with applications to emission imaging based on Compton scattered radiation. A back-projection inversion for this conical Radon transform was developed recently in (Cebeiro et al., 2015).

This paper is organised as follows. Section 2 describes this new CST modality, and presents image formation process as well as object reconstructions via a back-projection algorithm related to a half-space Radon transform in the framework of a two dimensional setup with back-scattering. In Section 3 we present numerical scheme and some simulation results for flat objects both for energy resolved image formation and sample reconstruction. Finally, Section 4 closes this paper with a conclusion and perspectives.

The three dimensional case, corresponding to the conical Radon transform, will not be presented due to fact that the azimuthal scattering angle is uniformly distributed in a Compton event, that is to say, the angular distribution of scattered photons has axial symmetry around the direction of incidence.

2 Modelling of the new CST modality

CST focuses to reconstruct the electron density map of the object. In this paper, this density will be represented by a nonnegative bump function (both smooth and of bounded support) $f : \mathbb{R}^+ \times \mathbb{R} \to \mathbb{R}^+$.

Fundamentally, an incident photon of energy E_0, coming from a point source **S**, is inelastically scattered by an electron located inside the object at **M** subtending an angle ω ($\frac{\pi}{2} < \omega < \pi$) with the direction of incidence. The scattered photon of energy E_ω, approximated by (1), arrives finally at a detecting point **D**. In this paper, **D** is located over the Oy-axis of the Cartesian reference plane and noted $\mathbf{D}_\zeta = (0, \zeta)$. Obviously we will have data for values of ζ verifying $|\zeta| > \zeta_0$ for some $\zeta_0 > 0$. The parallel beam is centred at the Ox-axis. See Figs. 3 and 4 for more details.

As already mentioned, in this paper we will considerer a two dimensional setup, *i.e.*, a slice of a three dimensional space through the z-axis.

2.1 Proposed setup by back-scattering

A synchrotron radiation setup with a monochromatic parallel X-ray beam (about 50 keV) and a space-energy resolved detector is proposed. As represented in Figure 3, the detector will be placed between the source and the object to capture back-scattered photons. It will have then a hole in the middle of length $2\zeta_0$ to allow the beam to go through. Vertical translations of the sample will allow the imaging of the full sample despite the limited beam size.

This configuration is considered to overcome limitations of getting data through classical methods mentioned before.

In Figure 4, scattered radiation arriving to a detecting point $\mathbf{D}_\zeta$ laying on the line that crosses both $\mathbf{M}_1$ and $\mathbf{D}_\zeta$ will have an energy loss related to ω_1, for example radiation scattered from $\mathbf{M}_3$. The same will occur related to $\mathbf{M}_2$ and ω_2. One will be able to identify, for example, points $\mathbf{M}_1$ and $\mathbf{M}_2$ radiated with the same X-ray beam at the same time through energy loss data.

2.2 Direct problem : Image formation

2.2.1 The half-space Radon transform (HRT)

The half-space Radon transform and its analytic inverse formula were introduced in (Truong and Nguyen, 2015). Briefly, it is a Radon transform, introduced in (Radon, 1917), defined on half-lines, starting on a detecting point towards the direction of where the sample is placed. The interest is that it performs an integration of the object, in this case a function representing an electron density distribution, over all locations where photons are scattered by the same angle and arriving at the same detecting point.

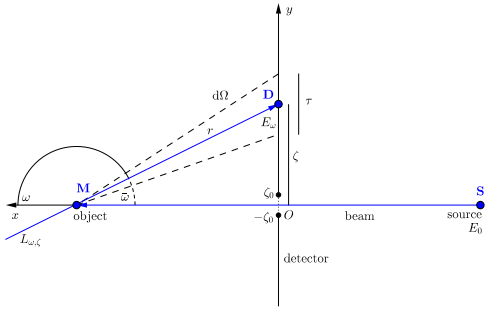

Figure 3. Simulated setup. Photons coming from a source at **S** are back-scattered at **M** by an angle ω into the solid angle dΩ. They are finally detected at **D**, who lays on the Oy-axis.

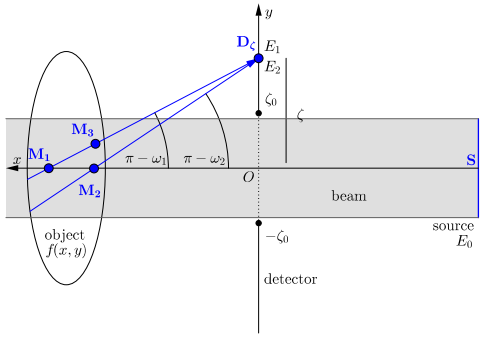

Figure 4. Three positions inside the sample producing scattered radiation captured at a detecting site $\mathbf{D}_\zeta$ at different energies $\{E_1, E_2\}$. $\mathbf{M}_1$ and $\mathbf{M}_3$ having the same scattering angle, generate both energy E_1, $\mathbf{M}_2$ does the same for energy E_2.

In a forward scattering framework, integration must be performed over a pair of half lines in the shape of a V, with fixed axis direction, these so-called V-line Radon transforms were introduced in (Morvidone et al., 2010) and developed in (Truong and Nguyen, 2011, 2015).

For simplicity, call $\bar{\omega} = \pi - \omega$ the supplementary angle of ω. To cover all projections from the sample to the full detector length, we have to consider $\frac{\pi}{2} < \omega < \frac{3\pi}{2}$ even if intervals $[\frac{\pi}{2}, \pi]$ and $[\pi, \frac{3\pi}{2}]$ are physically equivalents. Therefore, we will have $-\frac{\pi}{2} < \bar{\omega} < \frac{\pi}{2}$.

The half-space Radon transform, represented by R^*, is then defined in this paper, for $-\infty < \zeta < \infty$ and $-\frac{\pi}{2} < \bar{\omega} < \frac{\pi}{2}$, as the integral

$$R^* f(\bar{\omega}, \zeta) = \int_0^\infty \frac{1}{r} f(r\cos\bar{\omega}, \zeta - r\sin\bar{\omega})\,\mathrm{d}r. \qquad (2)$$

The factor $\frac{1}{r}$ in the last equation comes from the photometric law or the difference in solid angle from the scattering site to the detecting site. dr is the measure on the half-line.

2.2.2 Image formation

Let $\mathrm{d}I(E_\omega, \mathbf{D}_\zeta)$ represent the recorded scattered photon flux time density. It is the number of photons of energy laying in $E_\omega \mathrm{d}\omega$ recorded per unit time at $\mathbf{D}_\zeta$. It will incorporate the following parameters :

- I_0: the incident photon flux density before the scattering event.
- $\sigma^{2\mathrm{D}}(\omega)$: the 2D Klein-Nishina differential cross-section (Klein and Nishina, 1928) at an angle ω.
- $f(\mathbf{M})$: the electron density at $\mathbf{M}$.
- $\mathrm{d}\Omega(\mathbf{M}, \mathbf{D}_\zeta)$: the solid angle from $\mathbf{M}$ to $\mathbf{D}_\zeta$.
- $\mathrm{d}\mathbf{M}$: the elementary length around $\mathbf{M}$ over the half-line.
- $\mathrm{d}\omega$: the elementary variation of ω.

The solid angle $\mathrm{d}\Omega(\mathbf{M}, \mathbf{D}_\zeta)$ can be seen from Figure 3 to be

$$\mathrm{d}\Omega(\mathbf{M}, \mathbf{D}_\zeta) = 2 \arctan\left(\frac{\tau}{2r}\cos\bar{\omega}\right), \tag{3}$$

where τ is the length of the detecting element located at $\mathbf{D}$ and r the Euclidean distance from $\mathbf{M}$ to $\mathbf{D}$.

If τ is small enough, then $\mathrm{d}\Omega(\mathbf{M}, \mathbf{D}_\zeta)$ can be approximated by $\frac{1}{r}\tau\cos\bar{\omega}$.

The 2D Klein-Nishina differential cross-section is a function of the scattering angle ω giving the probability of a photon to be scattered by ω limited to a bi-dimensional scatter plane. It is given by

$$\sigma^{2\mathrm{D}}(\omega) = \frac{1}{2}\pi r_e^2 \left(\frac{E_\omega}{E_0}\right)^2 \left(\frac{E_\omega}{E_0} + \frac{E_0}{E_\omega} - \sin^2\omega\right), \tag{4}$$

where r_e is the classical electron radius.

Consequently, the scattered photon flux density at $\mathbf{D}_\zeta$, given a scattering site $\mathbf{M}$, is given by

$$\mathrm{d}I(E_\omega, \mathbf{D}_\zeta|\mathbf{M}) = I_0\, \sigma^{2\mathrm{D}}(\omega)\, \mathrm{d}\Omega(\mathbf{M}, \mathbf{D}_\zeta)\, f(\mathbf{M})\, \mathrm{d}\omega\, \mathrm{d}\mathbf{M}. \tag{5}$$

The recorded scattered flux time density $\mathrm{d}I(E_\omega, \mathbf{D}_\zeta)$ recorded at $\mathbf{D}_\zeta$ is the integral over all scattering sites laying on the half-line that starts at $\mathbf{D}_\zeta$ towards the object with slope $\tan\bar{\omega}$ noted $L_{\omega,\zeta}$. It is hence given by the integral

$$\mathrm{d}I(E_\omega, \mathbf{D}_\zeta) = \int_{\mathbf{M}\in L_{\omega,\zeta}} \mathrm{d}I(E_\omega, \mathbf{D}_\zeta|\mathbf{M}). \tag{6}$$

From the last integral, we can extract the half-space Radon transform, and we are able to express the scattered photon flux time density for photons laying in a recorded energy $E_\omega \mathrm{d}\omega$ as

$$\mathrm{d}I(E_\omega, \mathbf{D}_\zeta) = \tau I_0 \cos\bar{\omega}\, \sigma^{2\mathrm{D}}(\omega) R^* f(\bar{\omega}, \zeta)\, \mathrm{d}\omega. \tag{7}$$

2.3 Inverse problem : Object Reconstruction

2.3.1 Inversion of the HRT

In order to obtain an inverse formula for (2), we make use of Fourier techniques developed in (Morvidone et al., 2010) related to the V-line Radon transform.

Let $f(x,y)$ be expressed using its y-Fourier transform, noted $\hat{f}(x,q)$, as

$$f(x,y) = \int_{-\infty}^{\infty} \hat{f}(x,q) \mathrm{e}^{2\pi i y q}\, \mathrm{d}q. \tag{8}$$

Then (2) takes the form

$$R^* f(\bar{\omega}, \zeta) = \int_0^{\infty} \frac{1}{r} \int_{-\infty}^{\infty} \hat{f}(r\cos\bar{\omega}, q)\, \mathrm{e}^{2\pi i q(\zeta - r\sin\bar{\omega})}\, \mathrm{d}q\, \mathrm{d}r, \tag{9}$$

and applying Fubini's theorem,

$$R^* f(\bar{\omega}, \zeta) = \int_{-\infty}^{\infty} \mathrm{e}^{2\pi i q\zeta} \int_0^{\infty} \frac{1}{r} \hat{f}(r\cos\bar{\omega}, q)\, \mathrm{e}^{-2\pi i q r\sin\bar{\omega}}\, \mathrm{d}r\, \mathrm{d}q, \tag{10}$$

from where we can extract the ζ-Fourier transform of $R^* f(\bar{\omega}, \zeta)$ by writing

$$\widehat{R^* f}(\bar{\omega}, q) = \int_0^{\infty} \frac{1}{r} \hat{f}(r\cos\bar{\omega}, q) \mathrm{e}^{-2\pi i r q \sin\bar{\omega}}\, \mathrm{d}r. \tag{11}$$

With a change of variables $x = r\cos\bar{\omega}$, $t = \tan\bar{\omega}$ and defining the function $g : (t,q) \mapsto \widehat{R^* f}(\bar{\omega}, q)$, (11) becomes

$$g(t,q) = \int_0^{\infty} \frac{1}{x} \hat{f}(x,q) \mathrm{e}^{-2\pi i q t x}\, \mathrm{d}x, \tag{12}$$

which is the Fourier transform of the function $x \mapsto \frac{1}{x}\hat{f}(x,q)$ evaluated at qt. One can now apply the inverse formula and the scaling property of Fourier transforms to get $\hat{f}(x,q)$ in the form

$$\hat{f}(x,q) = |q| x \int_{-\infty}^{\infty} g(t,q) \mathrm{e}^{2\pi i q t x}\, \mathrm{d}t. \tag{13}$$

Finally, $f(x,y)$ can be reconstructed for all points (x,y) in the object through the q-inverse Fourier transform of the last expression.

2.3.2 Filtered back-projection

As the classical Radon Transform on straight lines, the filtered back-projection inversion on on a half-space combines the back-projection operation and a filtering operation. It says that the back-projection operator $b_\omega(x,y)$ at

(x,y) for an scattering angle ω assigns to (x,y) the value of the projection recorded at $\zeta = y + x\tan\bar{\omega}$ where (x,y) was projected, recalling that $\bar{\omega} = \pi - \omega$. That is to say, the back-projection operator is defined by

$$b_\omega(x,y) = R^* f(\bar{\omega}, y + x\tan\bar{\omega}). \tag{14}$$

A first rough reconstruction of the object can be done by applying the back-projection operator without filtering. The object can then be reconstructed by

$$f(x,y) = \int_0^{\pi/2} b_\omega(x,y)\,\mathrm{d}\bar{\omega}. \tag{15}$$

The filtering operation is applied to the ζ-Fourier transform of $R^* f(\bar{\omega},\zeta)$. To obtain the correct filter, we can write the inversion formula of (2) from (8), (13) and the Fubini's theorem as

$$f(x,y) = x\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} |q| g(t,q) \mathrm{e}^{2\pi i q(y+xt)}\,\mathrm{d}q\,\mathrm{d}t, \tag{16}$$

where we identify the inverse Fourier transform of the function $q \mapsto |q|g(t,q)$ evaluated at $y+xt$ by writing

$$f(x,y) = x\int_{-\infty}^{\infty} \mathscr{F}^{-1}(|q|g)(t, y+xt)\,\mathrm{d}t, \tag{17}$$

where $\mathscr{F}^{-1}$ is the inverse Fourier transform.

Finally, in terms of the angle $\bar{\omega}$, last inversion formula reads

$$f(x,y) = x\int_{-\pi/2}^{\pi/2} \mathscr{F}^{-1}(|q|\widehat{R^*f})(\bar{\omega}, y + x\tan\bar{\omega})\,\frac{\mathrm{d}\bar{\omega}}{\cos^2\bar{\omega}}. \tag{18}$$

The last inverse Fourier transform is called the filtered projection of R^*f using the so-called ramp filter $|q|$, it is represented by

$$\widetilde{R^*f}(\bar{\omega},\zeta) = \mathscr{F}^{-1}\left[|q|\widehat{R^*f}\right](\bar{\omega},\zeta), \tag{19}$$

and then one is able to write the back-projection operator related to this filtered projection as

$$\tilde{b}_\omega(x,y) = \widetilde{R^*f}(\bar{\omega}, y + x\tan\bar{\omega}), \tag{20}$$

to finally be able to write a filtered back-projection reconstruction of $f(x,y)$ for all (x,y) in the object under a compact form via the integral

$$f(x,y) = x\int_{-\pi/2}^{\pi/2} \tilde{b}_\omega(x,y)\,\frac{\mathrm{d}\bar{\omega}}{\cos^2\bar{\omega}}. \tag{21}$$

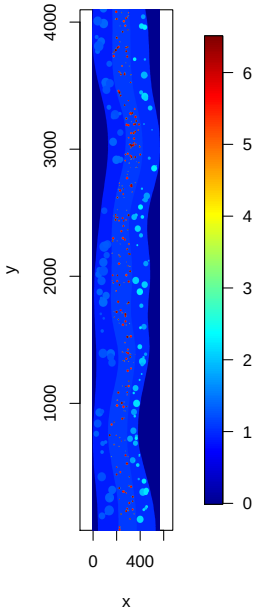

Figure 5. Test sample: A flat stratigraphic phantom.

3 Simulation of the new CST modality

A numerical phantom corresponding to a transversal section of a flattened stratigraphic sample is generated and reconstructed in Figs. 5 and 6 respectively via inversion formula (21).

The phantom presents three layers of about 150×4096 square micrometers with electron densities of 0.9, 1.1 and 1.0 respectively. Grains of random diameter and position were inserted inside the layers, having densities of $1.3 \pm .1$, 6.0 ± 0.5 and 2.0 ± 0.3 respectively.

In these first attempts, attenuation and multiple scattering are neglected.

3.1 Energy resolution of the detector

Simulation of this new CST modality requires to consider a realistic energy-resolved detector. Let ΔE be the energy resolution of the detector. Hence, for a fixed detector, we will have a limited number of energy channels recording photons laying on a specific energy range.

Let C_i be the energy channel detecting all photons laying on the energy range $[E_i, E_i + \Delta E]$. It can be equivalently defined in terms of the scattering angle through (1) for ω laying in $C_i = [\omega_i, \omega_{i+1}]$.

The measured intensity into a given energy channel for a given detecting site is then given by integrating the scattered intensity over that channel

$$I(C_i, \mathbf{D}_\zeta) = \int_{C_i} I(E, \mathbf{D}_\zeta)\,\mathrm{d}E, \tag{22}$$

where $\mathrm{d}I(E,\mathbf{D}_\zeta)$ is given in (7).

The trapezoidal rule was used to compute numerically last integral with an angular step corresponding to 5 eV by means of (1). Consequently, the same parameters are used for integral (21) with a simple change of variables from ω to E through (1). Two energy resolutions are considered in simulations, namely $\Delta E \in \{50, 100\}$ eV.

3.2 Spatial discretization

The unit length considered is 2 µm. Each pixel in image representations will represent then 2×2 µm^2.

A parallel X-ray beam of 8 µm of width crosses a hole in the detector of 12 µm of width, hence we have $\zeta_0 = 6$ µm. The medium considered has 512×4096 µm^2 and then we need 512 vertical translations due to the height of the sample to cover the full phantom. The considered detector located at 2 µm of the sample over the Oy-axis has a vertical length of 2048 µm including the hole. Thereby, we have $1024 - 24$ detecting sites. (24 sites not considered due to the hole.)

Figure 7 shows the bottom slice of the sample (8 µm of heigh corresponding to the beam width) and its associated image formation through a discretization of (2).

Numerical resolution of integral (2) is performed via the trapezoidal rule with a discretization spatial step $\mathrm{d}r = 2$ µm.

3.3 Window functions

Window functions $\mathrm{w}(q)$ are added to the ramp filter in numerical reconstructions to control high frequencies. Filtered projections related to R^*f written in (19) are then rewritten in the form

$$\widetilde{R^*f}(\bar{\omega}, \zeta) = \mathscr{F}^{-1}\left[|q|\mathrm{w}(q)\widehat{R^*f}\right](\bar{\omega}, \zeta). \qquad (23)$$

Cosine related window functions are widely used, they have the form

$$\mathrm{w}(q) = \cos^n(\pi q). \qquad (24)$$

Within this family of windows, the case $n = 2$ corresponds to the well characterised Hann Window function. During our simulation work we tested various values of n and found out that $n = 8$ was the one minimising the mean square error between the object and its reconstruction given the numerical noise produced by the simulation. Still different values of n gives satisfactory reconstructions as well. Horizontal artefacts in reconstructions are due to vertical translations of the object. Grains inside the matrix layers are reconstructed at the correct depth, size and relative densities, without the need of a relative rotation between phantom and detector.

4 Conclusions and perspectives

A new X-ray imaging modality based on Compton scattering is proposed, the particular aim is a 3D reconstruction of flat objects without relaying on a relative rotation between the studied sample and the imaging setup. Modelling of both image formation by means of the half-space

Radon transform and object reconstruction by a filtered back-projection inversion are presented, considering realistic energy resolved detectors, and supported with numerical simulations proving feasibility with experimental data. Simulations of the three-dimensional setup, regarding a conical Radon transform, are in progress for both forward and backward scattering. Yet the present results are already very encouraging considering the problem of non-destructive and non-invasive 3D imaging of samples supported by a deep or dense material.

Analysis of Optimal Diesel-electric Powertrain Transients during a Tip-in Maneuver

Vaheed Nezhadali Lars Eriksson

Vehicular Systems Division, Electrical Engineering Department
Linköping University, SE-581 83 Linköping, Sweden {vaheed.nezhadali,lars.eriksson}@liu.se

Abstract

Optimal transients of a hybrid powertrain are calculated with the aim to give a smooth and time efficient acceleration. It is shown that there is a trade-off between time and driveline oscillations where high oscillations can be avoided by slightly longer acceleration time and proper control of the electrical and diesel power sources. During a low oscillation acceleration, there is still the possibility to reduce the amount of total consumed electrical and fuel energy. This is investigated by calculation of optimal controls during acceleration for a fixed time while penalizing the usage of energy in a low oscillation acceleration. The balance between electrical and diesel energy usage during the acceleration is also investigated. The results show that to avoid extreme transients by optimal control, a multidimensional formulation of the objective function including different properties should be considered.

Keywords: numerical optimal control, acceleration, vehicle jerk

Nomenclature

The nomenclature for the paper with subscripts and variables is given in Tables 1 and 2 respectively.

Table 1. Subscripts used for variables.

Index	Description	Index	Description
im	Intake manifold	em	Exhaust manifold
gen	Generator	wg	Wastegate
e	Engine	a	Air
ds	Drive shaft	v	Vehicle
$mf, conv$	Fuel conversion	m_f	Fuel mass

1 Introduction

Hybridization of powertrains opens up new opportunities for faster and more efficient vehicle acceleration. With an electric power source assisting a diesel engine, there is an extra degree of freedom in powertrain control while the simultaneous control of the diesel and electric power sources becomes more complex.

Tip-in maneuver is referred to the situation where the driver suddenly asks for a fast vehicle acceleration by pressing accelerator pedal. This is a highly demanding and transient operation in a diesel-electric powertrain. The controls during this period can be optimized with respect to energy consumption or the operations time similar to (Sivertsson and Eriksson, 2012b), (Sivertsson and Eriksson, 2012a) and (Sivertsson and Eriksson, 2015b). Passenger comfort is also important when considering powertrain transients and can be accounted for by taking the driveline oscillations, referred to as Jerk, into account. The Jerk is also important considering its effects on the life length of driveline components, for more discussion see (Haj-Fraj and Pfeiffer, 2001) and (Haj-Fraj and Pfeiffer, 2002). In real world applications, not a single but all of these ob-

jectives are of importance and therefore it is desirable to obtain a compromise between these objectives by proper control of the powertrain.

The contribution of this paper is the development of a methodology for the calculation of efficient hybrid powertrain transients with the aim to obtain a compromise between time-energy-Jerk objectives during a tip-in maneuver. Numerical optimal control is used as an enabler for this where first the extreme transients obtained by improper objective function formulations are presented. Then the trade-off between time-Jerk and Jerk-energy are calculated. The problem is solved for different road slopes representing various loading scenarios. The analysis is extended by investigation of powertrain transients and the balance between usage of diesel and electric energy sources is analyzed.

2 Powertrain model

To enable optimal control problem (OCP) formulation, a model for the powertrain and driveline components is needed. The powertrain model representing a hybrid bus is comprised of a diesel engine and an electric motor/generator working in parallel. The dynamics are described by a mean value engine model (MVEM) and a model for generator efficiency in a validated diesel-electric powertrain (genset) model from (Sivertsson and Eriksson, 2014). The powertrain dynamics are described by four state variables as $\omega_e(t)$, $p_{im}(t)$, $p_{em}(t)$ and $\omega_{tc}(t)$. Two additional states describe the dynamics of the driveshaft twist angle $\theta_{ds}(t)$ and wheel speed $\omega_w(t)$. The model has three control inputs for injected fuel during each combustion cycle $u_{mf}(t)$, wastegate position $u_{wg}(t)$ and the the electric power of motor/generator $P_{gen}(t)$.

Dynamics of the four genset state variables are described by the following differential equations:

$$\frac{d\omega_e}{dt} = \frac{1}{J_{gs}}(M_{gs} - M_{gs,load}) \tag{1}$$

$$\frac{dp_{im}}{dt} = \frac{R_{im}T_{im}}{V_{im}}(\dot{m}_c - \dot{m}_{ac}) \tag{2}$$

$$\frac{dp_{em}}{dt} = \frac{R_{em}T_{em}}{V_{em}}(\dot{m}_{ac} + \dot{m}_f - \dot{m}_t - \dot{m}_{wg}) \tag{3}$$

$$\frac{d\omega_{tc}}{dt} = \frac{P_t\eta_{mech} - P_c}{\omega_{tc}J_{tc}} \tag{4}$$

The flexibilities in the driveline are lumped into one single flexibility in the driveshaft according to (Pettersson and Nielsen, 2000), and the torque transferred by the driveshaft is described using the stiffness and damping coefficients as follows:

$$M_{ds} = k_{ds}\,\theta_{ds} + b_{ds}\frac{d\theta_{ds}}{dt} \tag{5}$$

$$\frac{d\theta_{ds}}{dt} = \frac{\omega_e}{i_{gb}\,i_{fd}} - \omega_w \tag{6}$$

where (6) is used to describe the driveshaft deflection dynamics.

Considering rolling and aerodynamic resistances and gravitational force, as well as constant gearbox and final drive ratios, the wheel speed dynamics are calculated using Newton's second law of motion as follows:

$$\frac{d\omega_w}{dt} = \frac{M_{ds} - M_{resist}}{J_w + m_v r_w^2} \tag{7}$$

$$M_{resist} = 0.5\,\rho_{air}\,c_a\,A\,\omega_w^2 r_w^3 + m_v\,g\,r_w(c_r\cos(\alpha) + \sin(\alpha)) \tag{8}$$

The utilized electric and diesel energy are represented by the following integral states:

$$E_{gen} = \int_{t_0}^{t_f} P_{gen}\,dt \tag{9}$$

$$E_{m_f} = q_{hv}\int_{t_0}^{t_f} u_{mf}\,\omega_e\,n_{cyl}\frac{10^{-6}}{4\pi}\,dt \tag{10}$$

When formulating OCPs, the oscillations in the rotational speed of the transmission shaft is used to represent the driveline oscillation. These oscillations are referred to as Jerk that is defined as follows:

$$Jerk = \int_{t_0}^{t_f} \dot{\alpha}_{tr}^2\,dt \tag{11}$$

$$\alpha_{tr} = \frac{d\omega_e}{dt}\frac{1}{i_{gb}} \tag{12}$$

3 Problem formulation

In this section, first definition of the tip-in problem in terms of boundary conditions and constraints is described and then the objective function formulation for the OCPs are presented.

3.1 Tip-in problem constraints

3.1.1 Boundary conditions for the tip-in problem

The tip-in starts from a stationary operating condition at constant vehicle speed of 10 km/h and the final condition is that the speed should reach 15 km/h. The states and control inputs should remain within the allowed limits during the operation while the integral states and generator power are assumed to be zero at the beginning. All these can be summarized as:

$$\begin{cases} \omega_w(t_0) = \frac{\omega_e(t_0)}{i_{fd\times gb}} = \frac{10}{r_w}\frac{1}{3.6}, \quad \dot{x}(t_0) = 0, \\ \omega_w(t_f) = \frac{15}{r_w}\frac{1}{3.6}, \\ E_{gen}(t_0) = E_{m_f}(t_0) = P_{gen}(t_0) = 0, \\ u_{min} \le u \le u_{max},\ x_{min} \le x \le x_{max} \end{cases} \tag{13}$$

3.1.2 Path constraints during tip-in

The problem is solved for a hybrid bus where the maximum acceleration of 1 m/s^2 according to the limits in SORT (Standardised On-Road Test cycles (SORT), Last

accessed April 2016) are used as the highest allowed acceleration. The SORT standard is used in Europe to design on-road test cycles in order to measure fuel consumption of buses. There are also constraints regarding the turbocharger operation to avoid surge, and operational region for the turbine blade speed ratio. The maximum engine power is limited according to the maximum power curve at different engine speeds and finally, the air to fuel ratio should satisfy the smoke limit constraint λ_{min}. There is also a mechanical limit on how fast the wastegate can be actuated and the rate of change in generator power. These constraints are summarized as:

$$\begin{cases} \frac{d\omega_w}{dt} \times r_w < 1,\ \Pi_c \leq \Pi_{c,surge}, \\ BSR_{min} \leq BSR(x,u) \leq BSR_{max}, \\ P_e(x,u) \leq P_{e,max}(x),\ \frac{\dot{m}_{ac}}{\dot{m}_f}(A/F)_s \leq \frac{1}{\lambda_{min}}, \\ |\dot{u}_{wg}| \leq c_{wg},\ |\dot{P}_{gen}|/\omega_e \leq c_{gen} \end{cases} \tag{14}$$

3.2 Optimal control problem formulation

In analysis of powertrain dynamics during tip-in, one objective is to calculate the minimum time transients of the powertrain. For this, OCPs with objective function of the following form are solved:

$$\min_{(x,u)} \int_{t_0}^{t_f} dt \tag{15}$$

The trade-off between minimum time and minimum Jerk transients will be calculated by first calculating the shortest time via solving the minimum time problem, and then, minimizing the Jerk using a fixed t_f. The time is then increased step wise compared to the calculated minimum time duration. The OCP formulation in this case looks as follows:

$$\min_{(x,u)} \int_{t_0}^{t_{f,fix}} \text{Jerk}\ dt \tag{16}$$

The energy from fuel and electrical sources during the vehicle acceleration can be minimized solving for:

$$\min_{(x,u)} \int_{t_0}^{t_{f,fix}} (E_{m_f} + E_{gen})\, dt \tag{17}$$

In (Nezhadali and Eriksson, 2016) it is discussed that after minimizing the Jerk in a fixed time OCP, energy consumption minimization is the next dimension that can be analyzed for a low Jerk solution. This is done by calculating the Jerk optimal control transients including a penalty δ on energy consumption while using a fixed time. The penalty on the energy consumption is increased iteratively and the problem is solved several times to obtain the trade-off between Jerk and energy objectives. The objective function formulation for this case is:

$$\min_{(x,u)} \int_{t_0}^{t_{f,fix}} \text{Jerk} + \delta \times (E_{m_f} + E_{gen})\, dt \tag{18}$$

There is still another dimension to the optimization problem which is the balance between usage of diesel and electrical energy during the acceleration. To investigate how such balance affects the system transients, the energy consumption is reformulated including a penalty ψ on the electrical energy consumption. The objective function formulation then looks as:

$$\min_{(x,u)} \int_{t_0}^{t_{f,fix}} \text{Jerk} + \delta \times (E_{m_f} + \psi \times E_{gen})\, dt \tag{19}$$

The problem in (19) is solved with various combinations of δ and ψ penalties.

Finally, the different OCP formulations with the objective functions mentioned above become:

Objective function in (15) or (16) or (17) or (19)

subject to:

$$\dot{x} = f(x,u)$$

Constraints in (13) and (14)

3.3 Numerical solution of optimal control problems

To solve the formulated OCP in the previous section, a direct multiple shooting method using CasADi software package (Andersson, 2013) is used. The dynamics in each discretization interval are forward integrated using a 4 step Runge-Kutta integrator. After discretization of constraints, objective function and the dynamics, a nonlinear programming problem (NLP) is formulated and solved using IPOPT (Wächter and Biegler, 2006) to obtain the optimal controls and corresponding state transients.

To ensure that the solutions are not affected by the number of discretization intervals, the problem is solved with different values. It is seen that the transients remain unchanged for intervals close to and more than 300 so this is chosen as the number of discretization intervals.

4 Optimal control results

4.1 Extreme transients

To show the importance of finding a compromise between time, Jerk, and energy objectives, the state and control transients are first presented for extreme cases where only one of these are considered in the optimization. These transients are obtained by solving for (15), and (16) and (17) the latter two with final time locked $t_{f,fix} = 2$ s.

The min T transients, illustrated in Figure 1, are very oscillatory at the beginning for all controls and such control strategy would have severe negative impacts on the passenger comfort as well as the life length of genset and driveline components. For the bus to be able to smoothly continue its movement after reaching the final speed, the twist angle in the driveshaft should match the required torque and acceleration at wheels. In min T transients, due to the high deflection in the driveshaft, the vehicle speed even at the end of the acceleration is still increasing at a

high rate. A transition from this high acceleration to a low acceleration would be undesirable in terms of passenger comfort standards.

The minimum energy transients are less oscillatory but diesel engine power is not used for vehicle propulsion and all required power is provided only by the electric motor. The very low engine speed at the end of the minimum energy transients, increases the risk of engine stall when the diesel engine is going to take over the power production after the acceleration which makes the controls less applicable in real world applications.

For min Jerk transients, the undesirable non-smooth speed transition at the end time is similar to the min T case. The controls are less oscillatory compared to the min T case, but the bang-bang looking controls are what the manufacturers are less willing to implement because of the issues with component wear and durability accompanied with such control strategies.

Considering the mentioned drawbacks, these solutions are considered extreme and less applicable for control design in real world applications. In the following sections, the transients obtained by the suggested methodology for finding proper compromise between time-energy-Jerk objectives are presented and analyzed.

4.2 Compromise between time, Jerk and energy

Figure 2 shows the trade-off between time and Jerk objectives calculated by solving (16) as stated in Section 3.2 for three different road slopes. The Jerk in min T solution, calculated by solving (15), is extensively larger and therefore it is not included in the trade-offs. However, the Jerks in Figure 2 are normalized with respect to the largest Jerk belonging to the min T solution of the *0 degree slope* case which is referred to as $Jerk_{max}$. It is seen that the Jerk can be significantly decreased compared to the min T solution for all road slopes. It is desirable to have small Jerk during operation, specifically in a city bus application. Therefore, a duration of 2 [s] where the Jerk approach near zero values for all road slopes is chosen as the fixed time duration for which the energy-Jerk trade-off is calculated.

4.3 Jerk-Energy trade-off

To investigate the energy balance during the genset operation, different energy components and fuel conversion efficiency are defined as follows:

$$E_{tot} = E_{mf} + E_{gen} \tag{20}$$

$$E_{loss} = E_{mf} + E_e \tag{21}$$

$$E_e = \int_{t_0}^{t_f} M_e \omega_e \, dt \tag{22}$$

$$\eta_{mf,conv} = \frac{E_e}{E_{mf}} \tag{23}$$

where E_e represents the net energy from the diesel engine which is used for acceleration, and E_{loss} represents the losses such as engine friction and pumping work.

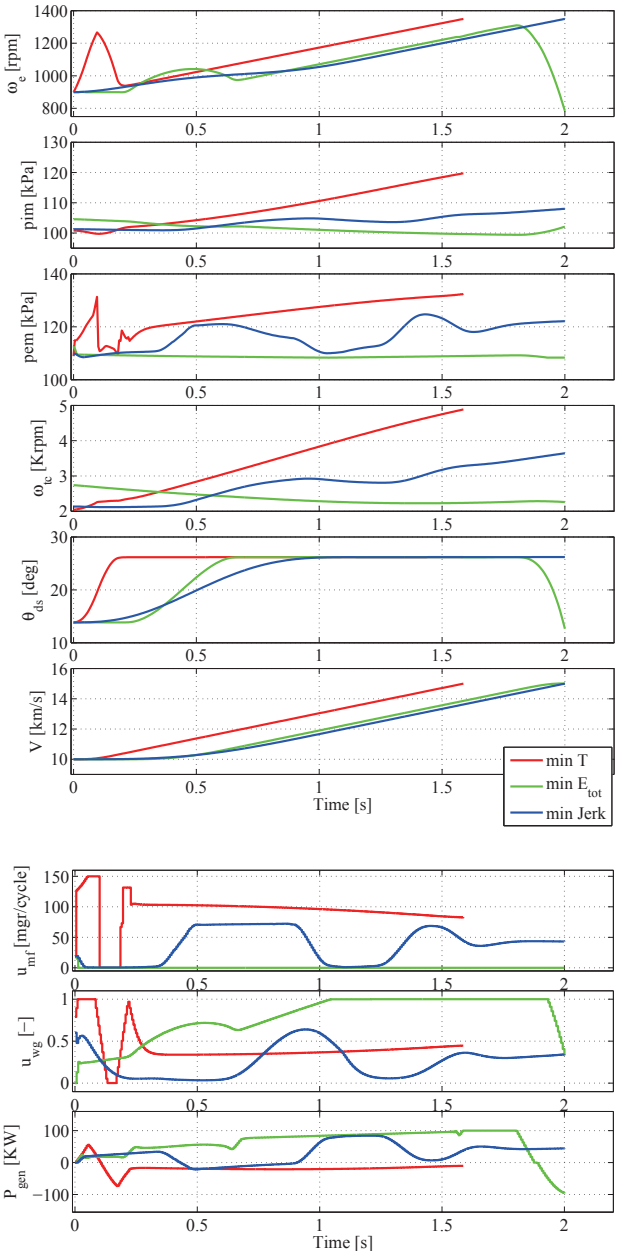

Figure 1. Optimal state and control transients for the extreme cases during acceleration ($E_{tot} = E_{mf} + E_{gen}$).

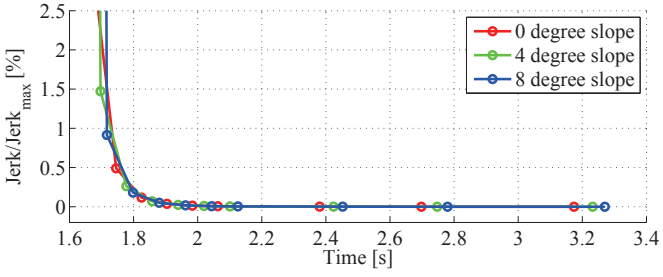

Figure 2. Trade-off between Jerk and time objectives.

To obtain the trade-off between Jerk and energy for different road slopes, (19) is solved while increasing δ and

ψ. The results for the three road slopes are presented in Figure 3. Reminding that the purpose of applying energy penalties is to avoid "extreme" low Jerk transients, a point with slightly increased Jerk on the trade-offs is chosen as a "candidate" case for which the energy balance is presented in Figure 4. Independent of what power is required for acceleration, the total required energy shows a decreasing trend when the penalty δ is increased. Also, when the penalty ψ is increased, meaning that the usage of electrical energy becomes more costly in the (19), more power is delivered by the diesel engine which has a low efficiency and therefore the total required energy for vehicle acceleration increases. As seen in Figure 4, for larger ψ values, less electrical energy is used and when total required energy for acceleration is low, the 0 degree case, diesel engine power is even used to produce electrical energy in addition to vehicle acceleration.

In case of the 0 degree slope, the required energy for the $\psi = 0$ remains unchanged for all δ values. This is because this operating condition requires smaller amount of energy compared to other cases while $\psi = 0$ in (19) implies that it does not have any cost to use electrical energy. Low efficiency of the diesel engine compared to the generator and the cheapness of electrical energy makes it optimal to perform the acceleration using only the electrical energy with no regard to the penalty δ on total energy consumption. This can be verified comparing the $\psi = 0$ energy balance for the three road slopes in Figure 4.

The first time diesel power is used for acceleration in the 0 degree slope is at $\psi \approx 2.05$. At this operating condition, a sudden decrease in E_{tot} takes place according to Figure 4. Moving from the first point on the $\psi = 2.05$ to the second point of the curve in Figure 3, the increase in δ makes the contribution from the energy term larger than the Jerk term in (19). As a result, a higher efficiency in energy consumption is favored. Since usage of the fuel energy accompanies high losses, achieving higher total efficiency is facilitated by altering the contribution of energy sources from very low electrical energy usage, similar to $\psi = 2.08$ in the 0 degree slope of Figure 4, into nearly equal contribution from the electrical and fuel energy sources, in $\psi = 2.05$.

Considering the fuel conversion efficiencies presented in Table 3, the efficiency is lower at low loads corresponding to the 0 degree slope and when electrical energy is cheaper to use (smaller ψ values). Other than this, an efficiency close to 40 % is maintained at different loading conditions.

Table 3. Fuel conversion efficiency.

road slope	ψ	0	2.05	2.08	2.5	4
0 [deg]	$\eta_{mf,conv}$[%]	-16.6	34.7	39.9	40.6	40.3

8 [deg]	$\eta_{mf,conv}$ [%]	39.6	40.94	41.08	40.59	39.43

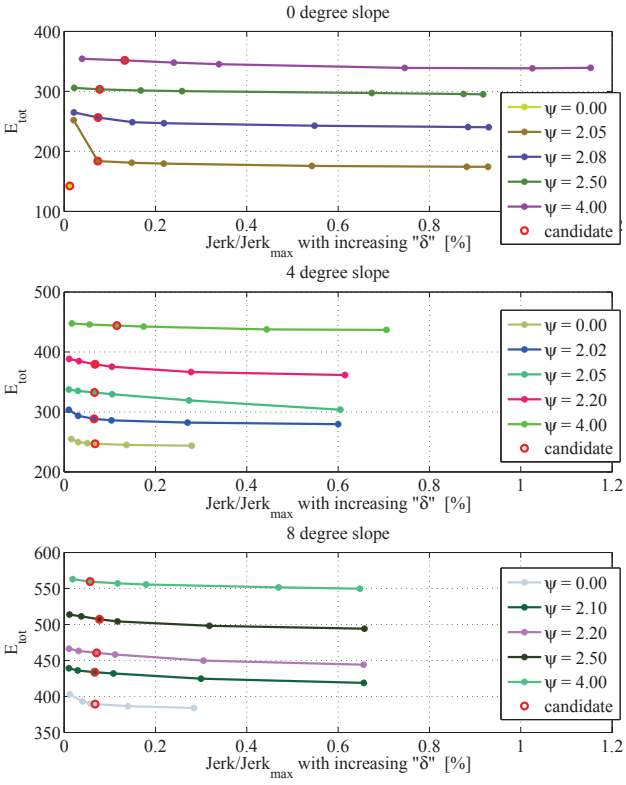

Figure 3. The trade-off between Jerk and energy with different energy penalties and road slopes.

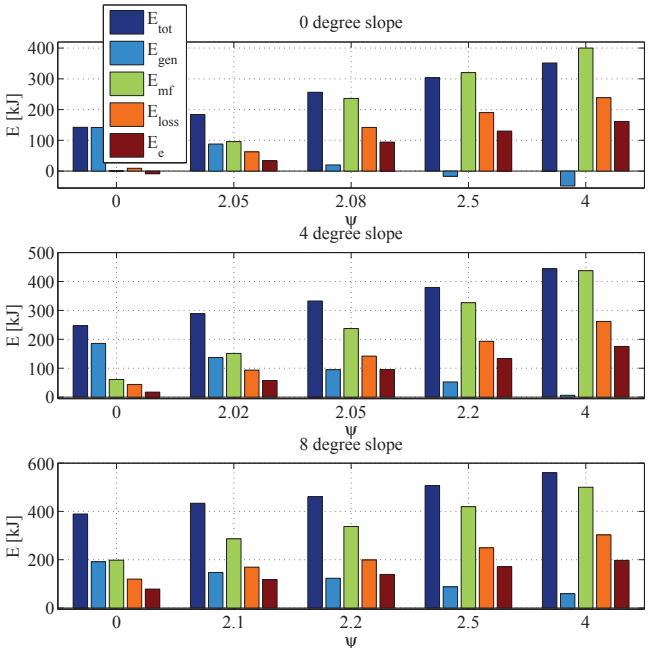

Figure 4. Energy balance for the candidate points in Figure 3.

4.4 Efficient state and control transients

The efficient state and control transients for the candidate points of the 0 degree slope case in Figure 3 are presented in Figure 5.

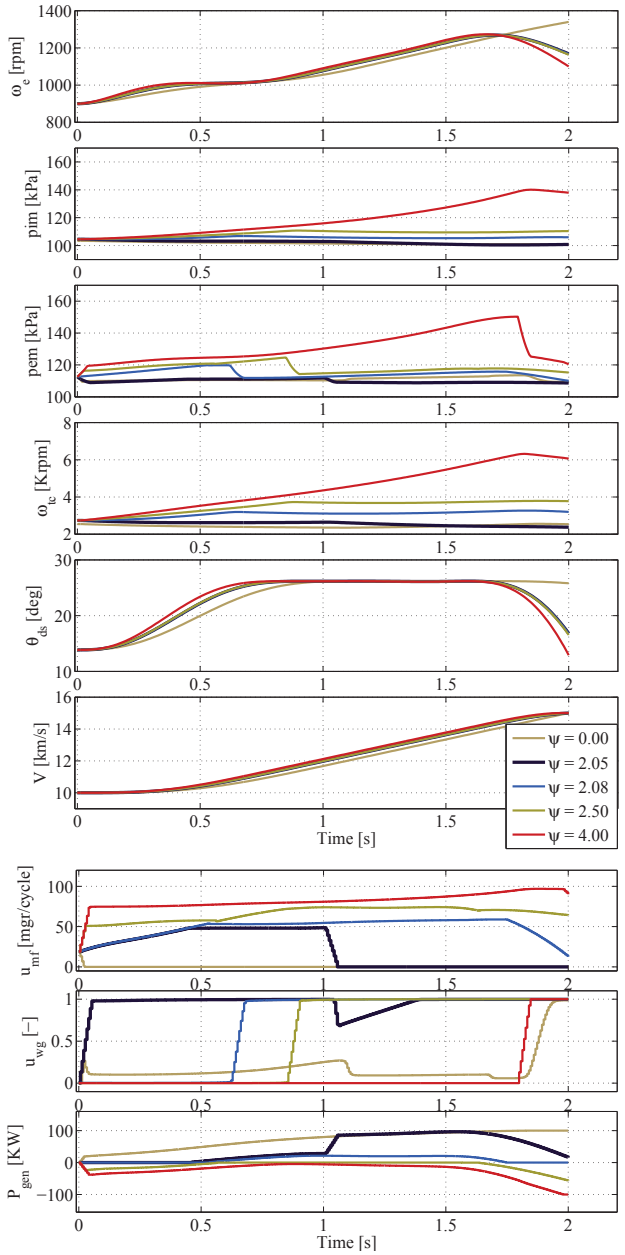

Figure 5. Optimal state and control transients during tip-in calculated for the candidate points in Figure 3.

According to the figures, as the cost for using electrical energy increases (larger ψ), the diesel engine transients are largely changed. for example comparing the $\psi = 0$ and $\psi = 4$ cases, when $\psi = 0$ fuel is cut-off, diesel engine power is not used and only electrical power accelerates the vehicle. But for $\psi = 4$, not only usage of the costly electrical energy is avoided but also parts of diesel engine power is used to store electrical energy at the end of the acceleration. Increasing the fuel conversion efficiency in the diesel engine operation is the main priority here and for that, fuel injection is selected such that the engine operates at the smoke limit delivering as large power as possible. This is similar to the discussion in (Sivertsson and Eriksson, 2015a) and (Sivertsson and Eriksson, 2015b) stating that the smoke limit dictates the solution during large parts of the transients. After an initial high power production which has facilitated fast vehicle acceleration, the wastegate which has been kept closed until this point, is opened at ca 1.7 [s] to lower the pumping work losses. Vehicle acceleration is reduced and less power from the engine is required to meet the final speed constraint. Instead, the engine power is used to build up electrical energy.

Considering the points mentioned about the extreme transients such as oscillatory controls or large acceleration at the end time, according to Figure 5, the transients for the $\psi \approx 2.05$ can be an example of improved control strategy with simple control transients and smooth vehicle speed transients at end time.

5 Conclusions

Optimal control of a diesel-electric powertrain during a tip-in acceleration is analyzed while importance of proper objective function formulation is highlighted. The extreme transients resulting from minimization of only jerk or time or energy are presented and the drawbacks in terms of oscillatory control signals are discussed. It is shown that by calculation of the trade-off between time and Jerk, low Jerk transients can be obtained. By applying penalties on energy consumptions in the Jerk minimization problem and solving for various fuel and electric energy weights in the objective function formulation, energy efficient transients are obtained. The calculated transients using this approach are presented which are simpler and more insightful for control design in real world applications. At the same time, the proposed controls maintain low Jerk and energy consumption compared to the extreme cases.

Numerical Efficiency of Inverse Simulation Methods applied to a Wheeled Rover

Thaleia Flessa Euan McGookin Douglas Thomson Kevin Worrall

Division of Aerospace Sciences, School of Engineering
University of Glasgow, UK, G12 8QQ

Abstract

A control method based on Inverse Simulation is applied to a four wheel rover. The method calculates the required inputs to achieve a desired, specified response; a trajectory in this case. Inverse Simulation considers the complete system dynamics to calculate the control input using an iterative, numerical Newton – Raphson scheme. Two methods for applying Inverse Simulation are presented, one based on a Differentiation scheme and one on Integration. The paper provides an insight into how the scheme formulation and selected parameters affect both methods' performance when applied to a rover. The selection of system outputs to control, their effect on each scheme's Jacobian, whether it is square or over-determined and the best method to factorize this Jacobian are investigated. The influence of the discretisation step and the convergence tolerance is also examined using two different sets for both schemes and in conjunction with the type of Jacobian used. The comparison is made in terms of the resulting trajectory, the execution time, and the quality of the calculated control input.

Keywords: inverse, simulation, control, navigation, model based, numerical, wheeled vehicle, rover

1 Introduction

A novel method based on Inverse Simulation is used for planetary rover guidance and control. Inverse simulation uses a mathematical model that is representative of the system and calculates the control inputs necessary to produce the desired response. This desired response is defined in terms of the system's output variables and represents their time history. Inverse Simulation is a model based, numerical, iterative process where step changes in the various controls are applied until the predicted response matches the desired response (Thomson and Bradley, 2006). Applied to rover navigation, the desired response is a specified, safe trajectory to a goal destination (Worrall *et al.*, 2015a; Worrall *et al.*, 2015b). Inverse Simulation is a novel way of addressing the issue of given a specified, safe path, what are the required control inputs for the rover to reach the destination goal through this path. The method can be applied (a) in situ: given a series of waypoints or a defined trajectory, the rover can calculate the necessary control inputs or (b) offline: operators define the trajectory, the control inputs are calculated and then sent to the rover.

Applications for Inverse Simulation are predominantly within the flight dynamics domain and the application to rotorcraft flight control is a major area. In these particular cases Inverse Simulation is used to produce the required control signals for specific flight manoeuvres (Hess and Gao, 1993; Murray-Smith, 2000; Thomson and Bradley, 2006) and (Avanzini *et al.*, 2013) also introduces a predictive element. The method has also been applied to unmanned aerial vehicles (Murray-Smith and McGookin, 2015) and autonomous underwater vehicles (Murray-Smith *et al.*, 2008). Inverse Simulation has also been used as a model validation method (Murray-Smith, 2000; Thomson and Bradley, 2006). Previous research has demonstrated the potential for Inverse Simulation as a guidance and control method for wheeled rovers (Worrall *et al.*, 2015a; Worrall *et al.*, 2015b).

Planetary rover navigation so far has been achieved using a combination of non-, semi- and fully autonomous methods (Bajracharya *et al.*, 2008). The NASA Mars Exploration Rovers (MER) use a combination of three main driving modes with varying degrees of autonomy. The first mode involves the rover executing a sequence of commands to follow a defined course of waypoints towards specific goal coordinates. In this mode the rover only performs basic safety checks (Biesiadecki *et al.*, 2007). The second mode is semi-autonomous navigation during which the rover is given a set of waypoints towards specific goal coordinates and uses its on-board capabilities for hazard avoidance and for planning a path towards the goal. A special case is when the rover drives towards an area that is unknown to the operators (Biesiadecki *et al.*, 2007; Bajracharya *et al.*, 2008). In this case the rover has to choose the waypoints for a safe path towards the goal and then drive along this path; this is fully autonomous navigation. The third mode is visual odometry: the rover uses images from the on-board cameras to accurately estimate and update its position

(Cheng *et al.*, 2005; Biesiadecki *et al.*, 2007). A similar combination of these driving modes is used for the Curiosity rover and autonomous navigation is used to plot a safe path towards an area unknown to the operators (Bakambu *et al.*, 2012). The fully autonomous and visual odometry modes are used when the rover moves into areas that are not visible to the operators (Cheng *et al.*, 2005; Biesiadecki *et al.*, 2007; Bajracharya *et al.*, 2008). The developers of the ExoMars mission have addressed the issue of control, navigation and autonomy by including an element of autonomous control (Silva *et al.*, 2013) and by conducting field experiments (Woods *et al.*, 2014). Another issue is the computational complexity of the algorithms that are running on-board. The MER and Curiosity rovers use special space qualified and radiation hardened microprocessors whose computational capabilities have been exceeded by more than two orders of magnitude by the average desktop computer (Howard *et al.*, 2012). Furthermore, the navigation algorithms must also be tested using a wide range of parameters, which is best done using simulation (Madison *et al.*, 2007).

The paper investigates the selection of outputs to control and the parameters that affect the application and execution time of Inverse Simulation to a four wheeled rover. The control inputs are calculated from Inverse Simulation, applied to the rover and the resulting trajectory is compared with the desired.

2 Methodology of Inverse Simulation

Inverse Simulation has two main requirements: a desired trajectory represented as a time history with an appropriate time step and a model of the system. The model's inputs and outputs must be representative of the inputs and outputs of the actual system. The desired trajectory is described using the model's outputs. There are two main implementations of Inverse Simulation for finding the control inputs given a desired output: Differentiation (Hess and Gao, 1993; Murray-Smith, 2000; Thomson and Bradley, 2006; Murray-Smith and McGookin, 2015) and Integration (Hess and Gao, 1993; Thomson and Bradley, 2006; Avanzini *et al.*, 2013; Worrall *et al.*, 2015a; Worrall *et al.*, 2015b). The basic framework for each is similar and uses a numerical Newton – Raphson algorithm; what differs is the method of convergence to the control signal. In Differentiation, a numerical differentiation scheme is used and the convergence is based on the system's state and output equations. In Integration, a numerical integration scheme is used and the convergence is based on whether the system's output matches the desired. An alternative approach to Inverse Simulation uses a modified version of the Integration scheme and search based optimisation (Lu *et al.*, 2008).

2.1 Implementation

A general non-linear system is used where $\boldsymbol{f}\in\mathbf{R}^{\mathbf{m}}$ are the state equations, $\boldsymbol{g}\in\mathbf{R}^{\mathbf{p}}$ are the output equations, $\boldsymbol{u}\in\mathbf{R}^{\mathbf{q}}$ is the control input vector, $\boldsymbol{x}\in\mathbf{R}^{\mathbf{m}}$ is the state variable vector and $\boldsymbol{y}\in\mathbf{R}^{\mathbf{p}}$ is the output vector. The desired output to control is $\boldsymbol{g_d}\in\mathbf{R}^{\mathbf{p}}$.

$$\dot{\mathbf{x}}=\mathbf{f}(\mathbf{x},\mathbf{u}),\ \mathbf{y}=\mathbf{g}(\mathbf{x},\mathbf{u}) \tag{1}$$

For the Differentiation method, (1) is discretised N times over a time interval T, where dt is the discretisation step. The unknowns in (2) are the states $\boldsymbol{x}$ and the input $\boldsymbol{u}$ at t_i. The known variables are the desired output $\boldsymbol{g_d}$ and the states, control and output from the previous discretisation step t_{i-1}. Then, the functions $\boldsymbol{F_1}$ and $\boldsymbol{F_2}$ in (3) are defined to find the values of input $\boldsymbol{u}$ and the states $\boldsymbol{x}$ for the given output $\boldsymbol{g_d}$. The system in (3) is solved using the Newton - Raphson method to update $\boldsymbol{u}$ and $\boldsymbol{x}$ until their values are such that $\boldsymbol{F_1}$ and $\boldsymbol{F_2}$ are both equal to zero within a certain tolerance. The updated equations are in (4) and $\boldsymbol{J}$ is the Jacobian of the system from (3).

$$\begin{aligned}&\frac{\mathbf{x}(t_i)-\mathbf{x}(t_{i-1})}{dt}=\mathbf{f}\left(\mathbf{x}(t_i),\mathbf{u}(t_i)\right),\ dt=t_i-t_{i-1}\\&\mathbf{y}(t_i)=\mathbf{g}\left(\mathbf{x}(t_i),\mathbf{u}(t_i)\right)\end{aligned} \tag{2}$$

$$\begin{aligned}&\mathbf{F}_1=\mathbf{f}\left(\mathbf{x}(t_i),\mathbf{u}(t_i)\right)-\frac{\mathbf{x}(t_i)-\mathbf{x}(t_{i-1})}{dt}\\&\mathbf{F}_2=\mathbf{g}\left(\mathbf{x}(t_i),\mathbf{u}(t_i)\right)-\mathbf{g}_d(t_i)\end{aligned} \tag{3}$$

$$\begin{bmatrix}\mathbf{x}_n\\\mathbf{u}_n\end{bmatrix}(t_i)=\begin{bmatrix}\mathbf{x}_{n-1}\\\mathbf{u}_{n-1}\end{bmatrix}-\mathbf{J}^{-1}\cdot\begin{bmatrix}\mathbf{F}_1(\mathbf{x}_{n-1},\mathbf{u}_{n-1})\\\mathbf{F}_2(\mathbf{x}_{n-1},\mathbf{u}_{n-1})\end{bmatrix}(t_i) \tag{4}$$

For the Integration approach the state and output equations from (1) are again discretised and dt is the discretisation step. The state equations are integrated at t_i. An error function between the current output and the desired $\boldsymbol{g_d}$ is defined in (6). Equation (6) is solved for $\boldsymbol{u}$ using the Newton – Raphson method and the iterative relationship in (7). $\boldsymbol{J_e}$ is the Jacobian of the error function $\boldsymbol{f_e}$ or equivalently the Jacobian of the system outputs when perturbing the inputs.

$$\begin{aligned}&\mathbf{x}(t_i)=\int_{t_{i-1}}^{t_i}\dot{\mathbf{x}}(\tau_i)\,d\tau+\mathbf{x}(t_{i-1})\\&\mathbf{y}(t_i)=\mathbf{g}\left(\mathbf{x}(t_i),\mathbf{u}(t_{i-1})\right)\end{aligned} \tag{5}$$

$$\mathbf{f_e}=\mathbf{g}\left(\mathbf{x}(t_i),\mathbf{u}(t_{i-1})\right)-\mathbf{g_d}(t_i) \tag{6}$$

$$\mathbf{u}_n(t_{i-1})=\mathbf{u}_{n-1}-\mathbf{J}_e^{-1}(\mathbf{x}_{n-1},\mathbf{u}_{n-1})\cdot\mathbf{f_e}(\mathbf{x}_{n-1},\mathbf{u}_{n-1}) \tag{7}$$

2.2 Numerical Properties

Both implementations use a Jacobian and care must be taken when trying to find its inverse or a suitable

factorization. For the Differentiation method, from Eq. (4) the dimension of the Jacobian $\boldsymbol{J}$ is $[m+p]\times[m+q]$. For the Integration method from Eq. (7) the dimension of the Jacobian $\boldsymbol{J_e}$ is $[p]\times[q]$. If there is an equal number of inputs and outputs ($p=q$), then the Jacobian is a square matrix. If however, the number of inputs and outputs is not equal, then factorization methodologies such as LU, QR or Cholesky decomposition or the Moore–Penrose pseudoinverse (Strang, 2009; Davis, 2013), can be used. When there are more outputs than inputs ($p>q$), this results in an over-determined system and the pseudoinverse or factorization can be used. In that case, the calculated outputs are a least-square fit to the desired outputs and not necessarily a good one. For this reason, systems where the number of inputs is equal to or greater than the number of outputs are preferred candidates (Hess and Gao, 1993; Murray-Smith, 2000; Thomson and Bradley, 2006; Murray-Smith *et al.*, 2008).

Each approach has advantages and disadvantages, which are usually identified as the following (Hess and Gao, 1993; Murray-Smith, 2000; Thomson and Bradley, 2006; Lu *et al.*, 2008): (a) The Integration method can use any representative model of the system. Differentiation requires both the states and the outputs and any change in the model results in a reformulation of the algorithm. Therefore, the Differentiation method is more time consuming to set up and maintain, whereas for Integration the model can be modified more easily, (b) The Integration method has a convergence rate that is up to an order of magnitude larger than that of the Differentiation method but it is generally more stable; what is gained in flexibility and stability, is lost in computing time. The numerical properties of Inverse Simulation have been examined mostly when the method is applied to flight dynamics (Hess and Gao, 1993; Thomson and Bradley, 2006; Lu *et al.*, 2008). It was observed that there are oscillations in the response of the uncontrolled states (constraint oscillations) (Thomson and Bradley, 2006; Lu *et al.*, 2008). However, these oscillations depend more on the dynamical properties of the system, its uncontrollable states and zero dynamics as well as on the discretisation step *dt*, rather than on the method used. They are also significantly reduced when a larger *dt* is used (Lu *et al.*, 2008). Also from (Thomson and Bradley, 2006) it was observed that there are low amplitude, high frequency oscillations superimposed on the calculated control input. These oscillations are due to several reasons (Hess and Gao, 1993; Murray-Smith, 2000; Thomson and Bradley, 2006; Lu *et al.*, 2008): redundancy issues, non-square Jacobian and multiple solutions, several local minima of the error function from (4), (7). The oscillations increase when the discretisation step *dt* is too small, as it could excite the uncontrollable states (Lu *et al.*, 2008). Nonetheless, a relatively small *dt* can have a positive effect because it captures the changes in the system dynamics and this may reduce or even remove them (Lu *et al.*, 2008).

3 Rover Model and Trajectory Generation

Inverse Simulation requires a mathematical model of the system and a desired response, which is a trajectory. First, a path to the destination is determined as a series of waypoints. This information provides the desired trajectory for the Inverse Simulation, which in turn generates the required guidance commands (control inputs) to follow the trajectory (Worrall *et al.*, 2015a; Worrall *et al.*, 2015b).

3.1 Rover Model

The model of the rover has been presented in (Worrall, 2010; Worrall *et al.*, 2015a; Worrall *et al.*, 2015b) and has been experimentally validated (Worrall, 2010). It is briefly described here for clarity. Each side has two wheels and the wheels at each side provide the same torque input. The dynamics are described by (8), where $\boldsymbol{v}$ is the state velocity vector (9) in the local body frame, $\boldsymbol{\eta}$ is the velocity vector in the global frame and $\boldsymbol{\tau}$ is the input vector (10).

$$\begin{bmatrix}\dot{\mathbf{v}}\\ \dot{\boldsymbol{\eta}}\end{bmatrix}=\begin{bmatrix}\mathbf{M}^{-1}\{\boldsymbol{\tau}-\mathbf{C}(\mathbf{v})\mathbf{v}-\mathbf{D}(\mathbf{v})\mathbf{v}-\mathbf{g}(\boldsymbol{\eta})\}\\ \mathbf{J}_t(\boldsymbol{\eta})\mathbf{v}\end{bmatrix} \quad (8)$$

$$\mathbf{v}=\begin{bmatrix}u & v & w & p & q & r\end{bmatrix}^T \quad (9)$$

$$\boldsymbol{\tau}=\begin{bmatrix}X & Y & Z & K & M & N\end{bmatrix}^T \quad (10)$$

In (9) u, v, w are the surge, sway and heave velocities and p, q, r are the roll, pitch and yaw rates respectively. In (10) X is the surge, Y is the sway and Z is the heave force, K is the roll, M is the pitch and N is the yaw moment. X and N are controllable by two inputs: one torque at each side. The remaining forces and moments are the unmatched dynamics.

3.2 Trajectory Generation

The trajectory is represented as a series of waypoints, each defined by an x-y coordinate with a common origin. A path between each waypoint and the next is calculated, with the robot stopping at each waypoint to turn on the spot to achieve the desired orientation and then move again.

The distance and time to travel between each waypoint is calculated assuming a constant velocity between stages with initial and final acceleration and deceleration transients: the constant forward speed is 0.1ms^{-1}, analogous to that of operating rovers, and the rotational velocity is 0.1rads^{-1}. At each waypoint a check is made to determine if the rover is at the correct angle for the next traversal forward. If not, then the

rover is commanded to turn on the spot until the desired angle is achieved. The path from one waypoint to the next is defined by specifying the acceleration as a 7th order polynomial function of time and is based on that presented in (Thomson and Bradley, 2006; Worrall *et al.*, 2015a). A 7th order polynomial has the benefit of producing smooth trajectory profiles with high order, continuous derivatives. The output is the acceleration time history, which is then integrated to provide the velocities and the displacements. The result is a continuous time history of acceleration, speed and distance between each successive waypoint that fully describes the rover's position and orientation; namely the elements of $\boldsymbol{v}$, $\boldsymbol{\eta}$.

4 Application Results

A series of waypoints are first defined and then a trajectory between them is generated as in Section 3. It is assumed that these waypoints represent a safe, feasible path. Inverse Simulation calculates the control inputs for each trajectory. Then these inputs are applied to the system and it is checked whether the resulting trajectory matches the desired. The following test trajectories were selected. The Long Distance test (Figure 1, 400s) involves several pose changes and will be used as a benchmark to show how the errors built up over time and to compare the different parameters. The Figure of Eight test (Figure 2, 175s) is used to demonstrate a complex path with multiple, sharp turns and how the method copes with successive pose changes.

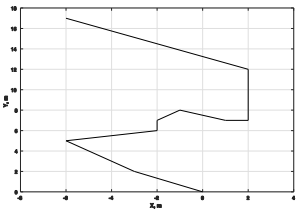

Figure 1. Long Distance.

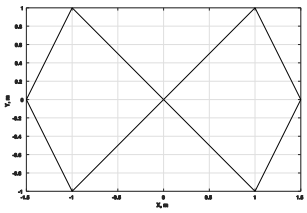

Figure 2. Figure of Eight.

The simulation parameters that need to be assigned values are: discretisation step *dt*, convergence tolerance *tol*, torque input initial estimate, maximum number of iterations for the Newton-Raphson algorithm. For *dt*, the timestep of the motors and the need to adequately follow the system are taken into account (Worrall *et al.*, 2015a). The rover starts from rest (zero motor torque). Here a very small value is set for the initial estimate. The number of iterations is set to ensure convergence without increasing the execution time.

The assessment criteria are the following: (a) mean error and standard deviation between the actual and the desired position x (integrated from u), (b) mean error and standard deviation between the actual and the desired heading angle θ (integrated from r), (c) calculation time, an important measurement for any control algorithm. The position and heading angle represent the rover position in space and hence how wells it follows the desired trajectory.

Table 1. Simulation Parameters.

Parameter	*Set 1*	*Set 2*
dt (s)	0.01	0.05
tol	5×10^{-7}	5×10^{-5}
initial control estimate (Nm)	2.5×10^{-7}	
maximum iterations	30	
MATLAB version	2014b, 64 bit	
hardware	Core 2 Duo T9300, 2.50 GHz, 4 GB RAM	

4.1 Selection of inputs, outputs and Jacobian inversion.

The two controllable outputs are the surge X and the yaw moment N. This is equivalent to controlling the surge and yaw velocities and so the desired outputs are u_d, r_d. There are two control inputs, one torque per side (τ_{left}, τ_{right}). For the Integration method, there are two inputs and two outputs and so the size of the Jacobian (Worrall *et al.*, 2015a; Worrall *et al.*, 2015b) in Eq. (7) is 2x2. For the Differentiation method, it was observed during the initial simulations that including as an additional output to control the sway velocity v, the overall results are significantly improved without sacrificing greatly in execution time. There are three desired outputs: u_d, r_d as before and v_d, which is set to zero. The sway velocity v is not matched dynamically to the actuators of the system and therefore cannot be directly controlled. It is however strongly coupled to u and r (Worrall, 2010) and this interaction can provide indirect control of sway and act as an additional constraint. For the Jacobian, Eq. (4), only the controllable states u, r and also v are taken into account and so its size is 6x5. The remaining states for (4) are estimated after convergence at each t_i. This is an over-determined system and to ensure that the solution is always a least square solution a suitable factorization method is used to find the pseudo-inverse of $\boldsymbol{J}$ and solve (4). There are several methods to find the Jacobian inverse. Table 2 shows the methods in MATLAB that are examined (Davis, 2013). Each method from Table 2 is tested using the Long Distance test and the first set of parameters.

Table 3 shows the results for the Differentiation scheme. The *backslash* method fails because $\boldsymbol{J}$ is (column) rank deficient; this is expected because the outputs to control are u, v and r and v is strongly coupled to u and r. Between *pinv(**J**)* and *factorize(**J**)*, the factorize command is superior in terms of errors and is the one selected, at the expense of increased execution time. The method used by *factorize(**J**)* is the complete orthogonal decomposition, which is suitable for rank deficient systems. Table 4 shows the results for

the Integration scheme. The *backslash* method is the best for the error and execution time and is the one selected. Integration is slower, which is in line with previous observations (Section 2.2).

Table 2. Inversion Methods.

Method	*Comments*
inv() - built-in function	Suitable only for square systems of full rank, can be very inaccurate.
pinv() - built-in function	Suitable for non-square systems, calculates the Moore–Penrose pseudoinverse using singular value decomposition (SVD).
\ (backslash operator) - built-in function	Suitable for square or over determined systems with full column rank, fast, accurate. Factorization cannot be reused. Suggested MATLAB method.
FACTORIZE (Davis, 2013) - additional package, acts as a wrapper for the built-in MATLAB functions	Selects the most suitable factorization method from LU decomposition, Cholesky decomposition, QR decomposition, SVD (singular value decomposition), COD (complete orthogonal decomposition). Suitable for square, rank deficient and over/under determined systems.

Table 3. Inversion: Differentiation (with sway), Long Distance (set 1).

	\	*pinv(J)*	*factorize(J)*
mean position x error (m)	-	0.00247	0.00082

execution time (s)	79.19	376.89	317.84

4.2 Scheme comparison

From Tables 3, 4 the main difference between the two schemes is the calculation time. Differentiation performs slightly better for the heading. Figure 3 shows the control inputs generated for Differentiation and Figure 4 for Integration.

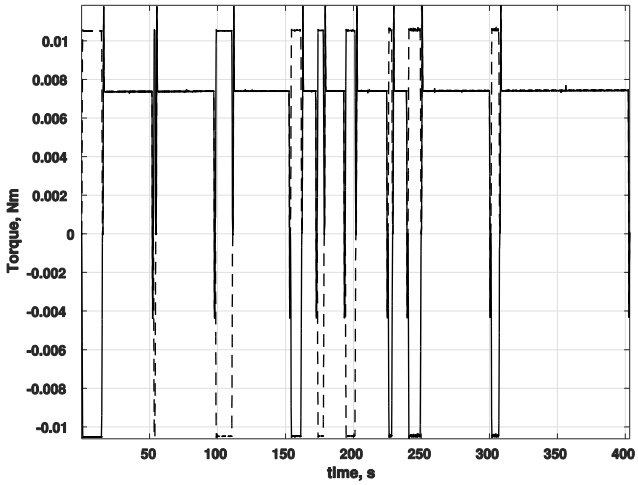

Figure 3. Differentiation Control, Long Distance (set 1).

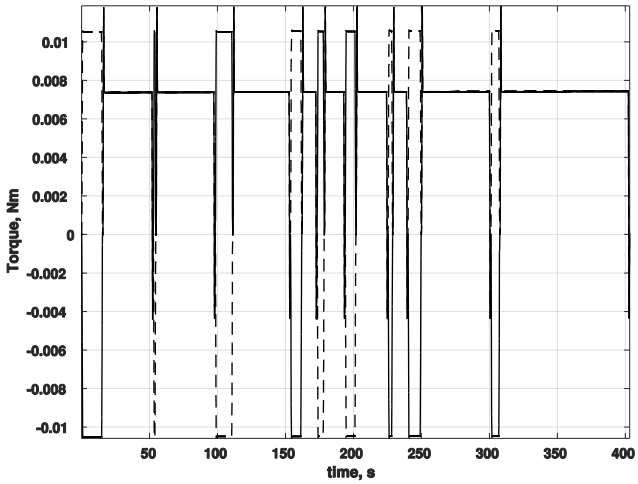

Figure 4. Integration Control, Long Distance (set 1).

The left side control is signified by the solid line and the right side by the dashed line. The left and right signals are symmetrical when the rover is moving forward (e.g. at 100s), which is expected since each side is controlled by one input. When the heading changes there is a momentary spike in the input. The control inputs from Integration are smoother, e.g. between 100 – 150s and at 250s in Figure 3 and 4. The oscillations from Differentiation have a small magnitude and high frequency and are due to the fact that the scheme uses an over-determined system which may have multiple solutions (Section 2.2).

Table 5 shows the results for the Long Distance test, set 2: *dt* is increased and so is the convergence tolerance. The execution time is significantly reduced, and Integration is now faster than Differentiation. Integration performs slightly better in terms of the

position error and Differentiation is better for the heading error. Compared with Tables 3, 4, the standard deviation of both the position and the heading error is larger; the rover has some sharper deviations from the desired position and heading. Figure 5 shows the calculated control input from Differentiation. By increasing the *dt* to 0.05s, the high frequency, low amplitude oscillations in the control input decrease significantly.

Table 5. Long Distance (set 2).

	Differentiation (with sway)	*Integration (without sway)*
mean position x error (m)	0.00468	0.00450
σ position error	0.00314	0.00196
mean heading θ error (rad)	0.00276	0.00736
σ heading error	0.00262	0.00700
execution time (s)	12.19	8.72

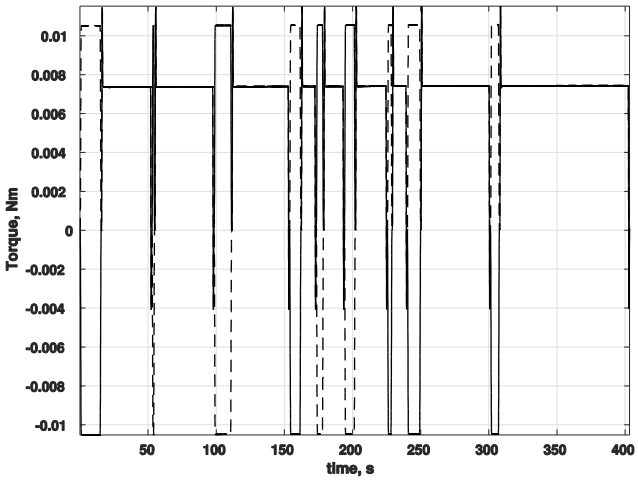

Figure 5. Differentiation Control, Long Distance (set 2).

Table 6 shows the results for the Figure of Eight test. Both methods perform similarly but Differentiation is faster and slightly better for the standard deviation of the heading error.

Figure 6 and 7 show the errors of *u*, *v* and *r* after the Newton–Raphson algorithm for Eq. (3) and (6) has converged at each t_i. The desired value of *v* is set to zero and the desired values of *u* and *r* are the same for both methods. For Differentiation, the error in *r* deviates about 10^{-16} rad/s from zero, whereas for Integration it deviates about 10^{-4} rad/s from zero. The *v* error deviates 10^{-7} m/s from zero and the *u* error deviates 10^{-8} m/s from zero for Differentiation. For Integration, the *v* error deviates 10^{-4} m/s and the *u* error 10^{-5} m/s from zero. At Figure 7, when the heading changes there is a spike in the errors. At Figure 6, the much smaller errors are due to *v* used as an additional output. This effect is particularly evident when comparing the errors in *r*.

Table 6. Figure of Eight (set 1).

	Differentiation (with sway)	*Integration (without sway)*
mean position x error (m)	0.00034	0.00060
σ position error	0.00036	0.00048
mean heading θ error (rad)	0.00202	0.00203
σ heading error	0.09501	0.11632
execution time (s)	25.94	40.45

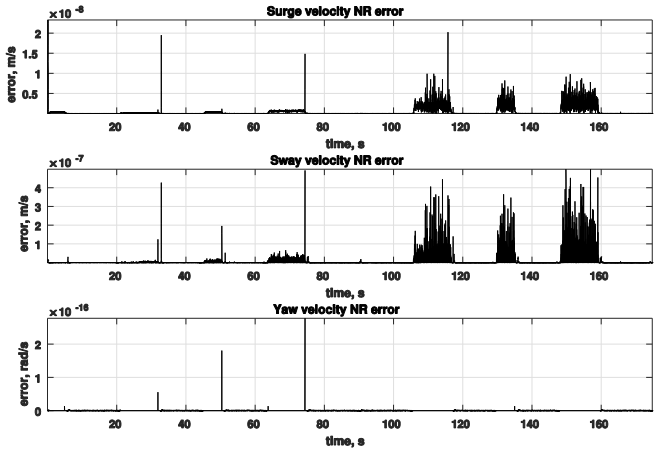

Figure 6. Differentiation NR Errors Fig of Eight (set 1).

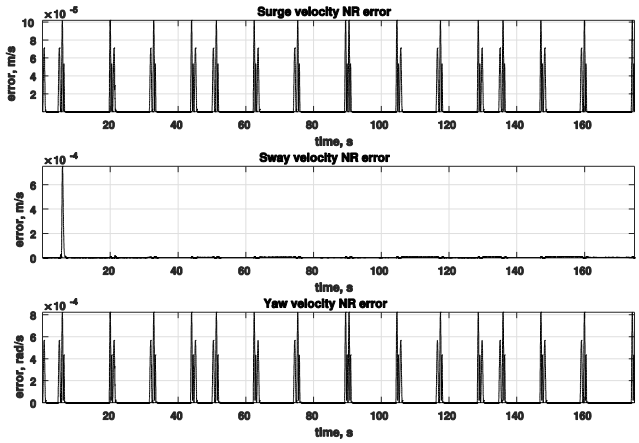

Figure 7. Integration NR Errors Fig. of Eight (set 1).

From Tables 3 - 6, Integration exhibits bigger errors for the heading angle. When the *dt* and the tolerance are small enough or when there are no abrupt orientation changes, this is negligible. As *dt* and the tolerance increase and the trajectory requires sharp heading changes, this difference becomes more important. This can be seen in the failure of Integration for the Figure of Eight test using parameter set 2. The errors in *r* are not corrected, the calculated control in (7) increases and the condition number of $\boldsymbol{J_e}$ by 22.5s (total time 175s) is infinite; the Jacobian is ill-conditioned and cannot be factorized.

4.3 Effect of sway velocity

To reduce the error in r and conversely in θ, the sway velocity v is used as an additional output for Integration. Then, $\boldsymbol{J_e}$ in Eq. (7) has a size of 3x2: three outputs (u, v, r), two inputs and the *factorize* command is used. Table 7 shows the results for the Figure of Eight test, set 2. Both methods produce similar results, however Integration is slower and still has a larger error and standard deviation for the heading. Nonetheless, the usage of v has here a positive effect and enables Integration to converge. When using v in Integration for the Long Distance test, set 2, the execution time increases to 29.71s compared to 8.72s (Table 5) without any error improvements. For the Long Distance test, set 1 (Table 4), the time is greatly increased to 791.99s.

Table 7. Figure of Eight Test (set 2).

	Differentiation (with sway)	*Integration (with sway)*
mean position x error (m)	0.00384	0.00332
σ position error	0.00259	0.00231
mean heading θ error (rad)	0.01047	0.02298
σ heading error	0.00259	0.27941
execution time (s)	5.30	20.71

Table 8. Differentiation: Long Distance (set 1).

	Differentiation (with sway)	*Differentiation (without sway)*
mean position x error (m)	0.00082s	0.002404
σ position error	0.00080	0.001960
mean heading θ error (rad)	0.00053	0.003154
σ heading error	0.00056	0.002864
execution time (s)	55.45	56.26

Table 8 shows the Differentiation results for the Long Distance test (set 1) with and without using v. Without v, $\boldsymbol{J}$ in (4) is square (4x4). The errors increase by two orders of magnitude and the execution time is almost the same: the method converges slower and with larger errors. Compared with Integration (Table 4), the inclusion of v has a greater effect on Differentiation. This confirms previous results, that Integration is more stable. Here, Differentiation performs slightly better but requires an over-determined system and specialized handling.

5 Conclusions

The selection of outputs to control, their effect on the size of the Jacobian and the best factorization method were examined. A square Jacobian is used for Integration and an over-determined for Differentiation. The schemes were compared for varying dt and convergence tolerance. A small dt results in high frequency, low amplitude oscillations in the control input from Differentiation. To remove these, the dt was increased. The effect of sway velocity v, which is strongly coupled with u, r but not directly controlled, was examined. For Differentiation, using v as an output is beneficial from the start. Integration performed well for both parameter sets for the Long Distance test without v. For the Figure of Eight test for a dt of 0.05s and tolerance 5×10^{-5}, including v was necessary. It is worth noting that this test is not a realistic trajectory and is used to test the method's limits. A dt of 0.01s and a tolerance of 5×10^{-7} produce the best results, with increased calculation time. For simplicity and overall stability, the Integration scheme is more appropriate. For decreased execution time, Differentiation is preferred, at the expense of slightly larger position errors and an over-determined system. In all cases, the control inputs from Inverse Simulation where within operational limits.

An Improved Kriging Model based on Differential Evolution

Xiaobing Shang, Ping Ma*, Ming Yang

Control and Simulation Center, Harbin Institute of Technology, P.R. China, shangxiaobing1992@126.com, pingma@hit.edu.cn, myang@hit.edu.cn

Abstract

Kriging model is a commonly interpolate approximation method which is widely used in the computer simulation in the past decade. The fitting accuracy is one of the fundamental problems in the research of kriging model, which can be summarized in two aspects, the accurate estimation of model's parameters and approximate form selection of kriging model. In order to solve the existed problems, an improved parameter estimation method of kriging model base on differential evolution (DE) algorithm is set out in the present paper. Firstly, establish the objective function of DE algorithm depends on the estimation of the model's accuracy, and get the optimum solution of model's parameters under the initial condition. Then, a variety of regression function and correlation function in kriging models are selected to compare the fitting accuracy. Finally, the simulation case for outer ballistic data on electromagnetic railgun is examined to determine whether the improved method has priority over traditional one in the approximation accuracy.

Keywords: Kriging model, DE algorithm, approximation accuracy, EM railgun

1 Introduction

Kriging interpolation model, which is an optimal linear unbiased estimate model, is a commonly spatial interpolation model based on the geostatistical variogram theory. In 1989, this theory is introduced to the computer simulation field, and then gradually become a frequently-used interpolation method, which is used in a variety of applications including mechanics engineering, structural optimization and sequential experimental design (Volpi *et al*, 2015). The approximation accuracy is one of the key problems of current research which including how to effectively estimate the kriging model's parameters and select the approximate form of model. These two aspects determine the fitting accuracy, which is the significant approach of model investigation.

A mounts of research is taken to solve the problems of improving the model's accuracy. Jay D. Martin proposed an estimate method of model's parameters by using maximum likelihood estimate (MLE) and cross validation (CV) methods. The analysis results showed that the MLE is prior to CV method, which are applied in three different dimensional fitting problems (Martin *et al*, 2005; Martin *et al*, 2004). Jack P.C. summarized currently research achievements and pointed out that the approximation accuracy is determined by the form and parameters of correlation function (Kleijnen *et al*, 2009). Søren N. Lophaven developed a matlab tool DACE, which used to compute the kriging model effectively. The model's parameters are made easy through DACE. Unfortunately, this tool need to limit the minimum and maximum value of parameters, and cannot find the optimal results, which determine the narrow application fields of this method (Lophaven *et al*, 2002; Lophaven *et al*, 2002). LIU Xiaolu considers the model's accuracy is not only determined by parameters estimation, but also by the sampling points. The improved general pattern search (IGPS) algorithm was used to get these points. And a satellite orbit parameter optimization problem is formulated, which showed that kriging models based on global approximations are more accurate than Analyzer. However, this improved method is too complexity and time-consuming and can't applied in the engineering (Hui *et al*, 2016; Huang *et al*, 2011; Liu *et al*, 2013).

Differential Evolution algorithm (DE) is a novel swarm intelligence method to search for the optimal result based on the cooperation and competition between different individualities. The DE algorithm is regarded as one of the best optimization method. Some experiments over several numerical benchmarks show that DE performs better than the Genetic algorithm (GA) or the Particle Swarm Optimization (Steentjes *et al*, 2016; Civicioglu *et al*, 2013). In order to improve the DE's performance and solve the problems such as convergence speed and time-consuming, some improved DE algorithm is proposed (Sharma *et al*, 2014; Padhye *et al*, 2015). Considering the robustness and briefness, the DE method gradually gets more and more concentration among pattern recognition, nonlinear optimize control, mechanical engineering and so on (Neri *et al*, 2010; Weber *et al*, 2010).

Considering current situation, how to establish a more accuracy model effectively and quickly is the main problem. Due to the disadvantage of existed approaches, an improved DE based method to estimate

kriging model's parameters is presented in this paper. DE algorithm is an outstanding method to search for the global optimization parameters with high speed. The approximate optimal parameters can be obtained by this algorithm and be used to build an optimal model. At the end of paper, an engineering example of electromagnetic railgun exterior ballistic data is examined to demonstrate the superiority of kriging model based on DE algorithm.

2 Theory of kriging model

Considering a simulation system, a set of m design sites and the output response sites be expressed as

$$\begin{aligned} S &= [s_1\ s_2 ... s_m]^T, s_i \in \mathbb{R}^n \\ Y &= [y_1\ y_2 ... y_m]^T, y_i \in \mathbb{R}^q \end{aligned} \tag{1}$$

Where $s_i = \{s_{i1}, s_{i2,} ... s_{in}\}$ and $y_i = \{y_{i1}, y_{i2,} ... y_{iq}\}$ is the *i*th order in the experiments. The kriging model regards the deterministic response $y(x)$ for an *n* dimensional input $x \in \mathbb{R}^n$ as a combination of a regression model and a random function

$$y(x) = f(x)^T \beta + z(x) \tag{2}$$

Where, $f(x)$ is a vector component of 1, *x* and the other high order items, β is the regression coefficient, $z(x)$ is the random function, which is assumed to have a zero mean and σ^2 variance. The covariance between *n* dimensional inputs x_i and x_j be expressed as

$$Cov\left(z(x_i), z(x_j)\right) = \sigma^2 R(\theta, x_i, x_j) \tag{3}$$

Where, $R(\theta, x_i, x_j)$ is the correlation function with specified parameters θ.

For the set *S* of design sites, a $m \times p$ design matrix *F* is constructed with $F_{ij} = f_j(s_i)$

$$F = \left[f(x_1), f(x_2), ..., f(x_m) \right]^T \tag{4}$$

Furthermore, a correlation matrix *R* between the design sites be defined as $R_{ij} = R(\theta, s_i, s_j)$

$$r(x) = \left[R(\theta, s_1, x), R(\theta, s_2, x), ..., R(\theta, s_m, x) \right]^T \tag{5}$$

The estimation value of output response $\hat{y}(x)$ is a linear combination of response in the design sites

$$\hat{y}(x) = \lambda(x)^T Y \tag{6}$$

The kriging model regards $\hat{y}(x)$ as an optimal linear unbiased estimation of output response $y(x)$. Then, the problem of kriging interpolation can be transformed to an optimization problem

$$\begin{aligned} &\min\ E\left\{ \hat{y}(x) - \lambda(x)^T Y \right\}^2 \\ &s.t.\ \ E\left(\hat{y}(x) - \lambda(x)^T Y \right) = 0 \end{aligned} \tag{7}$$

The solution to the optimization problem above is

$$\hat{y}(x) = f^T(x)\hat{\beta} + r^T(x) R^{-1}\left(Y - F\hat{\beta}\right) \tag{8}$$

Where, the least squares solution of parameter $\hat{\beta}$ is

$$\hat{\beta} = \left(F^T R^{-1} F\right)^{-1} F^T R^{-1} Y \tag{9}$$

The Mean Square Error (MSE) of $\hat{y}(x)$ is

$$\varphi(x) = \sigma^2 \left\{ 1 - \left[f^T(x)\ \ r^T(x) \right] \begin{bmatrix} 0 & F^T \\ F & R \end{bmatrix} \begin{bmatrix} f(x) \\ r(x) \end{bmatrix} \right\} \tag{10}$$

3 Kriging model based on DE algorithm

In this section, the improved method based on DE algorithm is described in detail. Firstly, the basic theory and operations are introduced to support the application in the kriging model. Then, the second part is to assess the kriging model's performance, and lead to an optimization problem. Finally, DE method is applied to solve the optimization problem, and the flowchart of DE based kriging model is used to show the process.

3.1 Theory of DE algorithm

Differential Evolution (DE) is a well-known and simple approach for global optimization, which consists of three basic operations: mutation, crossover and selection. The compute process of DE algorithm is familiar with GA method and can be summarized in the following steps:

- Initialization: set the algorithm's parameters including population members *NP*, variable number *D*, mutagenic factor *F* and crossover probability *CR*, then the initial population

$\left\{ x_{i,j}(0) \mid x_{i,j}^l \le x_{i,j}(0) \le x_{i,j}^u, i = 1, 2, ..., NP, j = 1, 2, ..., \mathrm{D} \right\}$

can be generated by

$$x_{i,j}(0) = x_{i,j}^l + rand(0,1) \times \left(x_{i,j}^u - x_{i,j}^l \right) \tag{11}$$

Where $x_{i,j}(0)$ is the *j*th variable among the *i*th individuality in the 0th generation, $x_{i,j}^u$ and $x_{i,j}^l$ are the upper and lower bound of $x_{i,j}$, respectively. The variable rand(0,1) is the random number of uniform distribution in the interval $(0,1)$.

- Mutation: mutation is a basic operation in the DE algorithm. Which is the largest difference compared with the GA method. The mutation operation can be described as

$$v_i(t+1) = x_{r_1}(t) + F \times \left(x_{r_2}(t) - x_{r_3}(t) \right) \tag{12}$$

Where, r_1, r_2, r_3, i are not equal with each other and $r_1, r_2, r_3 \in \{1, 2, ..., NP\}$, $v_i(t+1)$ is the (*t*+1)th generation mutation individuality, $x_i(t)$ is the *i*th individuality in the *t*th generation.

- Crossover: for the given individuality $x_i(t)$, it's necessary to use the operation of crossover to generate new experiment individuality $u_i(t)$. The equation is

$$u_{i,j}(t+1)=\begin{cases} v_{i,j}(t+1), \text{rand}(j)\le CR \text{ or } j=randn(i) \\ x_{i,j}(t), \text{rand}(j)>CR \text{ or } j\ne randn(i) \end{cases} \quad (13)$$

Where $\text{rand}(j)\in[0,1]$ is the random number of uniform distribution, j is the jth variable of the individuality, $randn(i)\in\{1,2,...,D\}$.

- Selection: the greedy strategy is applied in the DE algorithm to search for the best individuality in a population between $u_i(t)$ and $x_i(t)$, the operation can be expressed as

$$x_i(t+1)=\begin{cases} u_i(t+1), f(u_i(t+1))< f(x_i(t)) \\ x_i(t) \quad , f(u_i(t+1))\ge f(x_i(t)) \end{cases} \quad (14)$$

After iterating the operations above for many times, it is easy to get the optimal vector in the solving space, which will be used in the optimization of kriging model's parameters in the next step.

3.2 Kriging interpolation based on DE algorithm

In general, the quality of a model can be measured by two aspects: 1) the accuracy of data in the design sites. 2) Accuracy in predicting the output response at the estimating points. However, due to the unbiased predictor of kriging model, which means the estimation in the design sites is exactly, the first measurements don't need to consider in this work. And the second aspect to calculate the accuracy at the estimating points is very significant for kriging model.

For a simulation system, the input set of predictor is assumed as $P=[p_1\ p_2...\ p_l]^T, p_i\in\mathbb{R}^n$ and the system real output response and kriging predictor can be expressed as

$$\begin{aligned} Y_p &= [y_{p_1}\ y_{p_2}...\ y_{p_l}]^T, y_i\in\mathbb{R}^q \\ \hat{Y}_p &= [\hat{y}_{p_1}\ \hat{y}_{p_2}...\ \hat{y}_{p_l}]^T, \hat{y}_i\in\mathbb{R}^q \end{aligned} \quad (15)$$

The sum of squared prediction errors is

$$\begin{aligned} SS_T &= \sum_{i=1}^{n}\left(y_{p_i}-\bar{y}_p\right)^2 \\ &= \sum_{i=1}^{q}\left(\hat{y}_{p_i}-\bar{y}_p\right)^2+\sum_{i=1}^{n}\left(\hat{y}_{p_i}-y_{p_i}\right)^2 \\ &= SS_R+SS_E \end{aligned} \quad (16)$$

The accuracy of kriging model is defined as

$$R^2_{fit}=1-SS_E/SS_T, R^2_{fit}>0 \quad (17)$$

For the definition of kriging model accuracy, $R^2_{fit}\in(0,1)$, the value of R^2_{fit} determine the fitting accuracy. In order to get a higher accuracy, the value of R^2_{fit} is as large as it can be. Furthermore, the sum of squared errors of prediction is a fixed value for a specific set of predictors, which means the value of SS_E is as small as it can be. Thus, the model assessment can be transformed to an optimization problem

$$\begin{aligned} &\min\ \sum_{i=1}^{n}\left(\hat{y}_{p_i}-y_{p_i}\right)^2 \\ &s.t.\ \ \hat{y}_{p_i}=f^T(p_i)\hat{\beta}+r^T(p_i)R^{-1}\left(Y-F\hat{\beta}\right) \end{aligned} \quad (18)$$

For a given form of correlation function, the key factor that has a highest influence on the fitting accuracy is the parameters' estimation. From the objective function above, it's obvious that the kriging model accuracy is related with the parameters β and R. There are two methods to estimate the parameters, which are maximum likelihood estimation (MLE) and cross validation (CV). The MLE method was used in this paper and estimation results of β and σ^2 is

$$\begin{aligned} \hat{\beta} &= \left(F^TR^{-1}F\right)^{-1}F^TR^{-1}Y \\ \hat{\sigma}^2 &= \frac{1}{n}(y-F\beta)^T R^{-1}(y-F\beta) \end{aligned} \quad (19)$$

It's clearly that the parameters β and R are related with the estimate value of $\theta=\{\theta_1,\theta_2,...,\theta_n\}$, which transform the objective function's optimization to estimate the parameters θ. Two computational problems often exist when estimating the parameters using traditional method: *1)* the maximum likelihood estimate of the parameters may be multimodality and hardly to find the optimal result. Therefore, the selection of initial value of parameters has a strong influence on the estimation result. *2)* The method above is very suitable for approximating low dimensional model, and has a poor effect of high dimensional one. Considering the robustness and practicability of DE algorithm to solve nonlinear, non-differentiable, multi-extremum and high dimensional problems, an improved kriging model based on DE algorithm is proposed in this paper.

3.3 Process of kriging Model based on DE algorithm

The kriging model's parameters $\theta=\{\theta_1,\theta_2,...,\theta_n\}$ are the variable need to optimize which is determined by the system input. Due to the optimization's purpose is to improve the model fitting accuracy, (11) is utilized to act as the objective function of DE algorithm. The process to optimize kriging model's parameters is presented as show in Figure 1, which can summarize in three aspects:

- Setting DE algorithm parameters: set the objective function with (18) to evaluate the efficiency of DE algorithm. Depend on the research target and compute scope, initialization the DE algorithm's parameters and

carry out the operation of crossover, mutation and selection.

- Data preprocessing: generally, the establishment of kriging model is based on the assumption that the system's input and output data satisfy the normal distribution $N(0,1)$. So it's significant to verify and normalize data's normalization before constructing the kriging model. As stated in Sec. II, the system input samples and output response can be expressed as

$$\begin{aligned} S &= [s_1\ s_2 ... s_m]^T, s_i \in \mathbb{R}^n \\ Y &= [y_1\ y_2 ... y_m]^T, y_i \in \mathbb{R}^q \end{aligned} \tag{20}$$

For simple, data normalization can be described as follows:

$$\begin{aligned} I_i &= \left(s_{:,i} - \overline{s_{:,i}}\right) / \sigma_{s_{:,i}}, i = 1,2,.....,n, \\ O_j &= \left(y_{:,j} - \overline{y_{:,j}}\right) / \sigma_{y_{:,j}}, j = 1,2,...,q \end{aligned} \tag{21}$$

Where, $\overline{s_{:,i}}$ and $\overline{y_{:,j}}$ is the mean of ith input and jth output variable, respectively; $\sigma_{s_{:,i}}$ and $\sigma_{y_{:,j}}$ is the mean variance of ith input and jth output variable, respectively. The calculate equation is

$$\begin{aligned} \overline{s_{:,i}} &= 1/m \sum_{i=1}^{m} s_{ij}, \ \overline{y_{:,j}} = 1/m \sum_{i=1}^{m} y_{:,j} \\ \sigma_{s_{:,i}} &= \sqrt{\sum_{i=1}^{m} (s_{ij} - \overline{s_{:,i}})^2}, \ \sigma_{y_{:,j}} = \sqrt{\sum_{i=1}^{m} (y_{ij} - \overline{y_{:,j}})^2} \end{aligned} \tag{22}$$

After normalization, the mean and variance of the input and output data are 0 and 1, respectively.

- Model computation and optimization: select the specific kriging model including type of correlation function and form of regression function, and then optimize the kriging model's parameters based on DE algorithm, which is stated in Sec. II. As shown in Figure 1, the improved method can be divided into two aspects: the DE algorithm global search and kriging model establishment.

From the process above, it's obvious that the DE algorithm is very suitable for the kriging model's optimization. With the DE method, the best parameters can be gained to establish an optimal kriging model.

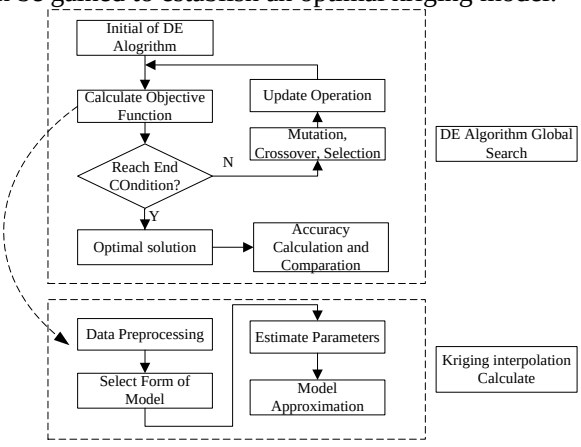

Figure 1. Flow chart of the kriging based on DE method.

4 An engineering example

To demonstrate the validity of kriging model based on DE algorithm, EM railgun exterior ballistic simulation data is taken for example. Due to the complexity of railgun ballistic, the flight range of projectile suffers from a variety of factors, which have a different degree of effect, and coupled with each other. Thus, during the research of projectile's performance, it's crucial to study the relation between projectile's flight range and a set of factors. The linear regression model is the ordinary method to solve this problem. However, the different factors may interaction with each other, and hardly to draw an expression with the projectile's range. Furthermore, the classic regression is the maximum likelihood estimation of sampling points and hardly to solve the problem of multivariable and multimodality. Thus, the kriging model based on DE algorithm is used to establish the model between range and factors.

In this paper, six separate factors including projectile mass, launch velocity, launch angle, deflection angle, wind velocity in x and z direction, are considered in the paper to establish the relationship with flight range using kriging model. Meanwhile, DE algorithm was utilized to optimize the kriging model's parameters and get a higher accuracy.

4.1 Setting DE algorithm parameters

In order to improve the efficiency of DE algorithm and speed up the algorithm convergence, the parameters of DE algorithm set as follows:

The size of population is 30. Mutagenic factor is 0.5, and crossover probability factor is 0.7. Considering the optimal parameters set $\theta = \{\theta_1, \theta_2, ..., \theta_n\}$ represent weight of each dimension, it's important to restrict the span of $\theta_i, i = 1,2...,n$. In general, the range of θ_i is set as $[0.1d_{\min}, 10.0d_{\max}]$, where $d_{\min}$ and $d_{\min}$ represents the minimum and maximum distance of ith input parameter sets, respectively.

4.2 Data preprocessing

Before establishing the kriging model, it's obvious to preprocess the flight range data. The normalization verification result is demonstrated in Figure 2 and 3, which including two graphs: the left and right one is the bar graph of flight range and result of normality test, respectively. As the verify result show, the disperse position of range data coincide with the standard normalization reference line. Furthermore, it's necessary to take the range data with normalization operation, which is obtained from (12) and (13). Thus, the railgun data meets the requirement of kriging model construction after preprocessing.

4.3 Model computation and optimization

After accomplishing the data preprocessing, the last step is to compare the model accuracy by two aspects: 1) the approximation accuracy of kriging model based on DE algorithm and ordinary one, 2) the accuracy of different forms of correlation function and regression function $f(x)$. In order to demonstrate the superiority of improved method, three types of correlation function and five forms of regression function $f(x)$ is adapted in the DE method in this paper. The types of correlation function consist of Exp, Gauss and Linear and the forms of regression function are summarized in Table 1.

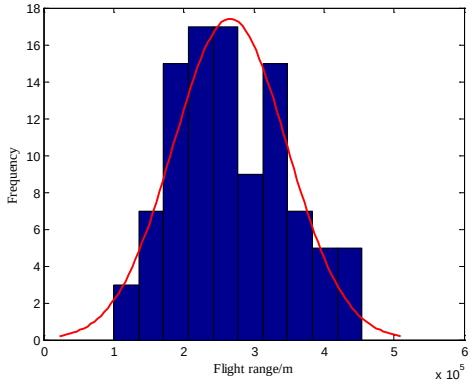

Figure 2. Histogram of the range data.

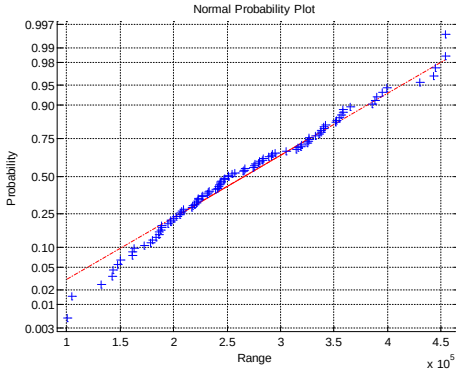

Figure 3. Normalized test result.

Given the different types of correlation function and forms of regression function in the kriging model, the DE algorithm is used to search for the optimization of kriging model's parameters. The sum error data of DE based kriging model and traditional one are listed in Table 2 and 3. In order to have an intuitive grasp of these two methods, a histogram of kriging model error is showed in the Figure 4, where the left and right bar is the improved method and traditional one, respectively. In the Figure 4, the horizontal and longitudinal ordinates of histogram represent the forms of $f(x)$ and sum of approximation error. The three colors indicate three type of correlation function Exp, Gauss and Linear. At the aspect of DE algorithm convergence speed, the kriging model which consists of the fourth form of regression function and Gauss correlation function is examined to reveal the iteration process in Figure 5.

Table 1. Forms of the regression function $f(x)$.

Indication	*Forms of* $f(x)$
1	1
2	$[1, x_1, x_2, ..., x_n]$
3	$[1, x_1, x_2, ..., x_n, x_1^2, x_1x_2, x_1x_3..., x_n^2]$
4	$[1, x_1, x_2, ..., x_n, x_1^2, x_2^2, ..., x_n^2]$
5	$[1, x_1, x_2, ..., x_n, x_1x_2, x_1x_3..., x_{n-1}x_n]$

Table 2. Sum errors of kriging model based On DE.

Indication	*EXP*	*GAUSS*	*LIN*
1	5.58e4	4.99e4	4.46e4
2	3.065e4	1.99e4	2.52e4
3	1.86e4	5.75e3	1.59e4
4	1.38e4	6.52e3	1.06e4
5	3.51e4	2.23e4	3.2e4

Table 3. Sum errors of traditonal kriging model.

Indication	*EXP*	*GAUSS*	*LIN*
1	9.77e4	1.08e5	2.34e5
2	3.11e4	2.53e4	3.43e4
3	1.93e4	1.2e4	3.29e4
4	1.47e4	8.49e3	2.72e4
5	3.77e4	3.21e4	4.05e4

As show in Figure 4, the kriging model based on DE algorithm is prior to the traditional one in the model's accuracy. For the different types of correlation function, the Gauss model has a significant advantage than the other models. Meanwhile, the fourth type of regression function has the highest accuracy in the five forms of regression function. So it's essential to compare different forms of regression function to select the highest accuracy one.

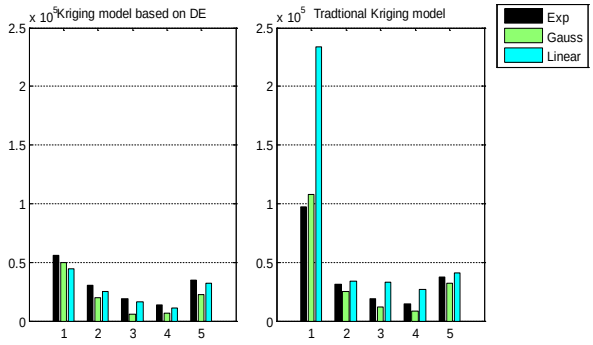

Figure 4. Histogram of the kriging model error.

Owing to the accuracy of kriging model has a slight relation with complexity of regression function. Figure 5 also prove the high speed of DE algorithm

convergence, it's obvious that the approach could find the optimization result quickly and effectively. Thus, the kriging model based on DE algorithm improves the approximate on accuracy and has a valuable application in engineering.

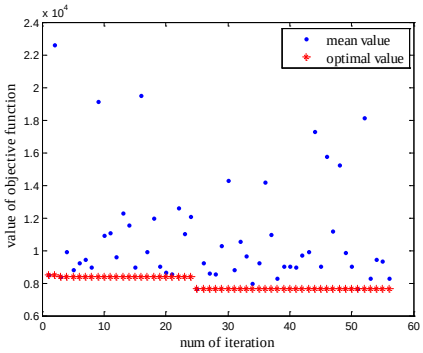

Figure 5. Iteration process of the DE optimization.

5 Conclusions

The parameters estimation and approximate form selection to obtain a higher accuracy model is a basic existed problem in the research of kriging interpolation. In the traditional method, the model parameters selection always depends on users. In order to solve the problem and get an optimal model, an improved kriging model based on DE algorithm to approximate simulation model was presented in this article. The research of kriging model proves that correlation function's parameters have a strong influence on the fitting accuracy. Then the DE algorithm establishes the objective function by fitting accuracy to optimize the kriging model's parameters. The EM railgun exterior ballistic data was taken for instance to demonstrate the priority of improved method. Three forms of correlation function and five types of regression model are used to compare the approximation accuracy of kriging model based on DE algorithm with traditional one. The simulation results show that the kriging model based on DE algorithm has the higher accuracy, and a fine prospect of engineering application.

There is a need for more research on the improved method. Although the DE algorithm perform well in kriging model, it's essential to have deep research of the DE parameters such as population members NP, variable number D and mutagenic factor F, which determine the search efficiency. So the future work can be concentrated on parameters selection strategy to obtain a higher speed.

Simulation of Control Structures for Slug Flow in Riser during Oil Production

Ole Magnus Brastein Roshan Sharma

Department of Electrical Engineering, IT, and Cybernetics, University College of Southeast Norway, Porsgrunn, Norway, {ole.m.brastein, roshan.sharma}@usn.no

Abstract

The occurrence of slug flow is a common problem arising in the oil well riser pipeline. To eliminate such slug flow, various control structures along with state estimation are designed and compared in this paper. Nonlinear model based predictive scheme are compared with classical PI controllers for three different control structures. One of the control structure is based on controlling the mass of the liquid in the riser pipeline, for which, an Unscented Kalman Filter is designed to estimate the mass. The simulation results show that the model based controllers perform relatively better than the classical controllers. Although computationally expensive, the control algorithm used in this paper for model based control still makes it real time implementable.

Keywords: slug flow, oil riser, model based control, PI control, unscented Kalman filter

1 Introduction

In oil well riser pipelines with low-point angle, the liquid column accumulated in the riser above the low point acts as a virtual valve (see Figure 1), alternately blocking and letting the gas produced from the reservoir to flow through the riser. This is due to the hydrostatic pressure exerted at the low point by the liquid column in the riser. The gas produced from the reservoir at first starts to accumulate below the low point. The pressure builds up and reaches to a critical point where the built-up pressure exceeds the hydrostatic pressure drop. This results in a rapid discharge of the accumulated gas to the riser. This large gas bubble/volume pushes up some of the liquid in the riser and out from the choke valve. However, with time, the liquid again starts to accumulate in the riser. The gas pressure at the horizontal flowline starts to build up again and the cycle repeats. This behavior of the fluid flow in the riser is known as slug flow. It is an unstable multiphase flow where oscillation in the production of oil from the reservoir occurs.

Formation of slug flow in oil well riser pipelines has been studied by many other researchers. Various control solutions to avoid the slug flow in oil wells along with the development of mathematical model and controllability analysis can be found at (Storkaas, 2005). Control of riser base pressure for stabilizing the slug flow have been studied by (Aamo et al., 2005; Dalsmo et al., 2005). A simplified model based on first principles modeling for reproducing slugging oscillations of a real oil well was developed by (Meglio et al., 2009). This model was later used by (Meglio et al., 2012b) for designing control structures. Control strategies for slug control and tuning rules was studied by (Godhavn et al., 2005). A nonlinear controller using integrator backstepping approach was used by (Kaasa et al., 2007) to stabilize unstable wells. A review of recent advances in the suppression of the slugging phenomenon by model-based control can be found at (Meglio et al., 2012a). This article gives a clear presentation of the evaluation and comparison of the existing solutions and proposes directions for improvement. A similar type of slugging phenomenon is also observed for gas-lifted oil wells. Stabilization of gas-lift wells by feedback control was studied by (Eikrem, 2006; Imsland, 2002). An insight and understanding into how feedback control can be used to avoid severe slugging, thereby bridging the gap between control and petroleum engineering can be found at (Havre and Dalsmo, 2002).

In this paper, three different control structures/strategies are developed to stabilize the flow in the riser so that the flow does not oscillate and becomes stable. In Section 2, a brief description of the model that captures the slug flow phenomenon in the riser is described. The model is simulated to illustrate its capability of capturing the formation of slug flow in the riser in Section 3. Implementation of an Unscented Kalman Filter(UKF) for estimating the states of the system is provided in Section 4. In Section 5, the formulation of the three different control strategies is presented. The simulation results obtained from the model based controller and the PI controller are clarified, compared and discussed in Section 6. A possibility for the real time implementation and the computational time required by the model predictive controller (MPC) is discussed in Section 7. A brief discussion on the maximum valve opening that can be achieved before the flow becomes unstable again is presented in Section 8. Finally, conclusions are provided in Section 9.

2 Model for slug flow

A widely used mathematical model for representing the slug flow in the oil well risers was developed by (Meglio et al., 2012b) and this model has been used in the present

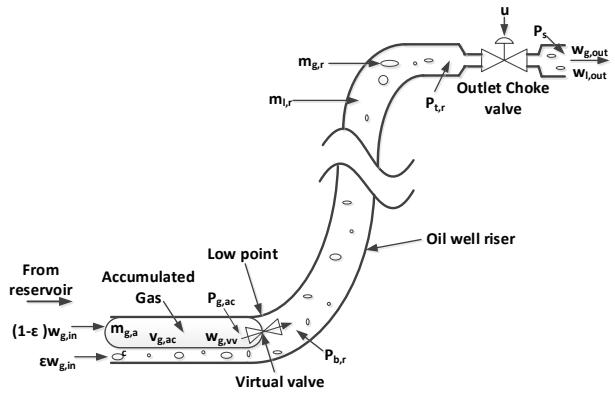

Figure 1. Schematic of fluid transportation in the flow line and riser.

work. Only a brief description of the model is presented in this section and the details about the development of the model can be found at (Meglio et al., 2012b). Let us consider the low point of the riser at the place where the virtual valve is located as shown in Figure 1.

The flowline and the riser are divided into three separate volumes/parts: (i) Volume at the horizontal part of the flowline where the incoming gas from the reservoir accumulates, (ii) Volume of the vertical riser filled with liquid only, and (iii) Volume of the vertical riser filled with gas only. The model is based on the conservation principle where the mass balance is applied to each of the three volumes. The state variables are the mass of the gas accumulated in the horizontal flowline $(m_{g,ac})$, the mass of the gas in the riser $(m_{g,r})$ and the mass of the liquid in the riser $(m_{g,l})$. From the mass balances we obtain,

$$\frac{dm_{g,ac}}{dt} = (1-\lambda)w_{g,in} - w_{g,vv}, \tag{1}$$

$$\frac{dm_{g,r}}{dt} = \lambda w_{g,in} + w_{g,vv} - w_{g,out}, \tag{2}$$

$$\frac{dm_{g,l}}{dt} = w_{l,in} - w_{l,out}. \tag{3}$$

Here, λ denotes the fraction of gas coming from the reservoir that directly flows to the riser, $w_{g,in}$ is the flow rate of the gas entering the riser, $w_{g,vv}$ is the flow rate of the gas through the virtual valve, $w_{g,out}$ is the flow rate of the gas flowing out of the riser through the outlet choke valve, $w_{l,in}$ is the flow rate of the liquid entering the riser and $w_{l,out}$ is the flow rate of the liquid flowing out of the riser through the outlet valve. The algebraic equations involved in the models are listed below. These are taken from (Meglio et al., 2012b) and the details about their development is not provided in this paper.

$$w_{g,vv} = C_{g,vv} max\left(0, (P_{g,ac} - P_{b,r})\right) \tag{4}$$

$$P_{g,ac} = \frac{m_{g,ac}RT}{MV_{g,ac}} \tag{5}$$

$$V_{g,r} = V_r - \frac{\left(m_{l,r} + m_{l,min}\right)}{\rho_l} \tag{6}$$

$$P_{t,r} = \frac{m_{g,r}RT}{MV_{g,r}} \tag{7}$$

$$P_{b,r} = P_{t,r} + \left(m_{l,r} + m_{l,min}\right)\frac{gsin\theta}{A} \tag{8}$$

$$w_{out} = C_{out}u\sqrt{\rho_m\left(P_{t,r} - P_s\right)} \tag{9}$$

$$w_{l,out} = \frac{m_{l,r}}{m_{l,r} + m_{g,r}} w_{out} \approx w_{out} \tag{10}$$

$$w_{g,out} = \frac{m_{g,r}}{m_{l,r} + m_{g,r}} w_{out} \approx \frac{m_{g,r}}{m_{l,r}} w_{out} \tag{11}$$

Here, $C_{g,vv}$ is the valve constant for the virtual valve, $P_{g,ac}$ is pressure of the gas accumulated in the horizontal flowline (upstream the virtual valve), $P_{b,r}$ is the pressure at the bottom of the riser, $P_{t,r}$ is the pressure at top of the riser, P_s is the separator pressure, R is the ideal gas constant, T is the temperature of the fluid in the riser, M is the molar mass of the gas, $V_{g,ac}$ is the volume of the horizontal flowline where the gas accumulates, V_r is the physical volume of the riser, $V_{g,r}$ is the volume of gas in the riser, $m_{l,min}$ is the minimum amount of liquid present in the riser at all times, ρ_l is the density of the liquid, θ is the mean inclination of the riser pipe, A is the cross section of the riser, C_{out} is the valve constant for the outlet choke valve, $u \in [0,1]$ is the valve opening and w_{out} is the total mass flow rate flowing out of the riser through the outlet valve.

3 Simulation for slug flow

The model presented in Section 2 is simulated in MATLAB to observe the occurrence of the slug flow in the riser pipeline. The mass flow rate of the gas and the liquid flowing into the well from the reservoir are considered to be constant. With a nominal valve opening of 0.35 or 35%, the fluid flow in the riser pipe i.e. the outflow from the outlet valve exhibits a slug flow as shown in Figure 2.

The flow of the liquid from the outlet valve oscillates with a time period of about 50 minutes. This is due to the virtual valve that alternately blocks and lets the gas to flow through the riser, thus producing a slug flow. The pressure at the bottom and top of the riser oscillates and this oscillating nature of the pressures in the riser actually creates the slug flow. The average production of oil from the field due to an unstable slug flow is lower than the theoretical steady state (or equilibrium) production. Such unstable slug flow should be controlled or stabilized.

In reality, the process operators choke the outlet valve manually to stabilize the slug flow. The slug flow can be stabilized by decreasing the opening of the output choke valve. A stabilized slug flow results in a non-oscillating pressure at the bottom of the riser. In Figure 3, the choke valve opening is decreased from 45% to 15% in steps. As can be seen from Figure 3, the pressure at the bottom of the riser still keeps on oscillating when the valve opening

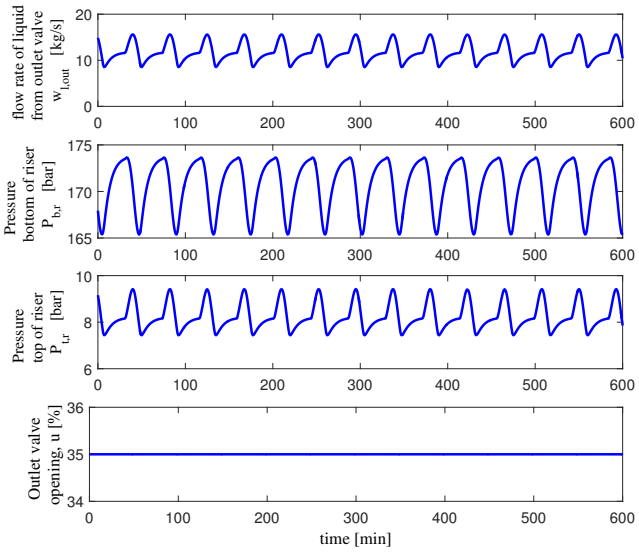

Figure 2. Slug flow in the riser for u = 35%.

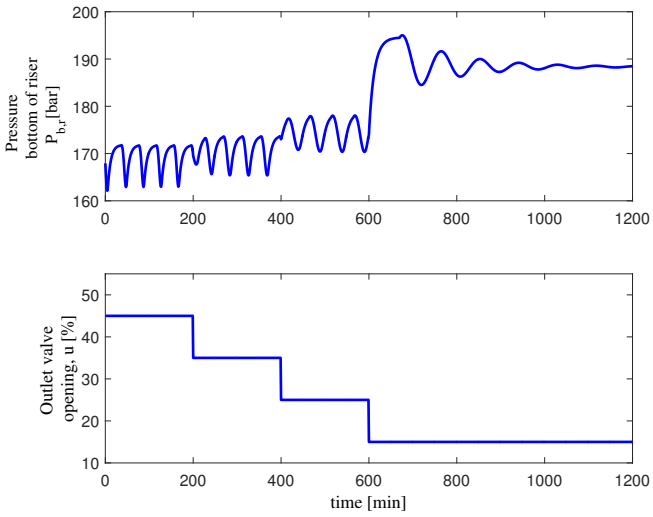

Figure 3. Variation of pressure at the bottom of the riser with valve opening.

is reduced from 45% to 25%. At time 600 min, the outlet valve opening is reduced to 15%. With this valve opening, the pressure at the bottom of the riser is stabilized and this results in a stabilized flow of the liquid through the outlet valve. As the valve is slowly choked, at one point, the flow is stabilized. This value of valve opening for which the flow starts to stabilize is called the bifurcation point. Above this point, the flow is unstable and below this point, the flow is stable. From the openloop simulations, the bifurcation point was found out to be around 20% valve opening.

From Figure 3, we can observe that the flow can be stabilized by remaining below the bifurcation point in the stable region. Usually, the bifurcation point corresponds to a low valve opening. With a lower valve opening, the flow rate of the oil produced from the well is also low which is economically not beneficial. Thus, it is of interest to investigate whether the flow can be stabilized by opening the valve in the unstable zone (i.e. by remaining above the bifurcation point) through the use of different control strategies.

4 State estimation

One of the control structure that is explained in detail in Section 5 utilizes the information about the mass of the liquid (which is a state variable) in the riser pipeline. This and the remaining two states of the process cannot be directly measured and hence should be estimated. For this, an Unscented Kalman Filter (UKF) that directly utilizes the nonlinear model of the process is implemented. Details of the UKF is not the main focus of this paper and interested readers are advised to follow (Simon, 2006). In this work, standard algorithm for UKF available at (Simon, 2006) is implemented in MATLAB.

In addition, it is assumed that the pressures at the bottom and top of the riser pipe are measured and available. Figure 4 shows the estimated states of the system and Figure 5 shows the estimated pressures at the bottom and top of the riser pipeline. The estimated states and the estimated measurements are then used by the control structures for stabilizing the flow.

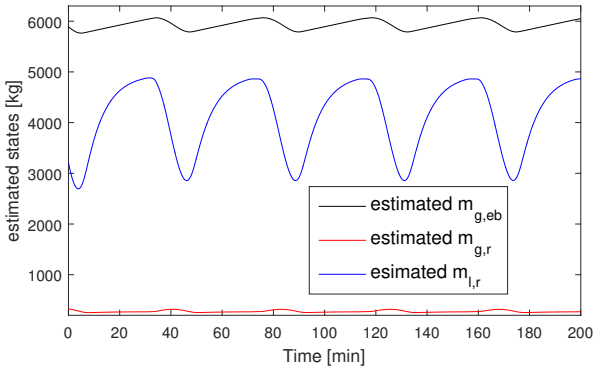

Figure 4. Estimated states by UKF.

5 Control strategies

For regulating the slug flow in the riser pipeline, three different control strategies/structures were developed.

- The first control structure stabilizes the slug flow by controlling the pressure at the bottom of the riser i.e. by controlling $P_{b,r}$ to a set point.
- The second control structure stabilizes the slug flow by controlling the pressure drop in the riser i.e. by controlling $\triangle P = (P_{b,r} - P_{t,r})$ to a set point.
- The third control structure stabilizes the slug flow by controlling the total mass of the liquid in the riser i.e. by controlling $m_{l,r}$ to a setpoint.

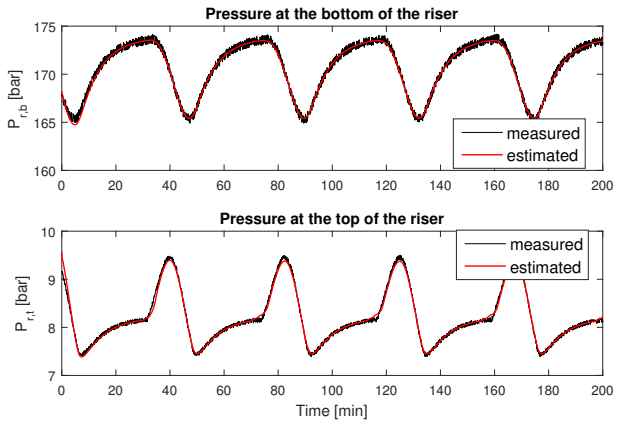

Figure 5. Estimated pressures at the bottom and top of the riser.

Each of these control strategies were implemented as a model based controller using model predictive control (MPC) scheme as well as using a standard Proportional-Integral (PI) control scheme.

5.1 Model predictive control

For designing a nonlinear model predictive controller, consider the following nonlinear objective function,

$$\min_{\triangle u_c} f(\triangle u_c) = \sum_{k=1}^{N_p} \left(XX_k - XX_k^{ref}\right)^T P_k \left(XX_k - XX_k^{ref}\right) + \sum_{k=1}^{N_c} (\triangle u_k)^T R_k (\triangle u_k) \tag{12}$$

Here, XX_k is the variable to be controlled and XX_k^{ref} is its reference value depending on the choice of the control structure. $XX_k = P_{b,r}$ for control structure 1, $XX_k = \triangle P = (P_{b,r} - P_{t,r})$ for control structure 2 and $XX_k = m_{l,r}$ for control structure 3. N_p is the prediction horizon length and N_c is the control horizon length. P_k is the weighting factor for the set point error and R_k is the weighting factor for the control deviation. $\triangle u_k = u_k - u_{k-1}$ is the rate of change of control action.

The choke valve opening should be between 0 and 1, i.e. the constraint in the control input is,

$$0 \leq u_k \leq 1 \tag{13}$$

In practice, the choke valves are opened in smaller steps, and larger abrupt changes in its opening is usually avoided. Consider that the choke valve can be opened or closed by only 0.5% per second i.e.

$$-0.5\% \leq \triangle u_k \leq 0.5\% \tag{14}$$

(13) and (14) together with the model of the process form the constraints for the optimization problem. Moreover, in order to improve the speed of computation without loosing any control dynamics, the prediction horizon was grouped into four groups.

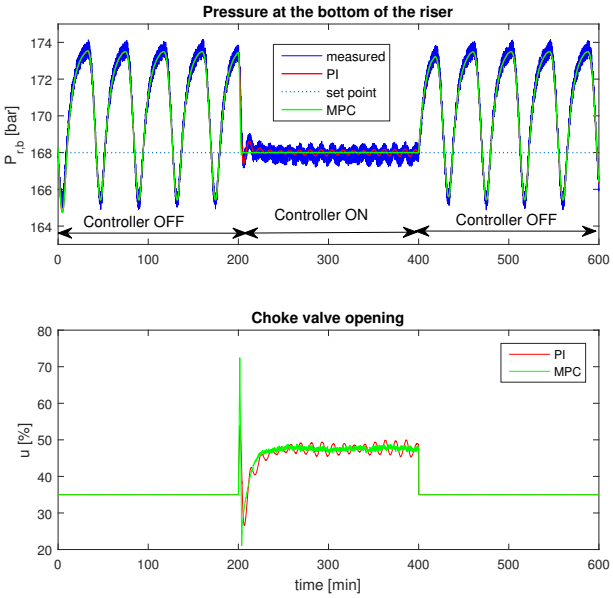

Figure 6. Pressure at the bottom of the riser with control structure 1.

5.2 PI control

A standard expression for the PI controller in the deviation form can be written as,

$$\triangle u_k = K_p \left(1 + \frac{dt}{2T_i}\right) e_k - K_p \left(1 - \frac{dt}{2T_i}\right) e_{k-1}, \tag{15}$$

with

$$e_k = XX_k^{ref} - XX_k, \tag{16}$$

corresponding to the three control structures respectively. The conditions fulfilling (13) and (14) were implemented together with (15) and (16). Here, K_p is the proportional gain of the controller, T_i is the integral time constant and dt is the sampling time taken to be 5 seconds.

6 Simulation results and discussion

6.1 Control structure I

The set point for the pressure at the bottom of the riser was chosen to be 168 bar. Figure 6 and Figure 7 show the simulation results both with the model predictive controller and with the PI controller. Each controller was turned on between the time interval of 200 and 400 minutes. Both controllers were able to stabilize the outflow (see Figure 7) however, the performance of the model predictive controller was better than the PI controller. Small oscillations of the pressure at the bottom of the riser and in the choke valve opening were seen with the PI controller. However with MPC, such small oscillations were completely eliminated.

From the openloop simulations it is known that the bifurcation point of the valve opening is around 20%. However, with this control structure, the valve remains opened

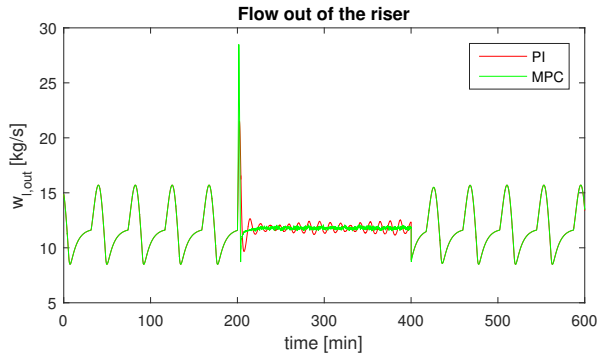

Figure 7. Stabilization of outflow with control structure 1.

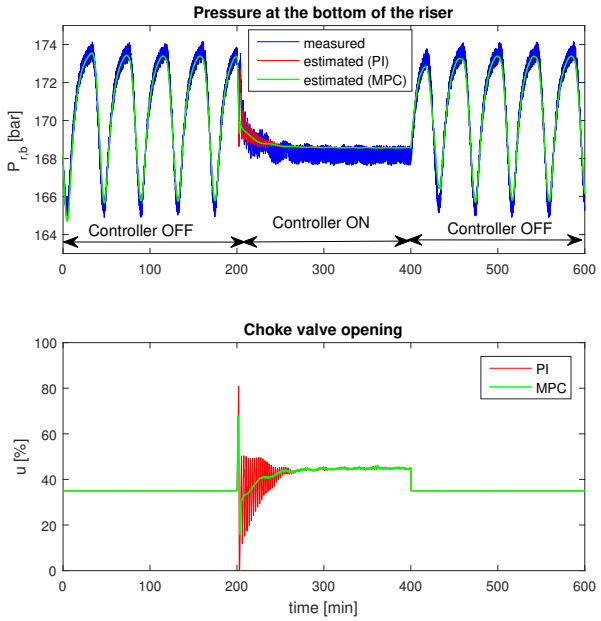

Figure 8. Pressure at the bottom of the riser with control structure 2.

at around 48% which is in the unstable region of the valve opening. This clearly indicates that it is possible to stabilize the flow flowing in the riser pipeline while still staying at the unstable region of the valve opening. This is an added benefit with respect to the operation of the process: the more the valve opening, the more is the amount of oil flowing out of the well (economically more beneficial).

6.2 Control structure II

For control structure II, the set point for the pressure difference between the bottom and the top of the riser was taken to be 161 bar. Figure 8 and Figure 9 show the simulation results both with the model based controller and with the PI controller. Both control schemes were able to stabilize the slug flow. The simulation results show that the bottom hole pressure can be indirectly stabilized by controlling the pressure drop over the riser. However, the model based controller outperforms the PI controller. High frequency oscillations in the valve opening

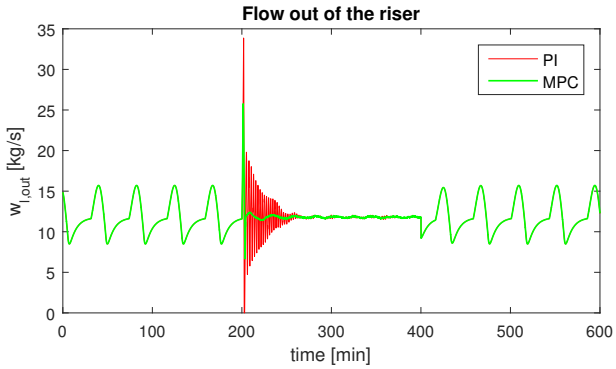

Figure 9. Stabilization of outflow with control structure 2.

(and in the flow through the choke valve) were observed at the beginning of the control action with the PI controller, while such oscillations were completely suppressed by the model predictive controller. The control scheme utilizes the estimated values calculated by the UKF. If the controller uses the measurement of the pressures directly for the calculation of control actions, the dynamics become even more oscillatory (with higher frequency oscillations). Therefore for this control structure, proper tuning of the UKF is very essential. Compared to control structure 1, more weight (10 times more) was put to the measurement noise covariance matrix during the implementation of UKF.

6.3 Control structure III

With this control structure, the mass of the liquid in the riser was controlled to a set point of 3800 kg. Since the mass of the liquid in the riser has a significant and a direct effect on the pressure at the bottom of the riser, controlling it allows the bottom hole pressure to be controlled indirectly. Figure 10 and Figure 11 show the simulation results. It is very clear that for this control structure, the PI controller does not stabilize the flow properly. The model predictive controller outperforms the PI controller. Although the amplitude of the oscillation for the pressure at the bottom of the riser was lowered with the PI controller (which is better than without any control at all), but at the same time the frequency of the oscillation was increased. The valve openings oscillated periodically and the flow of the fluid through it oscillated with a more higher frequency than before (without any control). However, with the model predictive controller, the control action was superior without any oscillations. The flow of fluid out of the riser and the pressure at the bottom of the riser were very stable.

7 Computational time for MPC

Model predictive controller is a computationally heavy algorithm. At each iteration, a constrained nonlinear optimization problem is solved. In this work, a prediction horizon of 30 samples with a sampling time of 5 sec which equals to 150 sec was used. The control inputs

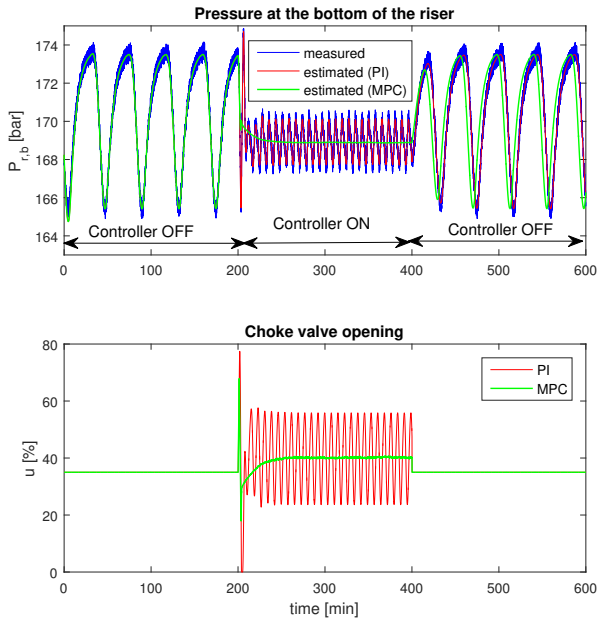

Figure 10. Pressure at the bottom of the riser with control structure 3.

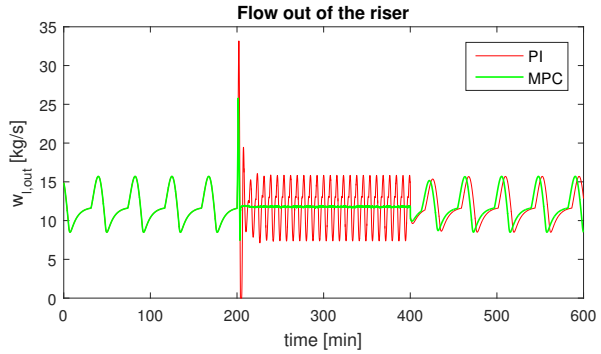

Figure 11. Stabilization of outflow with control structure 3.

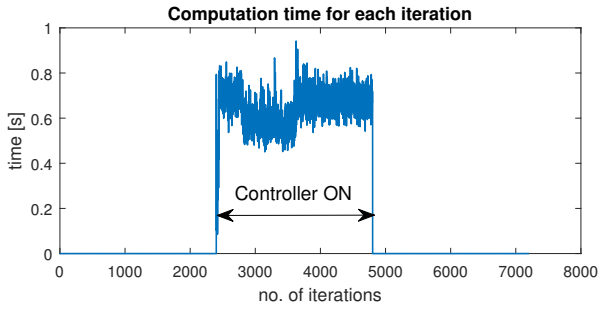

Figure 12. Computational time required by the model predictive controller for structure 2.

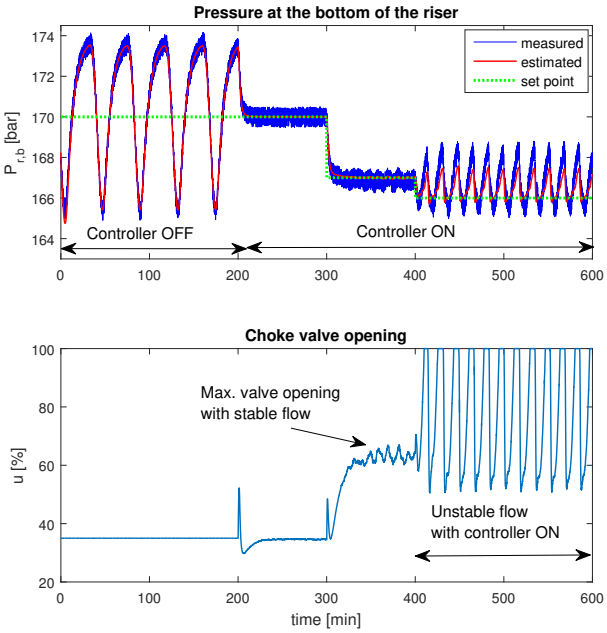

Figure 13. Maximum valve opening for stable flow with control structure 1.

were grouped into four groups. Thus, instead of optimizing 30 unknowns at each iteration, only 4 unknowns are optimized. This significantly reduces the computational time without deteriorating the control action. For all the three control structures, each iteration could be solved in less than a second, and for the chosen sampling interval, this means that the algorithm can be easily implemented for real time application. For an illustration, the computational time required by the MPC algorithm for control structure 2 is shown in Figure 12. A normal computer with 2.50 Ghz processor and 4 GB RAM was used for the simulations.

8 Maximum valve opening

The choice of the setpoint(s) for all the three control structures were arbitrary and can be freely chosen. However, the choice of the setpoint influences the ability of the controller to stabilize the flow. To illustrate this, consider the first control structure. Lowering the value of the setpoint for the pressure at the bottom of the well corresponds to a higher valve opening and hence more flow of oil through the outlet choke valve as shown in Figure 13. With respect to the production of oil, it is economically beneficial to have the outlet valve open as much as possible. In Figure 13, as the setpoint was decreased from 170 bar to 167 bar, the valve opening was increased from 35% to 65% (maximum opening that marks the boundary between the stable and the unstable flow). As the setpoint was further decreased to 166 bar after 400 min, the pressure started to oscillate and the flow became unstable again, even though the controller was still turned on.

The presence of a maximum valve opening before the flow again becomes unstable was also seen with the other two control structures but have not been shown in this paper to save space.

9 Conclusions

From this research work, it was observed that the model predictive control schemes outperform the standard PI controllers for stabilizing the slug flow in oil well riser. The differences are not so significant for the first two control strategies. However, for the third control strategy, the control actions are superior with the model based control. Nonlinear MPC with Unscented Kalman filter can be implemented for real time control of the slug flow in riser. Among the three control structures, with the model predictive control, all the control structures were equally able to stabilize the flow. It is difficult to conclude which of these control structure is the best with the model predictive control. However, with the PI controllers, the first control strategy stabilized the flow better than the remaining two control structures.

Security Threats and Recommendation in IoT Healthcare

Cansu Eken, Hanım Eken

Computer Science, Ankara University, Turkey, cansueken21@gmail.com
Türksat,Turkey,eken.hanim@gmail.com

Abstract

The Internet of Things (IoT) devices have become popular in recent year. All devices connect network and communicate each other. Therefore all devices become smart. They are used for some systems such as e-Health, e-Energy, e-Home, smart city, smart car etc. IoT device collect data for systems in order to analyze data and give right decision. Thus, attackers attack IoT systems. This paper gives an introduction to IoT healthcare systems and applications, the related security and privacy challenges. This paper tends to analyze the security threats in different layers of the loT, and give recommendation owing to provide security and privacy.

Keywords: internet of things (IoT), body area network, wearable devices, IoT healthcare systems, security of IoT, privacy, information security

1 Introduction

In recent years, many devices and goods are used in life and these devices and goods communicate with each other. These devices are radio-frequency identification (RFID) tags, mobile phones, mobile devices, sensors, actuators, etc. The term ‘‘Internet-of-Things’’ (IoT) is broadly used to refer to physical objects or "things" connect each other and exchange data on network. The term, internet of things (IoT) was first proposed in 1998 (Weber, 2010).

In the year of 2005, International Telecommunication Union (lTU) released an annual report on "Internet of Things. This report includes the development of information and communication technology and the future of smart devices, communicating with each other (ITU, 2005). Physical objects or "things” become smart by connecting to each other. In later years, physical objects or "things” in every aspect of our lives connect to internet and exchange to data. Therefore, ‘‘Internet-of-Things’’ (IoT) devices are used many sectors.

According to Gartner, Inc., there will be nearly 26 billion devices on the Internet of Things by 2020. Figure 1 presents a list of countries by IoT devices online per 100 inhabitants as published by the OECD in 2015.

Rank	Country	Devices online	Relative size
1	South Korea	37.9	
2	Denmark	32.7	
3	Switzerland	29.0	
4	United States	24.9	
5	Netherlands	24.7	
6	Germany	22.4	
7	Sweden	21.9	
8	Spain	19.9	
9	France	17.6	
10	Portugal	16.2	
11	Belgium	15.6	
12	United Kingdom	13.0	
13	Canada	11.6	
14	Italy	10.2	
15	Brazil	9.2	
16	Japan	8.2	
17	Australia	7.9	
18	Mexico	6.8	
19	Poland	6.3	
20	China	6.2	
21	Colombia	6.1	
22	Russia	4.9	
23	Turkey	2.3	
24	India	0.6	

Figure 1. IoT devices online per 100 in 2015.

In particular, sensors are used many different fields due to the development of sensor technology. Environmental sensing that could use urban planning, electricity, energy management, transportation system and intelligent shopping systems. Biological sensors could use healthcare and medicine systems (Atamli and Martin, 2014).

Table 1. Field of IoT application.

Field of Application	Application
Energy	Smart devices, Energy Management system, Energy Control system
Smart Home	Fire alarm system, Safety control system, Building Automation system
Environmental Monitoring	Air Pollution, Noise Monitoring, Waterways, Industry Monitoring
Green Agriculture	Green Houses, Compost, Irrigation Management, Soil Moisture Management.
Retail & Logistics	Supply Chain Control, Intelligent Shopping Applications, Smart Product Management, Item Tracking, Fleet Tracking
Smart Transportation	vehicular communication, smart traffic control, smart parking, electronic toll collection systems
E-Health	Patient monitoring, Doctor tracking, Personnel tracking, Real-time patient health status monitoring, Home health care

IoT devices have important role due to development of healthcare systems. Healthcare quality is improved with IoT devices such as biological sensors.

In addition, IoT devices are used different fields such as media, production, smart home, smart city, transportation, etc. Table 1 demonstrates field of IoT applications.

1.1 Environmental monitoring

Internet of Things is important for environmental analysis and monitoring in order to ensure environmental protection and control. Sensors are used due to measure the air, water, soil pollution. Internet of Things devices diffuse a large geographic area and collect data from large area.

In addition, Internet of Things applications provide that the checks of use of environmental resources. These applications are used to analysis environmental pollution and make right decision about using of environmental resources (Lee and Lee, 2015).

1.2 Infrastructure management

Urban and rural infrastructure management is important for countries. Therefore, every country has applications due to monitor and control dam, road, bridge, railway tracks, subway, and other critical infrastructure (Jayavardhana et al., 2013). Internet of Things (IoT) devices can be used to monitor and operate events or changes in structural conditions that can compromise safety and increase risk.

Furthermore, Internet of Things (IoT) applications are used for providing access to ships transition from bridge, measure and control the density of road vehicles, check dams' occupancy rate etc. They have big role to coordinate between different service providers and users in critical infrastructure in order to ensure cost effective and time schedule maintenance and repair. Usages of IoT devices provide improving the quality of service like incident management and emergency response (Michael et al., 2014).

1.3 Building, home automation and energy management

Devices has become smart with connect internet. So, systems used in buildings and houses began to be automated. People have become control devices in their home remotely. These smart devices are television, heater, air conditioning, and fridge in the home. Smart buildings include Fire alarm system, Safety control system, Building Automation system, Energy Management system, Energy Control system, Central, Control and monitoring system, Contact communication systems, Centralized information sharing service (Shrouf and Miragliotta, 2015).

Home automation systems, like other building automation systems, are typically used to control lighting, heating, ventilation, air conditioning, appliances, communication systems, entertainment and home security devices to improve convenience, comfort, energy efficiency, and security.

1.4 Transportation

IoT devices are important for transportation. They are used for control transport system. Application of the IoT extends to all aspects of transportation systems. All smart system is communicating each other in order to provide high quality transportation services. Smart transportation services are smart traffic control, smart parking, electronic toll collection systems, logistic and fleet management, vehicle control, and safety and road assistance (Alvi et al., 2015).

1.5 Medical and healthcare systems

The developments of health technology are presenting new opportunities and facilities in order to improve healthcare sectors. In these days, healthcare system use sensors, mobile devices. Internet of Things (IoT) devices are used all parts of healthcare systems.
Figure 2 shows sensors in the healthcare.

They are used for remote health monitoring and emergency notification systems. Monitoring system can enable patient monitoring for chronic issues, checkups, blood pressure and heart rate monitors and unnecessary appointments (Lubecke et al., 2014)

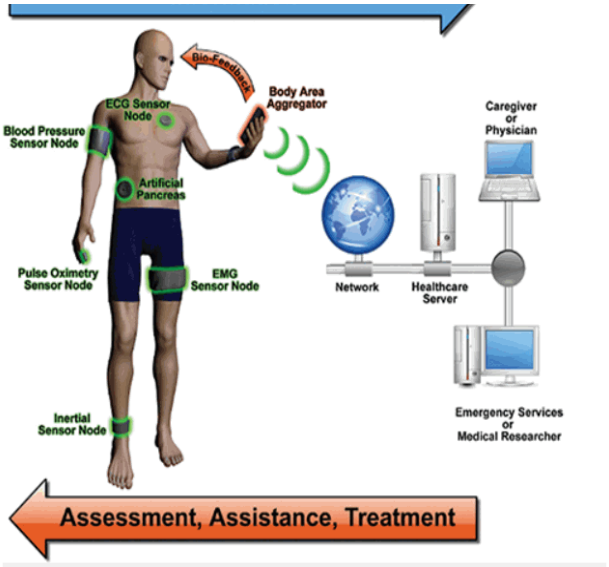

Figure 2. Sensors in the healthcare.

2 Related Work

There are many articles covering security of Internet of Things (IoT) devices in healthcare systems. Nguyen et al. (2015) define the security requirement for highly interconnected network of heterogeneous devices in Internet of Things (IoT). Kai et al. (2013) propound security and privacy methods for Health Internet of Things in order to protect patients' healthcare data. Neisse et al. (2015) propose a Model based Security Toolkit due to the control and protection of user data from Internet of Things (IoT).

Hamdi and Abie (2014) propose a game based model for security eHealth applications in the Internet of Things (IoT). They use security effectiveness and energyefficiency methods for evaluating security strategies.

3 Threats of IoT Health Applications

IoT devices are important for health applications. IoT devices collect measurable and analyzable healthcare data in order to facilitate the work healthcare applications. Therefore, security of IoT healthcare applications is important for healthcare systems. IoT devices are threatened by many security vulnerabilities. I give details about these vulnerabilities in this part of article.

3.1 Energy Optimization

Sensors are significant devices for healthcare systems. Measurable and analyzable healthcare data are gathered very easily with the development of sensor technology. In recent years, wearable devices are very popular for healthcare systems. Wearable devices could collect many healthcare data without disturbing patients. However, energy consuming is important problem for wearable devices. Because wearable devices are small and they are used to collect data form people body. They collect healthcare data from body continuously. Battery is not enough to collect and send health data to healthcare applications. In addition, battery of wearable devices is necessary to be constantly charge. These are serious problems for IoT devices in healthcare systems (Decuir, 2015).

3.2 Privacy

Privacy has many definitions in the literature. Privacy is important topic for information security at healthcare system in the world. Hence, many international organizations define privacy. The Organization for Economic Cooperation and Development (OECD) defines it as "any information relating to an identified or identifiable individual (data subject)" (Chen and Zhao, 2012).

Healthcare data are collected from IoT devices. These devices gather data by remote access mechanisms which have some challenging about privacy and security. Data collected by the sensor is transmitted to the database or cloud over internet. In addition, IoT devices connect internet and communicate with each other from the Internet. Security vulnerabilities on Internet and IoT devices are threatened health data. Additionally, healthcare data are collected from different health units. Health data is shared by various health units. Every unit must provide privacy of data. Because healthcare data includes essential significant information. All the world's attackers all the world's attackers want to capture health data. Thereof, privacy of data must be protected (Thilakanathan et al., 2013).

3.3 Trust

Trust management is important for IoT devices and applications due to provide security and privacy of data. Because all devices connect network and send data to applications. Therefore, devices on the internet must be trusted due to ensure privacy and security. Attackers could connect device IoT applications in order to manipulate data (Skarmeta et al., 2014).

Data collection trust is serious issue because of huge volumes of data are collected from devices. Big data is used by IoT health application owing to make right decision about patients and improve quality of healthcare. Moreover, IoT health care services include data process, analysis and mining. Attackers could be damaged big data with create damage or malicious input of IoT devices. Hence, researchers study about challenges of trust management in IoT. Trust management in IoT must implement network layer and application layer (Abomhara and Køien, 2004).

3.4 Denial-of-service attacks (DoS)

Denial-of-service attacks (DoS) are to make IoT devices and IoT applications cannot provide service. IoT devices connect network and transfer data and communicate with each other. IoT applications need to connect to network and receive data from these devices. Denial-of-service attacks (DoS) dangerous attacks for IoT applications because of machine or network resource. IoT devices have low memory capabilities and limited bandwidth, battery, and disk space. Hence, they are affected from Denial-of-service attacks (DoS) easily (Abomhara and Køien, 2004).

3.5 Physical attacks

Physical security is serious issue for IoT devices because of gathering data from of unprotected

environment. Further, IoT devices are small devices and they are integrated TVs, cars, air conditioning, ovens etc. Therefore, these devices could be stolen easily or changed configured settings. Attackers can change data sent by IoT devices. IoT devices areexposed many physical attacks such as a secret stealing, software manipulation, and hardware tampering.

3.6 Data Manipulation

Data is important IoT healthcare applications. Data is used all steps of healthcare systems. Thus, attacks are against to data security and privacy. Attacks are stealing data, data manipulation and damaging data. Health data is important and sensitive data for all country in the world because of including personally identifiable data. Data is used multiple paths in the IoT. These are IoT devices (data generator, data receiver, and aggregation point), the internet (multi-directional data transport), the cloud (data stored), the machine (application services, big data repositories, analytic) (Bing et al., 2011)

Attackers steal health data for malicious use and they damage victims. They steal data when data is generated and transported by IoT devices. Attackers manipulate or change data in order to redirect victims what attackers want. Doctors could give wrong decision about diagnosis and treatment because of data manipulation. In addition data loss is serious problem for IoT health application.

4 Security Solution of IoT Health Applications

Security is important IoT health applications because of sensitive health data privacy. This section classifies security solution in order to protect data from attacks. Figure 3 represents data security in IoT healthcare applications.

Figure 3. Data security in IoT healthcare applications.

Access Control is important step in protecting IoT healthcare applications and health data. Well-designed access control must be implemented IoT healthcare applications and devices. IoT devices collect health data from patients and transfer health data to healthcare databases. Hence, IoT healthcare applications must have strong access management in order to ensure healthcare data security and privacy. Through access control systems, an organization can restrict andmonitor the use of critical data, and protect privacy and security (Rush Carskadden, 2013).

In addition, employers in healthcare should have the awareness of information security owing to provide security of IoT healthcare applications and health data. Information security awareness training should be given to healthcare staff members. Furthermore, employees should receive all training about access control of priority for ensuring data security, privacy, and patient rights.

Access management in IoT healthcare applications protects to misuse healthcare data and perform malicious attacks on the users' healthcare data.

IoT health devices are tiny and integrated other systems. IoT health devices collect data from various environments. Hence, physical security is significant topic for IoT health devices. IoT health devices should be secure against physical threats (Shen and Liu, 2011).

Physical security of IoT health devices and health data involves protection against environmental threats, accidents, physical sabotage, and theft. IoT health devices should have replacement devices for protecting physical attacks. In this way, IoT health devices keep on collecting and transferring data. Countermeasures should be taken to decrease the damage and recover from attacks, accidents and disaster quickly.

Network security is important issue for IoT health devices and applications. All IoT devices connect to network and communicate each other over network. Therefore, network is required in all steps in the IoT health applications'. Some technologies are WiFi, Bluetooth, Zigbee, RFID etc. Especially, wireless body area network (WBAN) is used to data collect from wearable devices.

Firewalls, IPS, IDS, ingress/egress filtering structures, internet protocol security (IPsec), secure Sockets Layer/Transport Layer Security (SSL/TSL) should be used in order to ensure network security. HTTPS is used for application to encrypt to message (Sadeghi et al., 2015; Xingmei et al., 2013). Data privacy is major issue for IoT health devices and applications because of the ubiquitous character of the IoT environment. IoT health devices connected each other and send data. Strong encryption algorithm is used for data. Data must be encrypted and sent IoT application over a secure network. RFID technology is used for IoT devices to send data. However, RFID has

some security vulnerabilities such as reverse engineering, eavesdropping, man-in-the-middle attack, spoofing etc. When data is sent by RFID technology, some security measures are taken owing to provide privacy protection (Xingmei and Jing, 2013).

Besides, IoT health application should have strong access control management and trust management services due to ensure data security and privacy. Health data is collected from IoT health devices then share various health units. Healthcare data is used accurate assessment and right decision about patient treatment and diagnosis. IoT healthcare application must have "need-to-know" principle for authorization management (Weinberg et al., 2015).

Policies**,** standards and guidelines could be developed, documented, and implemented. Further, many standards about security of healthcare are published by international organizations. These documents are used for on account of providing security and privacy. Each employee and department should have enough information about procedures, guidelines, and standards related to data security and privacy. They could be reviewed and update regularly and change according to the needs of the healthcare sector (Weinberg et al., 2015). Trainings should be prepared owing to improve information security awareness of healthcare staff. These trainings give details about fundamental security and risk IoT healthcare applications and emphasize about privacy of health data. These trainings could be provided to employees regularly (Weinberg et al., 2015).

All IoT healthcare devices, IoT healthcare applications and network components' log must be collected with central log management systems. Logs are monitored, analyzed and evaluated so as to prevent unwanted events to healthcare systems. Besides, central log management or security information and event management (SIEM) must have auditing to ensure security. Undesirable events must be reported security team quickly to interfere unwanted events. Central log management or security information and event management (SIEM) must have strong authentication and authorization to monitor the audit log. The log should be checked continuously.

Unfortunately, auditing is a passive defense because of becoming aware of critical security event after the occurrence of the event. Auditing help people to response to unwanted-event quickly.

5 Conclusions

IoT devices are very important for systems. Today, many systems have become smart with IoT devices. These systems include big data. IoT devices collect data for these systems. Data is sensitive because of including personal information. Hence, these systems have many threats about data security and privacy. Security recommendation could be used to mitigate the security threats.

This paper presents detail about IoT healthcare applications and security threats in IoT application. In addition, this paper gives security solution in order to mitigate security threats.

Abstract

This paper continues the study, presented at the 8th EUROSIM Congress on Modeling and Simulation and devoted to creation of algorithm and simulation model of network functioning, taking into account dynamic characteristics of the network in condition of variable relationship signal-to-noise. Simulation algorithm was augmented for adequately representation of the state of the real network i.e. possible changes of topology due to the link failures and disabling individual nodes. It is possible to expand the capabilities of the model presented in the 8th Congress as a simulation model of Information Flow on Transport Layer of Open System Interconnection Model. The current version of the model realizes input of the adjacency matrix describing the network topology, the algorithm of the path search by Dijkstra on the network level, and simulation of the loss of connection. So the main goal of the new paper is to bring the structure of the model to the structure of the real network and to check the possibility of transferring a given amount of information in conditions of interference by means of evaluation of coefficient of readiness for Data Communication System.

Keywords: modeling, Monte-Carlo simulation, information technologies, algorithm

1 Introduction

Modeling of the dynamic properties of the Data Communication network is one of the urgent tasks in the modern theory of communication. Processes of data transmission have very high speed and the data transfer equipment includes specialized devices that provide perform the necessary calculations at speeds far exceeding the speed of imitation of processes of data transmission in modern software environments. At the same time, quite often in practice there is a need to evaluate the number of criteria of quality that are related not only internal properties of hardware and data transmission protocols but external integral characteristics.

They are related to external characteristics of the ne twork as a whole or its separate fragments. These characteristics usually are interested for the creators of information systems. One of the main criteria of quality is the availability of Data Communication System (DCS). The other important criterion is the probability of message delivery in the presence of noise. These criteria help to check the properties of the fragment of network or the network as a whole and test its suitability for the solution of the problem of the transfer of large amounts of information at any given time.

The throughput for different channels of network and communications centers and the procedures of changing network topology must be realized as part of the overall procedure of simulation of DCS for evaluating dataflow and network capacity in system as a whole. Thus the paper deals with a problem of construction of adequate simulation model of DCS taking into account dynamic processes in separate channels and nodes of system as a whole. Usually dynamic processes are emerged in form of various violations of the network topology, i.e. in node failures, in communication failures in the communication channels, in the packet loss and in the receiving an increased number of errors due to the increase of the level of interference in communication channels. A universal tool must be created for research and testing of various algorithms of network operation and for correction of new protocols at the stage of pre-project inspection.

The structure of paper is as follows. Introduction demonstrates some distinctive features of the statement of the problem. The section 2 is devoted to describing of a static variant of the simulation model. It contains brief analysis of results of imitation experiments. In the section 3 algorithm of simulation of DCS with variable topology and quick details about modeling computer's program are described. The section 4 involves simulation results for checking proposed algorithm.

For a formal definition of DCS designed for the transmission of big volume of information represented in a form of graph structure, we can use the definition in the form of a functional signed graph from (Shul'tsc, Kulba *et al*, 2011). A tuple of parametric functional graph $<(X, E), V, W, U>$ is introduced. In this recording

$G = (X, E)$ – directed graph, describing the structure of DCS, symbol V – a set of parameters of the vertices of the graph, where every vertex is according to node of network. Parameters of the vertices must define all characteristics of nodes necessary for modeling of DCS and evaluating its' criteria of quality. For example, parameters define procedure of modeling host-router, involved in the selection of the direction of information transmission, or node – repeater designed only to enhance the signal to increase the communication distance. $V = \{Pnode(x), x \in X\}$, where $Pnode(x)$ – a set of parameters of the vertex (node) x. Symbol U describes the parameter space, a W – weights of edges, simulating communication channels. Weights of edges can change during modeling, and finding the path for message transfer.

The main directions of modeling of DCS in modern theory of communication involve three different approaches.

First of all modeling of the propagation medium of the signal allows investigating new principles of design of equipment for communication. Mathematical and statistical models help to create estimates of main characteristics of communication technique for data transferring. They help to define requirements to new equipment. Such models are described in (Proakis, 1995; Rappaport, 2002; Saleh, Valenzuela, 1987; Spencer, Rice *et al*, 1997) and they expand possibilities of designing of new DCS.

Secondly the modeling of the functioning of DCS as complicate technical system opens new directions for optimization and improvement of existing constructions of DCS. A huge number of models are created over the years of development of the theory of communication. These include works (Foschini, 1996; Antonova, 2007), devoted to data transmission in condition of fading, and many other publications. For example, a set of works are the well-known (Irvine, Harle, 2001; Tanenbaum, 1996) and others.

Thirdly special direction is devoted to different modern problems. At the moment models for describing of various indicators of quality of service (QoS) have been actively developed. For example, for the transfer of information via packets the set of basic criteria involve Bandwidth, Delay, Packet loss and Jitter. A significant number of modern publications including the Russian-speaking illuminate this direction.

2 Algorithm of Simulation of Data Communication System

2.1 Statement of Simulation Problem

The problem of modeling the networks' dynamic properties may be solved by means of imitation statistical model of DCS, proposed in (Antonova, 2013; Antonova, Titov, 2011; Antonova, Kolutcsky, 2015). DCS is represented as a set of channels and communication centers. Large centers for data gathering create a set of signal office centers. In common with channels for information transferring they create graphical image of network topology with variable structure. In the existing networks information may be transmitted in different directions. So almost every node can be both a starting and an end node in the procedure of message delivery to the addressee. This fact determines dynamic changes in the network.

In order to simplify debugging and simulation procedures the assumption is introduced that data is transmitted in one direction from one initial vertex to the destination vertex in network fragment under consideration. This assumption simplifies the development of simulation algorithms, but it is a limitation in the development of a universal instrument for studying processes of transferring large amounts of data in DCS. However imitation statistical model will allow checking quality of data transferring by means of imitation experiments for dynamic stochastic DCS according to algorithm from (Antonova, 2013; Antonova, Titov, 2011; Antonova, Kolutcsky, 2015).

The proposed statement of the problem for simulation of dynamical features of DCS is considered in detail in (Antonova, Titov, 2011). The first variant of a simulation model for the static mode of operation and single state of network topology is presented in flow chart of simulation algorithm in Figure 1. It does not use the possibilities of modern software tools and focused on the tedious procedure of the source data preparation for modeling. Symbol S represents the number of message. Symbol Sk is labeling maximal quantity of messages under simulation.

Matrix $MK(IJ)$ contains symbol 1 on position with number of row I (node with number I) and column with number J (channel with number J) if such channel exists in network topology. Symbol $Jmax$ defines maximal quantity of channels, outgoing from current node with number I in accordance with network topology. Symbol Ik is maximal quantity of nodes.

Symbol Jt is a number of channel selected in simulation procedure according to special criterion. This channel connects the current node with node $I(Jt)$ in accordance with network topology.

After start of algorithm the necessary input data is read from a file. The movement of the first message from the first node to next node according the topology of fragment of network under consideration begins with the scanning of outgoing channels. All outgoing channels are described in matrix $MK(IJ)$. This matrix is continuously visible in the search of the outgoing path.

Simulation for every outgoing channel is fulfilled for transfer time evaluation. The level of errors for given signal-to-noise ratio or for given imitation model of transfer process is also determined. The channel is selected to send a message when the cycle of viewing

for channels leaving the current vertex is over. Selection criteria may be different.

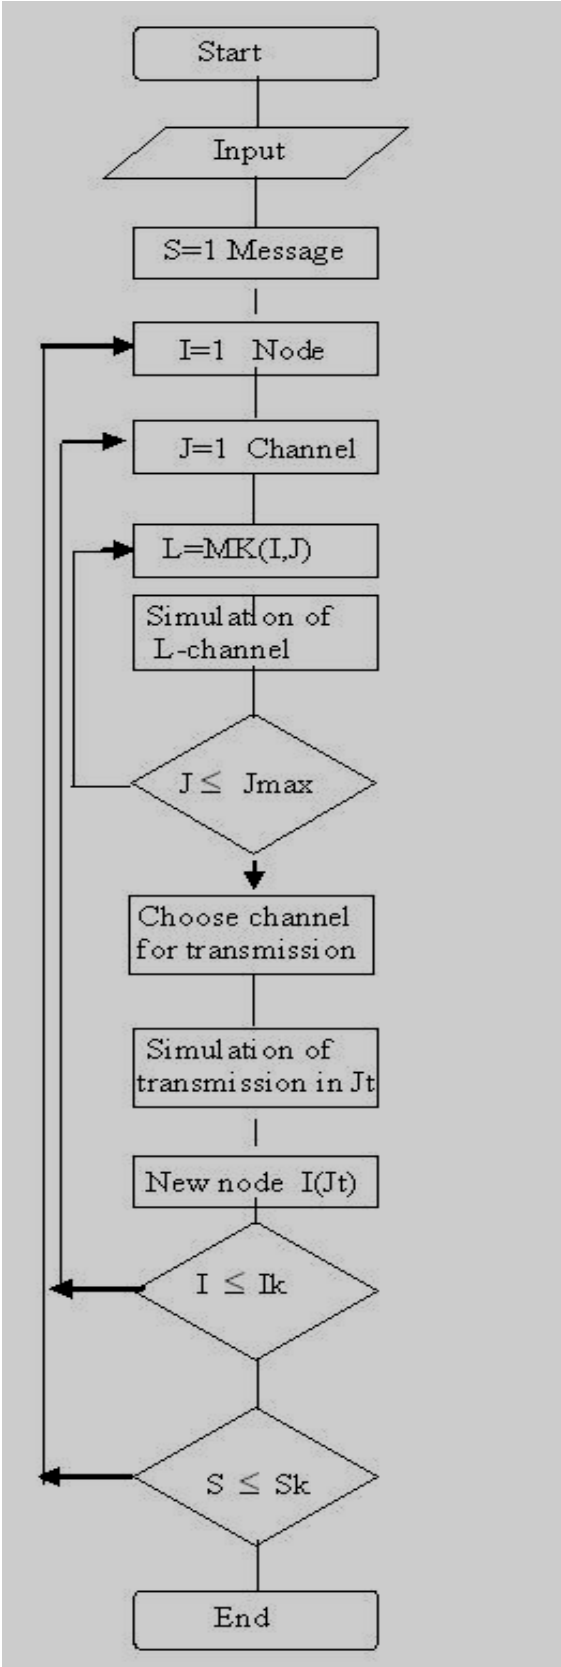

Figure 1. Flow Chart of a static variant of the simulation model.

After the end of the simulation of the transfer process new node is fixed. It will be that vertex of the graph in which the movement of the first message will stop. For new node all procedures for choice and simulation of the transfer process in the channel will be repeated. Thus the first message will continues the moving to final vertex of the graph. When message arrives in final vertex *Ik,* the number of message is tested. If transferring of information didn't over the next message is selected.

Further the moving of the following message will be simulated since first node and so on. At the end of list of messages when last message with number *Sk* will arrive in final node the availability coefficient will be calculated by means of definition of ratio of time of useful moving of messages along fragment of network to common time of simulation of the transfer process. This value is saved in special variables.

This scheme will be supplemented with the outer loop managing random changes in network topology under conditions of noise in functioning of communication channels and nodes. Such model will reflect the variable structure of the computer network in the DCS, i.e. the possibility of link failure or the blocking nodes of a communication network, and subsequent recovery as a result of urgent repair. It will allow checking the impact of interference on the delivery time of messages in the network. This model allows to estimate the availability of the network and to provide additional opportunities for evaluation of the possibility of Big Data accumulation.

2.2 The first results of modeling

The first variant of modeling program was realized by means of Pl-language and ES 1045 computer. It allowed evaluating transmission characteristics of the information flow for static mode of operation of the network under interference. This model did not take into account the variable structure of the network under real conditions of information transferring but was used in imitation experiments for testing and evaluating networks characteristics in noise conditions (Antonova, 1996; Antonova, 1999; and Antonova, 2007).

3 Simulation of Data Communication System with Variable Topology

The considered variant of simulation model of DCS was raw realization of proposed simulation algorithm by means of C++ language and personal computer. It created the basis for detailed implementation of the model reproducing the dynamic structure of data transferring network (Antonova, 2013; Antonova, Titov, 2011; Antonova, Kolutcsky, 2015). The flow chart of a new simulation algorithm is shown in Figure 2. Additional symbol *Nt* in this figure defines the

number of variant of network topology under consideration in simulation procedure. New variant of topology may be appearing only for new message. It limited models possibilities but it was necessary for testing simulation algorithm. New topology may involves the channel interference, the communication gap between individual nodes and the shutdown of the node, reducing noise, the restoration of the link between nodes, the repair of nodes.

A new variant of the simulation model is implemented in the environment of Microsoft Visual Studio 13. The developed algorithm simulates the process of transferring messages within the network fragment which is represented as oriented weighted graph. The vertices of the graph, i.e. the network nodes, simulated work of the packet switches via the TCP/IP Protocol with realization of procedures of determining the optimum route of messages transmission.

Edges of the graph simulate the communication channels with a certain bandwidth determined by the current value of the ratio signal-to-noise. In input data for simulation model the network graph is interpreted as the adjacency matrix, each element of which records the presence or absence of communication between nodes in network.

For adaptation to possible changes in the real network such as communication gap, a node failure, and addition of the node with specified links, an adjacency matrix reflecting the network topology duplicates the matrix allowing for program user to dynamically track the topology changes in the process of simulation program functioning.

Weights of connections between network nodes are defined by the relative time of messages' delivery between nodes according to the ratio, which varies with the changes in noise power:

$$T = 1/C, \quad (1)$$

where C – throughput capacity of communication lines that are installed dynamically from the known ratio of the C. Shannon:

$$C = F\,log(1 + P_S/P_{Sh}), \quad (2)$$

where F - is the bandwidth of the communication line, P_S – signal power, P_{Sh} - noise power.

A minimal message delivery time is selected as a criterion for choice an optimal route for messages transmission between the start and end nodes of the network in the simulation model.

Messages are transferred between the specified fixed network nodes (start and end nodes). At each vertex for determination the channel for transmission the optimal route to the destination node is searched and for transmission the first link of the found route is selected.

For the next point of the route the optimal route to the destination network node is searched again and so on until the end node will be reached. Finding of the optimal route based on the algorithm, which is used famous Dijkstra's algorithm.

Each message from the stream in the process of the simulation model functioning appears in the window indicating the route to the destination node and the relative time of motion.

The following objects are defined in proposed algorithm: the array of distances between vertices; active vertex; dynamic list of available vertices from the active vertex (the list of visited vertices). The dimension of the array of distances corresponds to the rank of the adjacency matrix. Each element of the distances array is a structure. It includes the distance from the initial vertex to the vertex corresponding to the element of the array with current number (the initial distance is infinity) and the list of vertices making the route from the initial vertex to the considered vertex from the array (at the initial moment the list is empty).

The active vertex is special variable. It contains number of the adjacency matrix row when the search algorithm fulfills definition of outgoing channels. The list of visited vertices is dynamical array. According algorithm vertices connected with active vertex are added in that list and visited vertices are deleted. At the beginning of the algorithm initial node is an active vertex. The list of vertices making the route for first element of the array of distances will contain initial node and the array of distances from initial node will contain zero. The optimal route search procedure involves following stages: the adjacency matrix row associated with active vertex is examined; adjacent vertices are defined and added in the end of the list of visited vertices. The node having visited vertices is deleted from the top of the list. The node, which became the first in the list, converts to active vertex. The distance from initial vertex to vertex associated with active vertex is defined. If it is less than distance fixed in the array of distances early, than both distance and route in the array of distances are corrected.

The algorithm ends when the list of visited vertices is over. The criterion for the optimal route search is value of the message delivery time. The optimal route is defined with using matrix contained values reverse of throughput of networks channels. These values are created automatically in procedure of algorithm realization. The relationship

$$Tp = 1/log(1 + P_S/P_{Sh}), \quad (3)$$

defines value of each existing connection.

Value Tp is formed by means of simulation of the signal-to-noise relationship. Different distribution laws known from the results of statistical studies of DCS may be used for describing the signal-to-noise relationship. The average value of the signal-to-noise relationship is chosen equal to 100. The system timer controls changes in topology. It is the lack of simulation model.

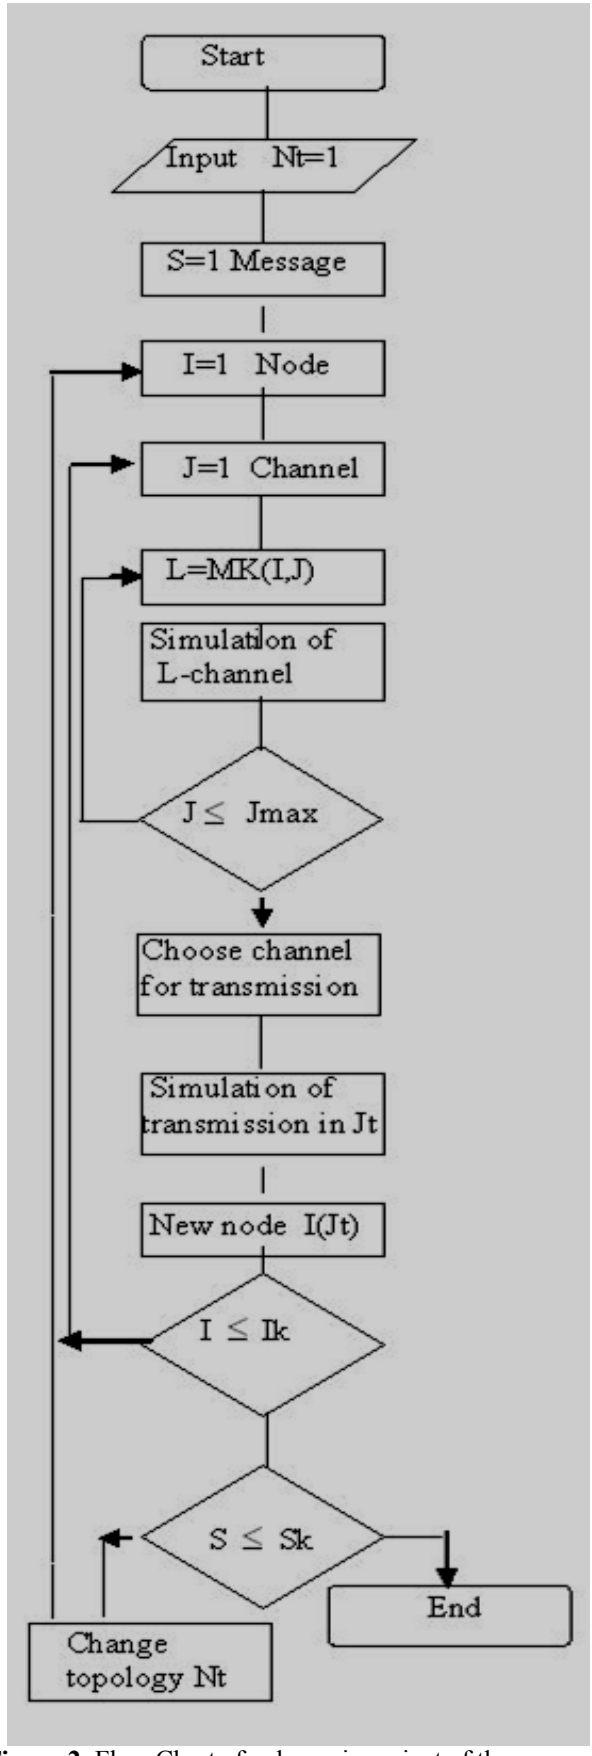

Figure 2. Flow Chart of a dynamic variant of the simulation model.

Every message from information stream appears in the window of simulation model. The route to final node and time of motion are demonstrated in window. All modeling events are fixed in track of events according to order of their receipt.

All changes to the network structure dynamically adjusted in the adjacency matrix. Because of calls to the adjacency matrix are happen from different threads in a model the mutual exclusion of these flows is organized. To do this a synchronization object "mutex" is used. This object is installed in a special signaling state if not busy by any thread. This object at any point in time can only hold one thread that prevents simultaneous access to a shared resource.

4 Results of Simulation Experiments

Initial network topology is selected in the form shown in the Figure 3. The adjacency matrix *M* describing this network fragment will sets by user of program in special Windows Forms with the use of element of control Data Grid View.

$$M = \begin{pmatrix} 1&1&1&0&0&0&0&0&0&0 \\ 0&0&0&1&1&0&0&0&0&0 \\ 0&0&0&0&1&0&0&0&0&0 \\ 0&0&0&0&1&1&0&0&0&0 \\ 0&0&0&0&0&0&1&0&0&0 \\ 0&0&0&0&0&0&1&1&0&0 \\ 0&0&0&0&0&0&0&1&1&0 \\ 0&0&0&0&0&0&0&0&0&1 \\ 0&0&0&0&0&0&0&0&0&1 \\ 0&0&0&0&0&0&0&0&0&1 \end{pmatrix}.$$

Weights of connections are established dynamically in the process of the functioning of simulation model. According to simulation algorithm experiment consists in transmission of message flow from the initial vertex of the network fragment to a final vertex of the network fragment. Channel interference, the link failure and disabling individual nodes are considered.

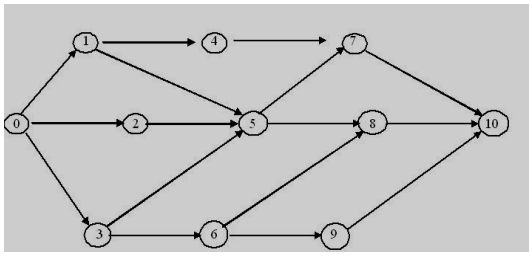

Figure 3. Scheme of a fragment of the communication network.

Results of simulation experiment are shown in Table I. The transmission of 30 messages in condition of change relationship signal-to-noise, the link failures and disabling individual nodes are considered. Table 1 contains results from Windows Forms: number of message (first column); time of message transmission

(second column); the order of the passage of nodes from network fragment (third column); delivery information about messages (fourth column). Because of a long period of disconnection in the network fragment is simulated, the last three messages are not delivered.

5 Conclusions

A series of simulation results is only a checking of proposed algorithm. It needs in quality programming and extensive testing in terms of the input variable factors reflecting the structure of real networks. Big volume of initial input data are needed for creation of detailed and adequate estimates of performance and availability of DCS, but this problem is much easier then the problem of creating models of dynamic network for data transfer. The instruments for control of information flow in real network involve the repair of failed channels, addition of new channels, increasing of velocity of data transmission and extension of channel bandwidth by means of installation of new equipment and others. Further improvement of the model consists in the development of the structure of the program modules for simulation of different types of communication channels, support modules and the control program, taking into account the received results. Once the application package has been validated, the adequate results of simulation may forecast a situation in functioning of equipment of communication network under conditions of large load.

Abstract

Long Term Evolution (LTE) enables bandwidth consuming HTTP applications as video streaming. Mobile Network Operator (MNO) is committed to guarantee acceptable levels of Quality of Service (QoS) and Quality of Experience (QoE) perceived by the end user. A correlation between the transport informations with the application informations is an important approach to be adopted by the MNO. This correlation is more useful if a second entity, as the Over The Top (OTT), cooperates for the content delivery process. In the scientific literature different mathematical models are used in order to correlate QoE to the QoS. This paper aims at analyse them in case of of HTTP based Web services as HTTP web browsing and HTTP video streaming. Different scenarios are simulated using OPNET simulation software tool. They can differ if the service is fully managed by the MNO (MNO-managed class) or if OTT cooperates with own content (OTT-managed). This is the case of YouTube. Results are analysed through regression k- means clustering techniques.

Keywords: LTE, QoS, QoE, over the top; YouTube; video streaming; key performance indicators

1 Introduction

In the last years, telecommunication technologies are enabling the delivery of bandwidth-consuming applications as web browsing or video streaming of several multimedia objects (Ericsson, 2008). The fourth generation of mobile networks, known as Long Term Evolution (LTE), is the first 3GPP cellular fully-IP standard. LTE is the most advanced technology to satisfy the increasing demand for mobile broadband services. It is able to offer to end users a download data rate up to 100 Mbps and an upload data rate up to 50 Mbps (3GPP, 2007). LTE is also characterized by a flexible and interoperable fully-IP network architecture. We have also a direct management of Quality of Service (QoS) policies based on bearers and QoS Class Identifier (QCI). These informations are managed by Mobile Network Operators (MNOs) in order to efficiently deliver acceptable service levels to the end-users. QoS policies in LTE are mainly focused on measurable parameters called Key Performance Indicators (KPIs), namely bandwidth, delay, jitter, packet loss rate, data rate, priority. These QoS native features are crucial for an efficient network management of both data and voice services. Here we introduce an exercise of correlating the Quality of Experience (QoE) as perceived by the end user to the QoS as measured by the MNO at the network level for the HTTP web browsing and video streaming applications. We will introduce some relevant study cases, grouped in either MNO-managed class or OTT-managed class. We will review related works in Section II and we propose our approach in Section III. Section IV describes the study cases and present results from extensive simulations. Section V presents the mathematical models for the data which well describe in our cases the QoE vs QoS correlation. A final discussion states the application range of the proposed approach and its future improvements.

2 Related Works

Several mathematical models are proposed for QoE vs QoS correlation (M. Alreshoodi, et al, 2013). (H.G. Msakni et alii, 2013) presents the concept of Quality of Service (QoS) and Quality of Experience (QoE) applied to video quality assessment. (A. Vizzarri et al, 2013) present a review of studies on QoS in LTE networks. The Quality assessment methodology are essentially three: subjective, objective and network-based. In the first category, some authors introduce Mean Opinion Score (MOS) as a synthetic indicator of QoE, while network KPIs are assumed as indicators of QoS (ITU-T, 2003). (A. Vizzarri, 2014) analyzes the relationship between QoE in terms of MOS and QoS KPIs in case of Voice Over LTE (VoLTE) service. The objective assessment methodology focuses on the measurement of the signal as it would be perceived by an end user. Objective methods can be divided in three main groups: Full Reference (FR), Reduced Reference (RR) and No Reference (NR) (B. Wang et al, 2009). The FR method is based on the estimation of difference between the source video and the received video. The RR method analyzes a portion of informations extracted from the original video. The NR method predicts the video

quality of the received video without accessing to the source video. The network assessment methodology gives an estimation of QoE on the basis of several QoS KPIs measured at network level. Network KPIs are essentially delay, jitter and packet loss rate (M. Siller, et al, 2003). In (M. Alreshoodi, 2013) a fuzzy-logic approach is proposed. (T.H Truong, 2012) analyzes the relationship between QoE and QoS in case of IPTV applications. Well known papers propose to express the QoE/QoS correlation through statistical analysis. The regression models more frequently used are: logarithmic (Weber-Fechner Law), exponential (IQX Hypothesis) and polynomial (S. Khorsandroo et al, 2012), M. Fiedler et al, 2010). In (J.Urrea , 2015) a multivariate statistical analysis has revealed the factors that influence the quality of a video streaming service on a Multi-hop Wireless Network. Relationships between the QoE and the QoS metrics have been identified via Multivariable Linear Regression (MLR) modeling. This methodology has supported the selection of the relevant factors and the reduction of the model dimensionality. A k-means clustering process allowed the authors to identify some operation ranges in terms of quality that relate the performances to KPIs.

3 Proposed Approach

3.1 Methodology

The methodology adopted for mapping QoE vs QoS in case of HTTP web browsing / video streaming is shown in Figure 1. It is to be remarked that we assume (coherently with some authors and differently from others):

- QoE metrics as Page Response Time (PRT), Video Response Time (VRT);
- QoS KPIs as end-to-end Delay (e2eDEL), Packet Loss Rate (PLR) and Throughput (THR).

3.2 Network models

The considered LTE network models are shown in Figure 2. The model is derived from LTE reference architecture and the related network nodes are the same as defined by 3GPP standard (3GPP, 2007), (3GPP, 2009). HTTP Web/Video Server is the content server containing both HMTL web pages and videos to deliver.

Depending on the owner of the contents to deliver (MNO or OTT), we distinguish for the sake of analysis two management cases for the HTTP web browsing and video streaming services: MNO-managed (class 1) and OTT-managed (class 2). In the first situation MNO is responsible for content ownership, service deliver and service transport. In the second situation MNO is only responsible for transport, while OTT is the content's owner and cooperates with MNO for service delivery. The two classes are shown in Figure 2.

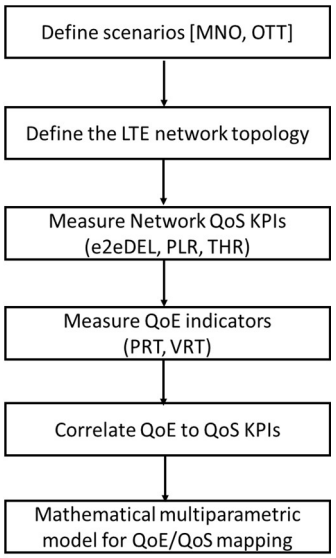

Figure 1. Workflow adopted for QoE/QoS correlation.

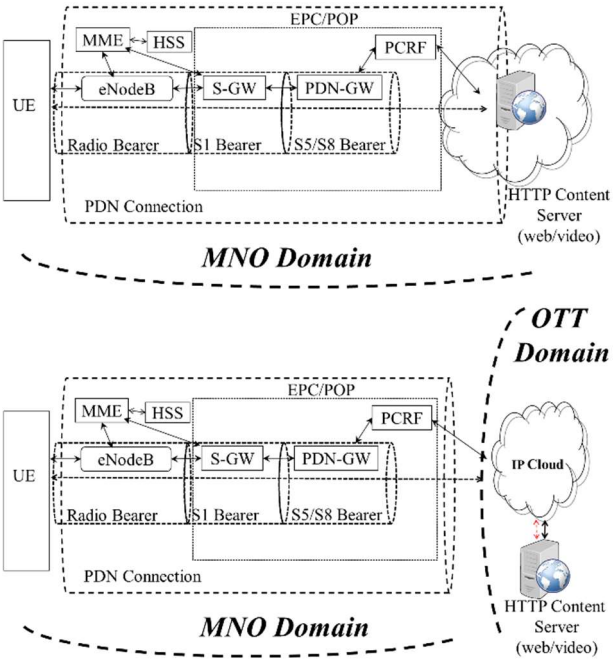

Figure 2. Workflow adopted for QoE/QoS correlation LTE service management classes: MNO-managed (uppermost), OTT-managed (lowermost).

4 Simulation

Network simulations have been performed using OPNET Modeler 17.5 PL6 software tool.

4.1 OPNET Settings

The User Equipment (UE) is modeled with -1 dBi Antenna Gain and -200 dBm receiver sensitivity. eNodeB bandwidth is 20 MHz with 3 antenna sectors; Frequency Division Duplexing (FDD) is the Duplex mode, antenna gain of 15 dBi. As transmission model

we chose a free space model. Evolved Packet System (EPS) bearer is characterized by a QCI equal to 6 (non-Guaranteed Bit Rate) with an Allocation Retention Priority (ARP) equal to 6. Simulation period is 3 minutes.

4.2 Assumptions on users and networks

On the end-user's side we have made a number of reasonable assumptions, as shown in Figure 3. The user sends a first request for a web page in HTML format. After 2 seconds starting from a download of complete web page, user sends a second request for a short video with duration of 20 seconds and a size around 1 MB. The HTML page is composed of: text (180 KB); a figure as top banner (5 KB); 30 small images (7 KB each; 15 large images (20 KB each); a large image (35 KB) as the initial video frame.

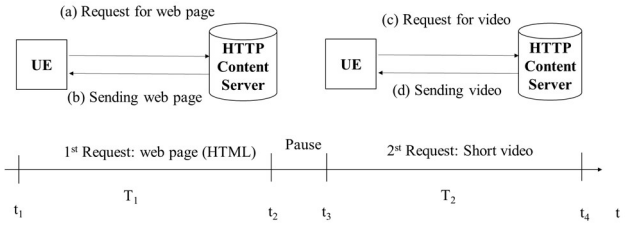

Figure 3. End-user's simulated activity.

On the network side we have modeled the two network models. In the network model of the first class the LTE network topology follows the following criteria:

- unique eNodeB and UE are located in the Rome area;
- EPC and HTTP server, managed by MNO, are located in the Milan area;
- Trunk link type is 1 Gbit/s.

In the network model of the second class (OTT-managed service), the LTE network topology is similar to the previous one but with some differences:

- HTTP server is a YouTube Primary Cache Server located in the Milan area. It is fully managed by You Tube, that plays the role of the OTT;
- The distance between the EPC and the HTTP web server is 100 km;
- An IP cloud is considered, with additive 0.5% Packet Discard Ratio and 50ms Packet Latency. That to take into account impairments due to interconnection between the networks of MNO and OTT.

4.3 Scenarios

Fifteen study cases, called scenarios, are simulated for each class. Table 1 counts 30 scenarios, fifteen cases per class. Scenarios for class 2 are marked with (*).

Table 1. Scenario Configurations – both MNO and OTT Management.

4.4 Results

Table 2 shows the results of simulations for the study cases. Results for class 2 are marked with (*).

5 Linear Models Fit

Multiple variable regression model is used for the identification of the relationship of QoE metrics Page Response Time (PRT), Video Response Time (VRT) with QoS KPIs, namely end-to-end Delay (DEL), Packet Loss Rate (PLR) and Throughput (THR). MNO-managed and OTT-managed classes are separately analyzed. In order to assess the regression model, QoS KPIs are considered as variable predictors (independent variables), QoE is the corresponding response (dependent variable). Since the regression model with one variable predictor (one QoS KPI) and one response (QoE) gives unsatisfying scatter plot of residuals a Multivariate Linear Regression (MLR) model has been here applied. A generic MLR model is represented by

$$QoE = \beta_0 + \beta_1 * DEL + \beta_2 * PLR + \beta_3 * THR + \varepsilon_i \quad (1)$$

where β_0, β_1, β_2,…, β_n are the unknown regression coefficients and $\varepsilon i \sim (N,\sigma 2)$ is the error of each observed response. QoE as the response (dependent variable) may be one PRT or VRT, while DEL, PLR, THR are the independent variables.

Table 2. Simulation Results.

(*) Service managed by OTT

5.1 MNO-managed class

5.1.1 PRT as the QoE Metric

The estimated regression model is as in

$$PRT = 9.357 + 2.368 * DEL + 9.619 * PLR - 1.749 * THR_i \quad (2)$$

This MLR model provides a low Root Mean Squared Error (RMSE) value equal to 0.443, an R-squared value equal to 0.982 and an Adjusted R-Squared value equal to 0.97: i.e. quite a good fit. The overall p-value is 6.15e-10. It allows us to reject the null hypothesis. Figure 4 shows relevant statistical indicators for this model: the fit looks actually good, while residuals are well distributed and adequately symmetric.

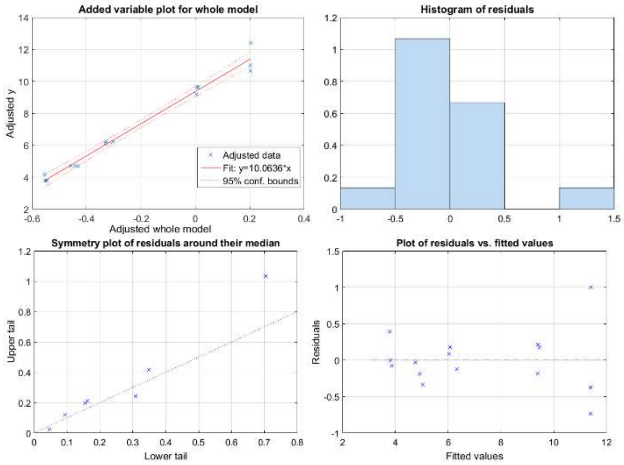

Figure 4. Statistical indicators for MLR of PRT in MNO-managed class. From upper leftmost to right: plot for whole model vs samples; histograms of residuals; symmetry plot of residuals around their median; residuals vs fitted values.

5.1.2 VRT as the QoE Metric

The estimated regression model is as in

$$VRT = 22.24 + 18.56 * DEL + 148.7 * PLR - 5.660 * THR \quad (3)$$

This MLR model provides a low Root Mean Squared Error (RMSE) value equal to 0.802, an R-squared value equal to 0.998 and an Adjusted R-squared equal to 0.986: i.e. quite a good fit. The overall p-value is 1.09e-15. It allow us to reject the null hypothesis. Figure 5 shows relevant statistical indicators for this model: the fit looks actually good, while residuals are well distributed and adequately symmetric.

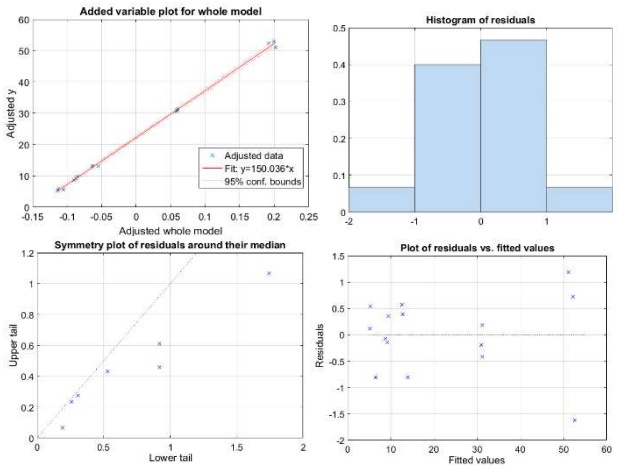

Figure 5. Statistical indicators for MLR of VRT in MNO-managed class. From upper leftmost to right: plot for whole model vs samples; histograms of residuals; symmetry plot of residuals around their median; residuals vs fitted values.

5.1.3 Cluster Analysis for MNO-managed class

Scenarios of the MNO-managed class, expressed in the 5 dimensional feature space, consisting of two QoE metrics and four QoS KPIs, have been clustered in three clusters, thanks to the well-known k-means technique [15]. Separation between clusters is fair as shown by the plot on the first two principal components (Figure 6).

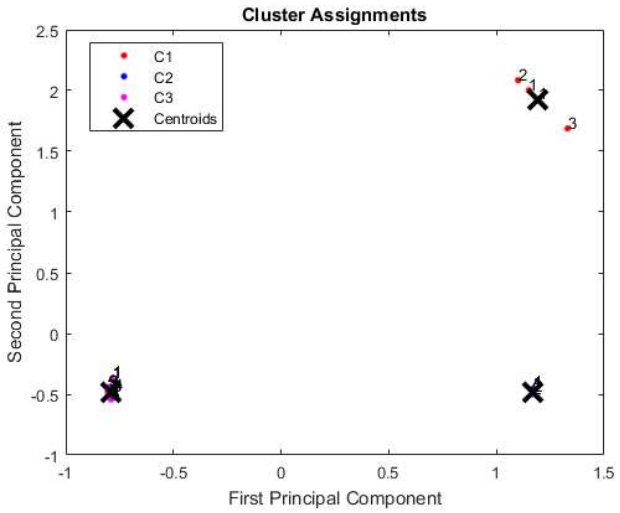

Figure 6. Clustering of scenarios for the MNO-managed class in the joint space of QoE metrics and QoS KPIs. Plot is on the plane of the first two principal components.

Meaning of the clusters is expressed in Table 3, which reports the position of the centroids of the three identified clusters in the 5-dim space. The quality of this clustering is evident from the changes of QoE between centroids: the VRT has the worst performance in C1, improves of 4.5 dB for C2, and 14.9 dB for C3. Same holds for PRT, though with lower gains (1.6 and 7.2 dB). As a conclusion, clustering well depicts differences between the scenarios in the MNO-managed class.

Table 3. Cluster Centroids generated by k-Means for MNO-managed Scenarios.

Cluster Centroid Id.	*DEL [s]*	*PLR [%]*	*THR [Mbps]*	*PRT [s]*	*VRT [s]*
1	0.7724	12.54 %	0.5783	11.36	52.05
2	0.7641	0.3600 %	1.025	9.489	31.01
3	0.0833	0.3700 %	2.650	4.944	9.339

5.2 OTT-managed class

5.2.1 PRT as the QoE Metric

The estimated regression model is as in

$$PRT = 7.347 - 0.813 * DEL + 13.00 * PLR + 6.796 * THR \quad (4)$$

This MLR model is affected by an excess Root RMSE at 3.11 and an insufficient R-squared value at 0.13, while Adjusted R-Squared is meaningless (-0.08). The overall p-value is 0.591. Thus we don't reject the null hypothesis. Let also remark that also the positive gain PRT/THR makes no sense. Figure 7 shows some evidences of the fact that the MLR model poorly describes the potential relationship QoE vs QoS in case of PRT.

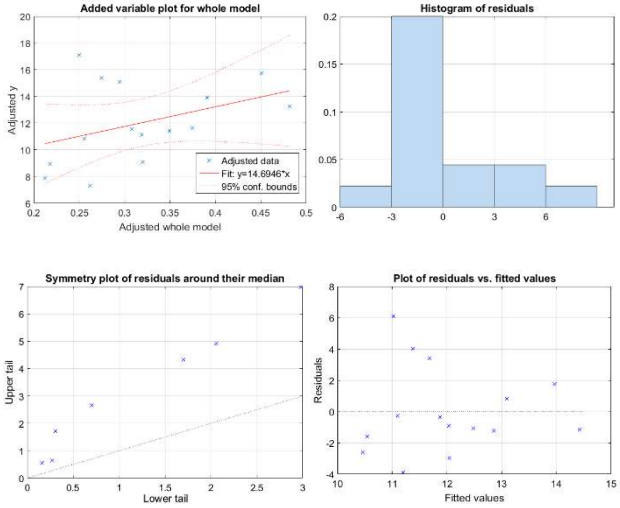

Figure 7. Statistical indicators for MLR of PRT in OTT-managed class. From upper leftmost to right: plot for whole model vs samples; histograms of residuals; symmetry plot of residuals around their median; residuals vs fitted values.

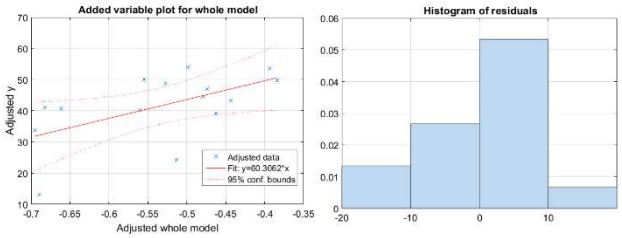
5.2.2 VRT as the QoE Metric

The estimated regression model is as in

$$VRT = 73.78 - 3.200 * DEL + 32.46 * PLR - 50.72 * THR \quad (5)$$

However, the MLR model is even worse than (4) (RMSE=10.2 and Adjusted R-Squared=0.14). The overall p-value of 0.211 makes the null hypothesis really likely. Figure 8 shows some evidences of the fact that the MLR model poorly describes the potential relationship QoE vs QoS in case of VRT.



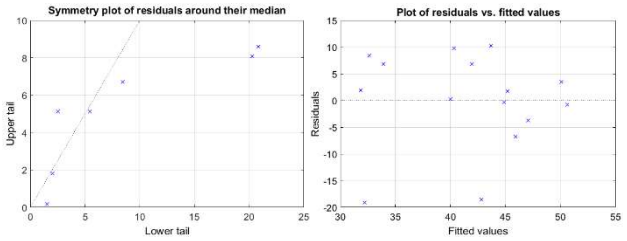


Figure 8. Statistical indicators for MLR of VRT in OTT-managed class. From upperleftmost to right: plot for whole model vs samples; histograms of residuals; symmetry plot of residuals around their median; residuals vs fitted values.

5.2.3 Cluster Analysis for OTT-managed class

The statistical indicators in the OTT-managed class do not allow to take the fit as trusted. It means that a linear relationship between QoE KPIs and QoS metrics cannot really be ascertained. Cluster analysis can gives some more insight on relationships between scenarios of the OTT-Managed class, represented in the 5 dimensional feature space, consisting of two QoE metrics and three QoS KPIs. Figure 9 plots two clusters identified thanks to the k-means algorithm [15] on the plane identified by the first two principal components.

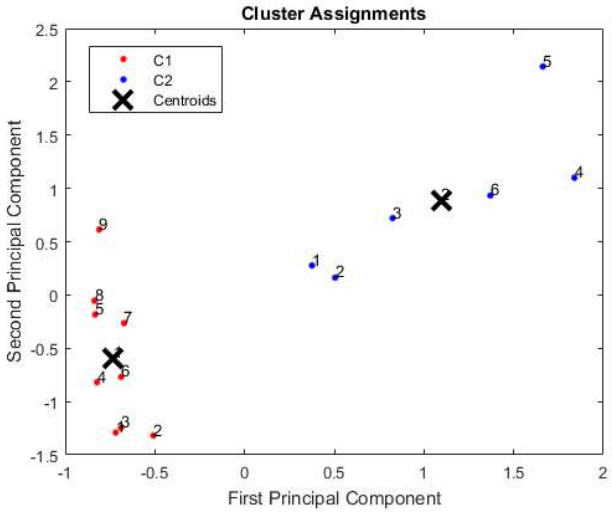

Figure 9. Identified clusters for the OTT-managed class including jointly both PRT and VRT as QoE metrics.

Separation between the two clusters is fair as per Figure 9. Though meaning of this separation is quite different as for the MNO-managed class. Table 4 reports the position of the centroids of the three identified clusters in the 5-dim space. It is straightforward noting that the two cluster centers are different as to the QoS KPIs, while they are nearly undistinguishable as for the QoE KPIs. Therefore, clustering reveals under a different perspective that QoE KPIs are not predictable starting from the QoS metrics.

Table 4. Cluster Centroids generated by k-Means for MNO-managed Scenarios.

Cluster Centroid Id.	*DEL [s]*	*PLR [%]*	*THR [Mbps]*	*PRT [s]*	*VRT [s]*
1	0.5026	8.610	0.6473	12.09	41.58
2	3.829	24.84	0.5720	11.89	41.45

6 Discussion and Final Remarks

The procedure of QoE metrics estimation out of QoS KPIs measured at network level is a consolidated process, and still a due attempt, regardless the complexity of networks and service architectures. Here we attempted for LTE networks the estimation of QOE vs QoS mapping thanks to MLR technique, with two distinct classes of scenarios. Our approach worked well as long as the MNO has been able to perform an end-to-end management of the service delivered to the end user (MNO-managed class). It is possible to give a reliable estimation of QoE out of the QoS due to the MNO. This case may represent an incentive for OTT, who is supposed to have the ownership of contents, to cooperate with the MNO within the service delivery process. In the OTT-managed class the MNO loses the end-to-end control and the MLR technique turns out to give unsatisfactory results. In our understanding this is due to the fact that there is no-one with a full end-to-end management of the HTTP service.

Our results bring us to two key considerations. First, regression models are suitable for QoE vs QoS mapping if the QoS KPIs measured by MNO are the only factors that determine QoE. Second, if other factors out of the MNO's control affects the service delivery process (as the IP cloud considered in this work), the identification of the QoE vs QoS mapping comes to an unsatisfactory end.

A future step is to determine for the OTT-Managed class the minimal Service Level Agreement (SLA) of IP cloud that assures the existence of a QoE vs QoS (on the MNO side) mapping. This enables the OTT to negotiate with the MNO consistent QoS KPIs for the intended QoS metrics. Next steps regard how to assure that reliable mappings can be utilized on both sides, MNO and OTT, to deliver a quality-safe service to the end-user, within a sustainable business model. Impact of the QoE vs QoS mapping on costs and economic measures has to take part in the analysis

Abstract

One the most important features of a Long Term Evolution (LTE) system is the high transmission data rate in downlink and in uplink. This is not sufficient for a good Quality of Experience (QoE) perceived by the end user. The Mobile Network Operator (MNO) has to adopt appropriate techniques for an effective management of the Quality of Service (QoS) not only for bandwidth-consuming applications as video streaming but also for voice application as Voice Over LTE (VoLTE). These techniques can be based on the QoE/QoS correlation especially in case of a delaysensitive application as VoLTE. This paper formulates a method for the QoE estimation starting from QoS informations available at network level. Different scenarios are simulated using OPNET software tool. Results are statistically analyzed using regression cluster analysis techniques. Mathematical functions representing relationship between QoE/QoS metrics are identified.

Keywords: LTE, QoS, QoE, VoLTE, key performance indicators, regression, cluster

1 Introduction

Wireless telecommunication networks have enabled broadband applications with very high throughput. With the introduction of Long Term Evolution (LTE) the download data rate can reach 100 Mbps, while the upload data rate may be up to 50 Mbps (3GPP,2008). The Quality of Service (QoS) have been so strongly impacted by these new important capabilities that an efficient management of the LTE network is needed in order to guarantee acceptable levels of Quality of Experience (QoE) to the end users. Together with data applications, the voice application called Voice Over LTE (VoLTE) is also to be carefully managed. This implies the importance for the Mobile Network Operator (MNO) to make a reliable QoE estimation. MNOs need to integrate LTE native QoS features with other techniques that consider the entire communication chain. One approach is to correlate the QoS measured at network level to the QoE perceived by end user. In the scientific literature several mathematical models have been defined.

This work is focused on the QoE estimation for VoLTE application on the basis of network QoS indicators, called Key Performance Indicators (KPIs). The paper presents in Sect. II an overview of the related work and the proposed approach for QoE/QOS correlation in Sect. III. In Sect. IV a simulation activity is detailed and the results are analyzed in the Sect. V. Sect. VI resumes the main conclusions.

2 Related Works

Reference (3GPP, 2008) introduces the end-to-end QoS reference architecture for LTE systems as standardized by ETSI together with the basic management functions. A. Vizzarri et alii in (Vizzarri, 2013) present a review of most important papers on end-to-end QoS approach in LTE networks. Horvath et alii in (Horvath, 2013) present an innovative signalling protocol named LQSIG for the resource reservation.

A first attempt for correlating quality informations of the LTE network to those of the application is made by S. Shen et alii in (Shen, 2011). They propose a performance framework based on the mapping of the Class of Service (CoS) to the QoS. Margoc et alii in (Margoc, 2013) analyze QoS in LTE systems in order to analyze the better performances for higher priority services. Policies and strategies for priority service allocation are left to operators. This is also confirmed by Medbo et alii in (Medbo,2009), where different type of data traffic over LTE network are analyzed, e.g. VoIP and HTTP web browsing/video streaming.

In (Alreshoodi,2013) QoS/QoE correlation is studied assuming QoS as a source of disturb for QoE. In (Alreshoodi,2013) fuzzy-logic approach is proposed for QoS/QoE mapping. In (Truong, 2012) the QoS/QoE mapping for IPTV service is made on the basis of the Mean Opinion Score (MOS) (intended as the QoE metric) delay, jitter and Packet Loss Rate (intended as the QoS metrics). A. Vizzarri in (Vizzarri, 2014) analyzes the impact of the voice codec on the end-to-end QoS for a VoLTE service. In [Vizzarri, 2014) A. Vizzarri studies the impact of the network congestion (in terms of link utilization) on end-to-end QoS for a VoLTE service.

3 Proposed Approach

3.1 Methodology

LTE system enables fully IP-based applications thanks to data transmitted through Packet Switching (PS) paths. That implies VoLTE to be treated as an IP-based application (3GPP, 2008). IP Multimedia Sub System (IMS) (3GPP, 2008) and Session Initiation Protocol (SIP) are integrated with LTE network nodes (IETF, 2005).

Figure 1 shows the LTE logical architecture supporting VoLTE service includes VoLTE User Equipment (UE), Evolved Universal Terrestrial Radio Access Network (E-UTRAN), Evolved Packet Core (EPC) and IMS Core Network.

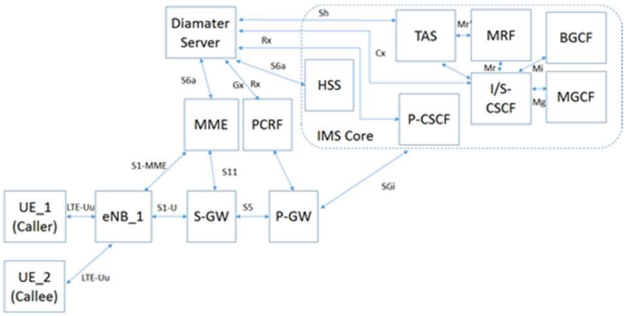

Figure 1. Logical architecture for VoLTE service [3GPP TS 23.002].

As a fully IP-based application, VoLTE is delivered over the LTE in a best effort modality. That implies the Mobile Network Operator (MNO) has to manage in order to guarantee acceptable levels of both QoS measured at the network level and QoE perceived by the end user at the application level. QoE is usually represented by a subjective measure called Mean Opinion Score (MOS). MOS is a scalar variable that measures the degree of service acceptance by the end user on range from 1 (worst case) to 5 (best case) (ITU, 2016). A MOS value equal to 5 is indicative of an Excellent Quality (imperceptible impairment), 4 of a Good Quality (perceptible but non annoying impairment), 3 of a Fair Quality (slightly annoying impairment), 2 of a Poor Quality (annoying impairment) and 1 of a Bad Quality (very annoying impairment). MOS value is derived from to R factor provided by ITU E-Model (ITU,2008) which takes in account several factors impacting the QoS, e.g. choose of voice codec, transmission delay, etc.

KPIs measured at the network level are typically Delay (DEL), Jitter (JIT) and Packet Loss Rate (PLR) (Yu et alii, 2007). The delay is represented as the amount of time a packet sent by source (caller) takes to reach destination (callee). Jitter is the variation in the time between packets arriving, caused by network congestion or route changes. Negative effects of Delay and Jitter are represented by phenomena of voice echoes. A high value of PLR can produce overlapping of words with a strong negative impact on voice intelligibility.

The present paper is mainly focused on the study and the identification of mathematical models for QoS/QoE correlation in different VoLTE realistic scenarios. Considered metrics are:

- QoE metrics: MOS;
- QoS KPIs: end-to-end Delay (e2eDEL), Jitter (JIT) and Packet Loss Rate (PLR).

Correlation techniques here adopted by the authors are statistical regression and cluster analysis.

3.2 Network models

In order to build realistic scenarios for VoLTE, network impairments are included. They are modelled on the basis of two constraints:

- Presence of mixed traffic: VoLTE application is delivered over LTE network together with HTTP web browsing application;
- Presence errors on end-to-end transmission: they are modelled inserting an IP cloud which introduces both additive delay (0.1 seconds) and IP packet discard ratio (1%).

On the basis of the VoLTE logical architecture shown in Figure 1, Figure 2 reports four different LTE network models, built in order to model realistic conditions for the VoLTE application and compute QoS and QoE metrics.

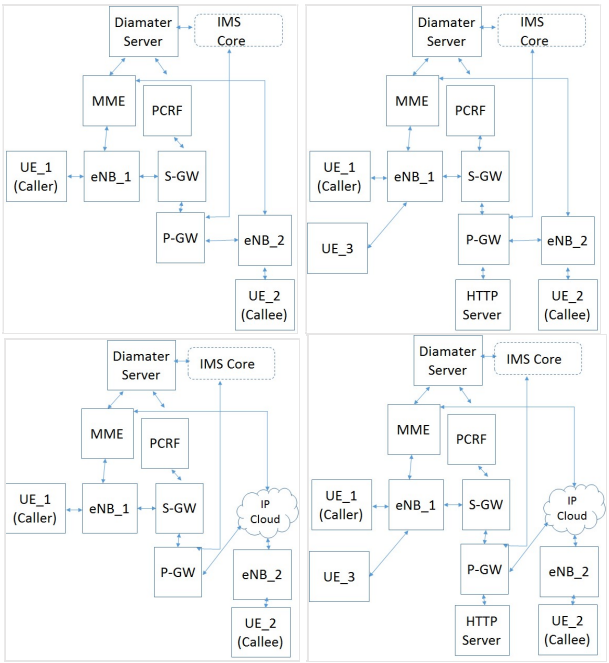

Figure 2. Four LTE network models identified to model realistic conditions for for VoLTE application. From the upper leftmost to right: UE for VoLTE without IP cloud; two UEs for VoLTE and HTTP browsing without IP cloud; One UE for VoLTE with IP cloud; two UEs for VoLTE and HTTP browsing with IP cloud.

The first model is related to a classic VoLTE call between two LTE UEs: a caller (UE_1) and a callee (UE_2). It is the situation with a single LTE application (VoLTE) without any network impairment. The second model is related to a situation with two different services delivered over the same LTE network. VoLTE is the first application between UE_1 and UE_2; HTTP web browsing is the second one and it is performed by UE_3 contacting an HTTP server. UE_1 (VoLTE caller) and UE_3 are attached to the same eNodeB (eNB_1). The third model is an extension of the first one. VoLTE application is affected by only the insertion of an IP cloud across the end-to-end transmission chain. The fourth model is an extension of the second one. Here VoLTE application is affected by both the presence of IP cloud and the presence of a second application (HTTP web browsing) performed by another user.

4 Simulation

All scenarios are simulated using the LTE network model provided by OPNET 17.5 PL6.

4.1 OPNET Settings

Both the antenna gain equal to -1 dBi and the receiver sensitivity to -200 dBm characterize the UE. eNodeB transmission mode is FDD Duplex Mode. Link type among LTE network nodes is PPP D3: the data rate is 44.736 Mbps. Voice codec is GSM EFR with one voice frame per packet. EPS bearer has a QoS Class Identifier (QCI) equal to 1 (GBR) and an Allocation and Retention Priority (ARP) equal to 1. Through the HTTP application, UE_3 can download 1 KB web page, n. 5 medium images with dimension up to 2 KB and two short videos with dimension up to 350 KB. The simulation period is equal to 3 minutes for all scenarios. The simulation area is a typical campus area (100 Km^2).

4.2 Assumptions on users and networks

According to the four network models defined in the Sect. III, we identified 48 scenarios to be simulated.

The scenario set includes two tunable parameters:

- S1 link capacity: starting form 100% (corresponding to 1,073,741,824 bps), the link capacity is decreased to 75%, 50% and 30%;
- eNodeB Bandwidth: 5 MHz, 10 MHZ, 20 MHz.

Table 1 reports scenarios grouped in four subsets, and their parameters.

4.3 Results

Table 2 gives a view of simulation results per homogeneous groups of scenarios, in terms of related QoS metrics and QoE metric. As a first remark, MOS is acceptable for the first two subsets (fair quality), and too low for the third (poor quality) and fourth (bad quality) subsets.

Table 1. Scenario Configurations.

Subset No.	*Scenario No.*	*LTE Service Type*	*S1 Link Capacity [%]*	*eNB Band [MHz]*	*Impairments due to IP Cloud*	
					Packet Discard Ratio [%]	*Packet Latency [s]*
1	1-12	VoLTE	100; 75; 50; 30	5; 10; 20	Not present	Not present
2	13-24	VoLTE + HTTP Browsing	100; 75; 50; 30	5; 10; 20	Not present	Not present

5 Statistical Analysis

5.1 Single Variable Non Linear Regression Model

A generic regression model is representable as

$$Y = f(x) + \varepsilon_i \quad (1)$$

where Y is the response (dependent variable) to the predictor x (independent variable), with $\varepsilon_i \sim (N,\sigma_i^2)$ the error for each observation. The relationship function f(x) can be linear or not. Based on available dataset the model of choice for regression is non-linear, and

specifically exponential (Alreshoodi, 2013). In case of MOS as response and a KPI as predictor, (1) becomes

$$QoE = a * exp(-b * QoS) + c \qquad (2)$$

where a and b are numerical coefficients. QoS may be Delay, Jitter and PLR in turn.

5.1.1 MOS vs DEL fitting.

In case of fitting between MOS and Delay, the regression model is

$$MOS = -13.96 * exp(-1.133 * DEL) - 8.783 \qquad (3)$$

Figure 3 gives a graphic representation of (3). The fitting quality is proved by a good value of R-squared (0.9487) (the adjusted R-Squared is quite near, i.e. 0.9464). Further the value of Root Mean Square Error (RMSE) is low enough, i.e. 0.185.

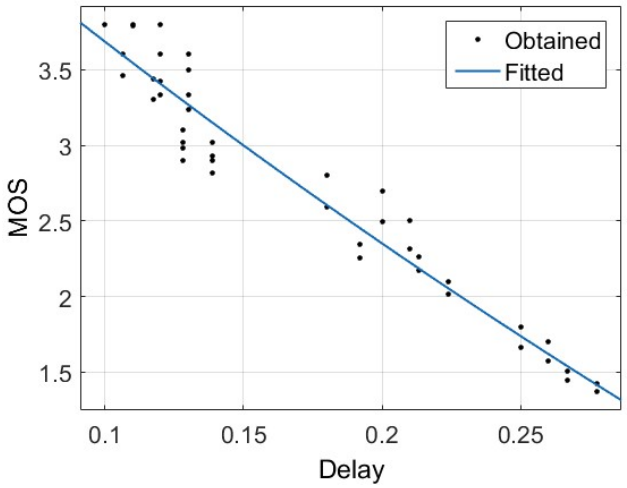

Figure 3. MOS to Delay regression model.

5.1.2 MOS vs JIT fitting.

In case Jitter is considered as a QoS, the regression model is estimated as

$$MOS = -94.21 * exp(-0.1219 * JIT) - 98.78 \qquad (4)$$

Figure 4 shows the plot for (4). R-squared value is as for (3), i.e. 0.9374 (as much as the adjusted R-squared, i.e. 0.9352). The RMSE value is 0.2034. We can conclude the fit to be adequate.

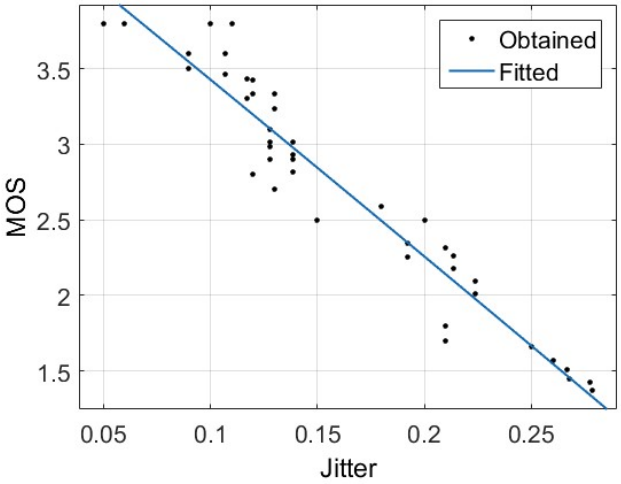

Figure 4. MOS to Jitter regression model.

5.1.3 MOS vs PLR fitting.

As far as PLR is considered, the regression model comes out to be

$$MOS = 2.198 * exp(-11.06 * PLR) + 1.391 \qquad (5)$$

Figure 5 shows graphically the regression model. Data exhibit a strong non linear character. R-square value is 0.8969, while RMSE value is 0.226. The quality of fitting is slightly lower than for (3) and (4).

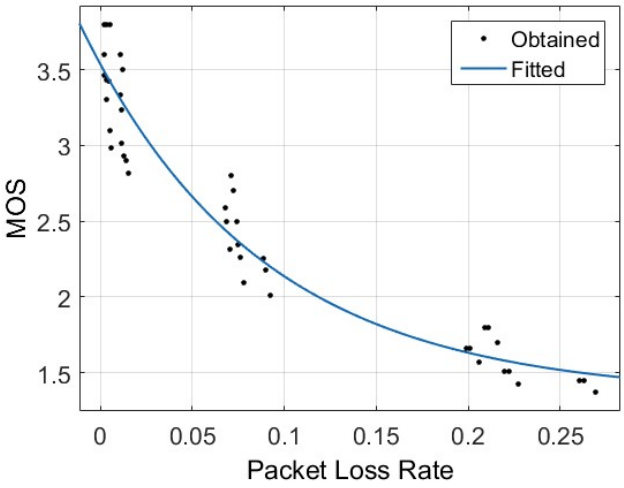

Figure 5. MOS to PLR regression model.

Further Figure 5 reports the existence of 3 clusters in the scenarios set. The clusters are linearly separable. This effect is similar in the (MOS, DEL) plane, and not evident in the (MOS, JIT) plane.

5.2 Multiple Variable Linear Regression Model

The previous fitting models are able to identify a (sometimes-strong) non-linear relationship between MOS and QoS KPIs taken once a time. These models give for VoLTE an idea of the QoE/QoS mapping but have a limited validity. In this section we look for a relationship between all QoS KPIs and QoE, a multi-variable approach is helpful. The Multiple variable regression (MLR) model is usually represented as

$$Y = \beta_0 + \beta_1 * x_1 + \beta_2 * x_2 + ... + \beta_n * x_n + \varepsilon_i \qquad (6)$$

where β_0, β_1, β_2,…, β_n are the unknown regression coefficients and $\varepsilon_i \sim (N,\sigma_i^2)$ is the error for each observation.

As far as MOS is the response (dependent variable) and DEL, PLR, THR are the independent variables, from (6) we have

$$MOS = \beta_0 + \beta_1 * DEL + \beta_2 * JIT + \beta_3 * PLR \qquad (7)$$

For our dataset, the regression model comes out as

$$MOS = 4.824 - 6.958 * DEL - 5.533 * JIT - 0.1477 * PLR \qquad (8)$$

Figure 6 shows relevant statistical indicators for model (8): the fit looks actually good, and residuals are well distributed and adequately symmetric. The goodness of the regression model (8) is proved by R-squared quite high 0.973 (with an adjusted R-squared equal to 0.971) and a quite low value of RMSE, i.e. 0.136. The overall pValue is very low: 1.75e-34. This means the null hypothesis can be firmly rejected.

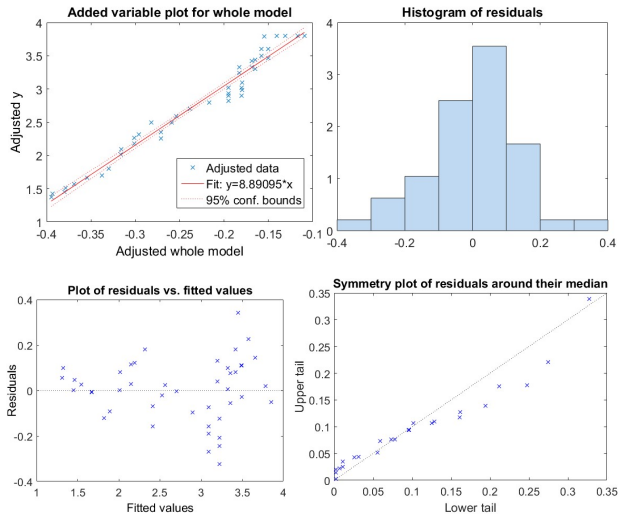

Figure 6. Statistical indicators for MLR in case of MOS, DEL, JIT and PLR. From upperleftmost to right: plot for whole model vs samples; histograms of residuals; symmetry plot of residuals around their median; residuals vs fitted values.

Table 3 presents the main statistical parameters for the coefficients in (7) and (8).

Table 3. MLR Results.

Coefficients	*Estimated Value*	*Standard Error (SE)*	*tStat*	*pValue*
β0 (intercept)	4.824	0.1339	36.035	2.67e-34
β_1	-6.958	1.36	-5.116	6.568e-06
β_2	-5.533	0.8751	-6.323	1.131e-07
β_3	-0.1477	0.6879	-0.2147	0.8310

5.3 Cluster Analysis

Besides the results coming out of the regression analysis, we need to gain a better insight in the QoE/QoS mapping. Clustering may provide that. Let us map the scenarios in the 4 dimensional feature space, whose dimensions are MOS, DEL, JIT and PLR. If we apply the well-known k-means technique [20] [21], we get three clusters as a result after the algorithm stabilization. Figure 7 shows the clusters projected onto the first two principal components. Clusters are linearly separable and fairly separated.

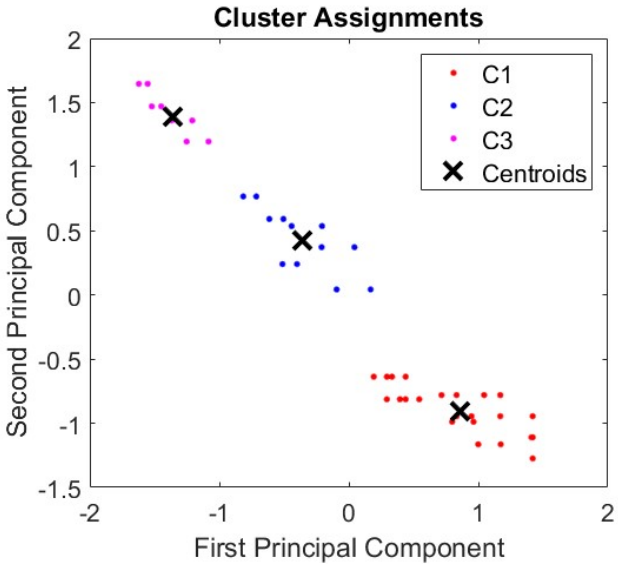

Figure 7. Clusters of VoLTE scenarios. Plot is a projection on the plane of the first two principal components. Centroids are marked as crosses.

Table 4 reports the position of the centroids of the three identified clusters in the 4-dim space. The utility of this clustering is evident from the changes of QoE between the centroids: MOS assumes the best value in C1 that consists of 24 scenarios, characterized by a single application: (VoLTE in the scenarios 1-12) or by

a mixed traffic, (VoLTE and HTTP web browsing applications, scenarios 13-24).

The MOS gets worse of -3.1 dB for C2 when the VoLTE application co-exists with end-to-end transmission errors due to an IP cloud (scenarios 25-36). The MOS decreases of -6.8 dB in C3 where both a mixed traffic (VoLTE and HTTP web browsing) and end-to-end transmission errors are present.

Table 4. MLR Results.

Cluster No.	*Scenario No.*	*MOS*	*Delay [s]*	*Jitter [s]*	*PLR [%]*
1	[1-24]	3.40	0.12	0.11	0.77
2	[25-36]	2.39	0.20	0.19	8.20
3	[37-48]	1.56	0.26	0.25	22.54

To be remarked that cluster C1 gathers scenarios from subsets 1 and 2. C2 is overlapping with subset 2 of the scenarios. C3 is overlapping with subset 3. Based on Table II, Table IV shows both this relationship and related cluster characteristics.

6 Conclusions

VoLTE is an important service for LTE networks since it is the basic voice service in the 4G wireless standard. Since LTE is a fully IP-based system, VoLTE application is delivered in the best effort modality. Mapping QoE/QoS is of key importance for the MNOs. Here we studied how the correlation between QoE and QoS can be expressed through mathematical models.

We designed a certain number of scenarios, that include as network impairments both mixed traffic (co-presence of VoLTE and HTTP web browsing), and end-to-end transmission errors (presence of an IP cloud). We analyzed results from simulation through different techniques: single variable regression, Multi Linear Regression (MLR) and cluster analysis.

From the single variable nonlinear regression, we learnt that DEL and JIT have linear models. On the contrary, the PLR model exhibits a stronger non-linearity, which is the reason why presence of clusters in data has been anticipated from Figure 5.

The multivariable linear regression came to results comparable with the single variable regression for dependence from DEL and JIT. This is straightforward from the linearization of (3) and (4). Further, model (8) expresses the joint influence of all QoS metrics on MOS, with a good statistical quality. Nonetheless, the coefficient related to PLR has an unsatisfying pValue. This may be motivated by the irrelevance of the variable (that is the likelihood of the null hypothesis). Further, it may be a signature of statistical instability when a nonlinear behavior is forced to accommodate into a linear model. Related work demonstrated PLR to be a relevant predictor for MOS. Thus we consider (8) relevant under a theoretical viewpoint, but of limited use as far as a large PLR variation is considered.

The cluster analysis showed that the designed scenarios naturally group into three distinct clusters. Each of them has different features in terms of QoE and QoS metrics. As a first result, the authors observed that scenarios of C3 have an unacceptable MOS, due to errors of end-to-end transmission (modeled through IP cloud). About the role of PLR, clustering reveals a strong capability of PLR to predict existence of cluster (compare Figure 3 and Figure 7), and a very high discrimination between the clusters based on the PLR value (see Table IV)

Future works will be focused on the mapping QoE/QoS for LTE networks with different scenarios and design parameters. Applications in the scope will be video streaming and HTTP web browsing.

Constructive Assessment Method for Simulator Training

Laura Marcano Tiina Komulainen
Department of Electronic Engineering, Oslo and Akershus University College of Applied Sciences (HiOA), Norway
{Laura.Marcano,Tiina.Komulainen}@hioa.no

Abstract

Industrial operator assessment is a very controversial subject in the scientific community, as determining the most suitable, objective and effective means of giving feedback on an operator's performance is a great challenge. This paper presents a proposal on assessment methods for simulation training. The development is based on the results from simulator training courses held at Oslo and Akershus University College of Applied Sciences (HiOA) from 2010 to 2014. The results and course evaluation were analyzed to identify where new methods could be applied that would lead to improvement. The method proposed consists of an automatic assessment procedure, which will give feedback to the simulator course participants during the simulator session and help the students to achieve the learning outcomes. The proposed method will be tested in the simulator training courses at HiOA in spring 2017 and the results will be presented in a later paper.

Keywords: assessment, performance, operator, feedback, students, learning outcome

1 Introduction

1.1 Simulator training and performance assessment challenges

The evaluation of operators' performance represents a significant challenge for the process industry, as the appropriate assessment of operators' performance is of great importance to ensuring the right competencies and safe plant operations.

A recent study in the Norwegian oil and gas industry (Komulainen and Sannerud, 2014) reveals that only 30% of the respondents take exams after the simulation courses. The evaluation of the simulator trainee performance is based on the instructor's verbal feedback during the scenario and the instructor's verbal assessment after the scenario.

The automatic assessment tools available require the implementation of a specific sequence of actions for each scenario. The main criticism of automatic assessment is the high implementation and maintenance workload of the scenarios, the difficulty of implementing just one optimal sequence for complex scenarios, i.e. there can be many good alternative solutions, and the interpretation of operators' learning outcomes, competencies and skills from the figures generated by the automatic assessment system. Thus, the use of automatic assessment tools is not widespread in the Norwegian oil and gas industry.

Virtual laboratories i.e. complex process simulators, are important learning tools in modern engineering education; they are relevant to industrial practice, they facilitate collaborative, active learning among the students, and they are time and cost effective (Coble et al., 2010; Corter et al., 2011; Edgar et al., 2006; Komulainen and Løvmo, 2014; Martin-Villalba et al., 2008; Rasteiro et al., 2009; Rutten et al., 2012; Wankat, 2002).

Dynamic process simulators have been used as an additional learning tool at HiOA since 2010 (Komulainen and Løvmo, 2014). Our experience shows that simulator training provides industrially relevant practice for large student groups. However, in order to provide prompt assessment of learning outcomes at an individual level, an effective personal feedback and assessment tool is required.

Both industrial and academic experience on simulator training indicate a need for effective automatic assessment measures. The challenge in developing such a tool is to avoid too deterministic measures (i.e. scenario-specific sequences), and to ensure the clarity and measurability of the learning outcomes.

1.2 Introduction to the proposed work

The simulation module is built up using the six categories of the didactic relation model: learning goals, content, learning process, learning conditions, settings, and assessment. These categories are relative to each other i.e. if changes are made in one of the categories this will lead to changes in the other categories (Bjørndal and Lieberg, 1978; Hiim and Hippe, 1998).

Thus, the assessment of the simulation module has to be directly related to the learning goals of the simulation module. In the following, we suggest measuring the theoretical knowledge using key performance indicators (KPI) and to measure practical competencies using operator performance indicators (OPI).

1) Key performance indicators (KPI): The evaluation of the performance of any process is a matter of high

priority, as it is necessary to determine how efficient the process is and whether it is being executed as optimally as possible. In the research of Manca et al. (2012), it is indicated that from the 1980s, the scientific community became aware of the industry's need for performance assessment. Therefore, it was necessary to establish quantitative indicators that could help to measure the production efficiency of a process; these indicators are known as Key Performance Indicators (KPIs).

Key Performance Indicators express the performance of a whole process; they measure the performance of all types of equipment that form a plant and of the entire plant itself (Lindberg et al., 2015). In the industry sector, performance indicators based on human factors are called operator performance indicators (Manca et al., 2012), which, conversely to KPIs require a more complex evaluation due to their implicit human attributes.

2) Operator performance indicators (OPI): Kluge et al. (2009) carried out extensive research on different training methods used for process control simulators. They explain several of the goals of simulator training, some of which are summarized below:

- Lead the trainees to an understanding of physical processes, the overall operation of the plant, and system functionality.
- Start-up and shut-down procedures.
- Procedural knowledge for normal plant operation and the use of checklists.
- Operators should be able to improvise and adapt to the contingencies of abnormal events.

The goals of simulator training are thereby to meet an overall main objective: efficient operator performance.

From the research of (Nazir et al., 2015), several relevant factors can be recognized that can be considered as operator performance indicators. In the process industry, there are two kinds of operators, Control Room Operators (CROPs) and Field Operators (FOPs). One of the most important features of the teamwork between these two kinds of operators is communication. Effective collaboration between CROPs and FOPs leads to the necessary actions to avoid accidents. Therefore, one important OPI is effective communication. Another OPI that can be associated with the teamwork between CROPs and FOPs is the accomplishment of tasks. Process safety is determined by different capabilities that must be associated with operators. Hence, these capabilities are related to OPIs as well: the ability to interpret the available information; ability to identify abnormalities; understanding the process in terms of operation, equipment, and instruments; being able to interact with different teams and deal with abnormal and escalating situations. Another specific characteristic of great importance, which is also related to OPIs, is time. The time taken to execute certain tasks and more specifically, the time taken to deal with abnormal or emergency scenarios, as this is a direct reflection of the responsiveness and attention skills of the operator (Nazir et al., 2015).

Similarly, based on the research conducted by (Nazir et al., 2012) on situation awareness in industrial plants, Manca et al. (2012) identified some characteristics that are related to the concept of OPI. These characteristics are:

- level of knowledge of the fundamentals of the process;
- the role played by the streams involved in the process;
- the ability to run the process under new conditions;
- the ability to deal with abnormal situations;
- the ability to establish a safety culture and
- the ability to coordinate actions.

There is a common factor in the last four studies referred to above, namely the understanding of the process; this can be considered as one of the most important OPIs, as good performance is based on good knowledge of what is done. Kluge et al. (2009) suggested that "knowledge of how to operate the plant to achieve certain goals can lead to good performance". Nevertheless, it is becoming a challenge for operators to obtain good and sufficient knowledge of the processes they operate due to the great advancements in automation, which are more and more complex and lead to information overload and difficulties related to human machine interface (Nazir et al., 2014; Zou et al., 2015).

Nazir et al. (2013) mention the relevant role played by the execution of an appropriate performance evaluation of the operators. The authors suggest that a correct assessment of the operators is also part of a well-designed training method, in order to reduce the number of accidents occurring in the industrial sector and their impact. It is indicated in the study, that the assessment procedure should be completely objective, in order to guarantee consistency, quantitative assessment, repeatability, and neutrality. Therefore, the assessment process must be automatic. In order to do so, the specific characteristics that the system will evaluate must be identified. These are: OPIs, KPIs and help requirement analysis. In their article, they present an example of the methodology of performance assessment for a catalytic inject process and a C3/C4 splitter. The operator performance indicators evaluated in this case were: Reaction time, Identification ability, Self-dependence, Attentiveness, Multitask handling, Voice communication, Identification ability, Recalling ability, and Situation handling.

Within the same context, Manca et al. (2012) conducted research where they indicate the importance of the assessment of the training performance of CROPs. The authors indicate that developing these evaluations represents a challenge, because the assessment is based on performance indicators related to

human beings and therefore on their intrinsic complexity, which leads to subjective evaluations by the instructors. Because of this, it is very important to develop assessment methods based on quantitative values and not just qualitative appreciation, so the assessment can be as unbiased as possible. In the research, they present a hierarchy scheme with different categories and classifications that form the overall CROP mark. The structure is used as a basis for determining the importance and the weighting of each OPI for the operator assessment. Each OPI is assigned a different value according to its place in the hierarchy using the Analytic Hierarchy Process (AHP). The authors suggested this method in order to overcome the drawbacks related to the subjectivity of the trainers.

Characteristics of the OPIs: One of the main features of OPIs is that they are intrinsically related to human factors as they are linked with the assessment of human beings; this is precisely what makes their evaluation so complex. However, Manca et al. (2012) explain that OPIs are not only based on human factors, there are other parameters that also contribute to the OPIs' definition, such as consistency and association.

2 Materials and Methods

2.1 Software tools for simulator training

The dynamic simulation software used is K-Spice® by (Kongsberg, 2016). K-Spice® is a modular simulation tool for oil and gas unit operations based on first principles physics, chemistry, and engineering.

Exercise Manager is an automatic assessment software product for the K-Spice tool. The simulation model used for the study is a generic oil and gas production simulator model that consists of a three-stage, three-phase oil and gas separation train, the utility systems, and emulated control and safety systems. An overview of the plant is given in Figure 1. More details on the model and the assessment tool are given by (Komulainen and Løvmo, 2014).

2.2 Software tools for simulator training

1) Sample selection: All the participating students attend two different courses at HiOA.

2) Data collection: The anonymous data collected included a multiple-choice questionnaire and the numerical results of the final exam. The questionnaire included several questions about simulators as an additional learning tool, and was evaluated on a 5-point scale. The questionnaire was given to the students at the end of the simulation module. The exam results were obtained from the teacher, who prepares and grades the final exam.

3) Data analysis: Questions on whether simulation enhanced the students' learning outcomes were evaluated on a 5-point scale, the percentages for "agree" and "highly agree" are presented in the following. The marks of the simulation task(s) in the final exam were compared to the average marks in the final exam.

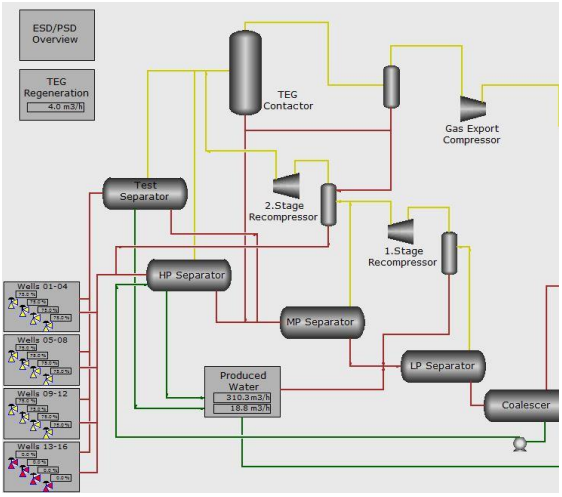

Figure 1. Overview of the large-scale oil and gas production plant model.

3 Teaching and Learning in Simulator Training

3.1 Teaching and learning in simulator training at HiOA

The simulator training at HiOA follows the industrial briefing – simulation – debriefing structure. During the two-hour briefing session, the teacher presents the simulator, the dynamic trends, and the tasks in a classroom for all the students. For the four-hour simulation sessions, the students are divided into larger groups. Typically, the students work on familiarization tasks (60-75min) before the simulation scenarios (2-3h). The students start writing a preliminary simulation report during the simulation session, and spend approximately two hours afterwards to finish the report before the debriefing workshop. In the two-hour debriefing workshop, the students compare and discuss the simulation results in new groups of four students. At the end of the workshop, the teacher facilitates the summarization of the simulation results and of the overall experience on a whiteboard. The total time spent on one simulation training module is 7-10 hours.

The teacher explains the basics of the simulation tasks and gives a simulation demonstration during the introduction lecture. During the simulation sessions, the teacher has an instructor role, only providing help if the student group cannot find the solution themselves. In the workshop, the teacher is a facilitator, setting a framework for the group discussions on the simulation results and guiding the final plenary presentation of the results. The teacher gives the students feedback during the simulation sessions and the workshop, and grades the simulation reports.

The simulation tasks aim to enhance social interaction in small groups while the main focus is for each student to learn by doing the simulation tasks and reporting at their own pace. Discussions on the simulation results are encouraged during the simulation sessions and during the debriefing workshop, i.e. learning from peers and through reflection.

3.2 Current feedback and evaluation methods for simulator training

There is no feedback during the simulation scenarios if the students do not ask the instructor questions. During the debriefing workshop, students get feedback from their peers.

The learning outcomes of the simulation module are measured using the results of the formal final exam.

The students evaluate the simulation module as part of the compulsory report using a multiple-choice questionnaire.

3.3 Experience with simulator modules at HiOA

In the following, the results of two different simulation modules, namely laboratory distillation system and industrial large-scale oil production facility, are presented. The simulation modules were taught to two groups of chemistry students and two groups of electrical engineering students over a period of four years.

The simulation modules were taught in three sessions using briefing–simulation–debriefing (i.e. lecture–computer exercise–workshop) structure, which is typical for industrial simulator training. At the end of the simulation module, the students deliver their simulation reports in groups and present their results in groups at the workshop. The instructor for all simulator modules was the main teacher of the course.

The undergraduate chemical engineering course (fall 2010-spring 2011, 20 chemistry students) where mandatory dynamic distillation simulator exercises were given prior to laboratory experiments: 95% of the chemistry students agreed that simulation enhanced their learning. The average final exam result was 56%, whereas the simulation tasks received an average mark of 70% (Komulainen et al., 2012).

The results for the undergraduate chemical engineering course (fall 2011-spring 2012, 20 chemistry students) were similar, 90% of the students agreed that simulation enhanced their learning. The average final exam result was 43%, whereas the four simulation tasks received an average mark of 47%. The reason for the generally lower exam scores in 2012 was the change of exam type from written to multiple-choice with similar calculation task (Komulainen, 2013).

The undergraduate course in dynamic systems (fall 2013, 60 electrical engineering students) resulted in 97% of students agreeing that simulation exercises increase their understanding of process dynamics in fluid systems. The average final exam result was 59%, whereas the simulation tasks received an average of 48%. One possible explanation for the low score of the simulation tasks was an unclear simulation chart (Komulainen and Løvmo, 2014).

The following year (fall 2014, 60 electrical engineering students) in the exam, the simulation chart was prepared with better resolution and clearer marking of the axes. The final exam result was 58% on average and the simulation task received an average mark of 54%.

In the final exam, the students scored higher than average when the simulation exercise was related to a practical laboratory experiment, and lower than average when the simulation results were not applied afterwards. One possible explanation is that group work without direct feedback might lead to misconceptions.

The students' evaluation of the simulation module and the students' evaluation of their own learning from simulation were very positive for all the groups. The students learn to use industrially relevant tools and their understanding of industrial processes increases.

3.4 Conclusions based on previous experiences

Utilization of industrial large-scale simulators enables students to gain additional skills: industrially relevant process knowledge, and teamwork skills. However, the feedback and assessment system needs to be developed further in order to clearly indicate whether the students have reached the learning goals.

4 Suggested Practices

4.1 Suggested effective assessment method for simulator learning

The main goal of the simulation module is to help the students obtain a better understanding of complex processes and to see the application of theoretical equations and concepts by means of realistic examples and methods. Therefore, there is always an academic commitment to develop revised strategies and procedures that can lead to improvement of the learning outcome.

The aim of this project is to improve the learning outcome of the practices that apply to the simulation module at HiOA. Hence, it is important to be able to measure the knowledge of the students before and after taking the simulation module. This will enable us to make a more formal and reliable evaluation of the benefits of using simulators as a learning tool. In order to achieve this, a diagnostic test based on the required conceptual knowledge about the subject in question should be applied.

The tasks connected to the simulation course have, until now, been based on the students making certain changes to the system and then analyzing the results.

The proposed idea is to add a new section to the simulation module, where the changes in the system will be pre-established, and the students should be able to recognize the abnormal situation and fix it.

The abnormal situation scenarios will be developed using a simulation program associated with the subject or topic of interest. In the case of the present project, which is based on industrial process control, the K-Spice Exercise Manager will be used. The students will have to run different simulation scenarios and observe the possible deviations from normal operations. They will see on the screen the corresponding alarm(s) that will lead them to the source(s) of the abnormal situation. Once the students recognize the problem, they should correct it based on their knowledge of the process. Once the scenario task is completed, a short assessment report will be delivered. The assessment report will be based on strategic performance indicators so that the evaluation is objective and unbiased. The total assessment will correspond to a main performance indicator, which is the Abnormal Situation Management (ASM). This main indicator at the same time may depend on different complementary factors as can be seen from Figure 2.

In Figure 2, the effectivity of the trainee refers to the total time required by the student to fully complete the task. The oil production must be monitored since this is the main goal of the industrial process related to the simulation module, and abnormal situations must be solved as soon as possible and efficiently, in order to avoid major oil production losses. It is also very important to monitor the environmental indicators, such as the flare flow rate or the produced water composition, since abnormal situations can also have serious repercussions for the environment. Another significant factor is the energy efficiency of the process, which is analyzed through the total power consumption of the plant.

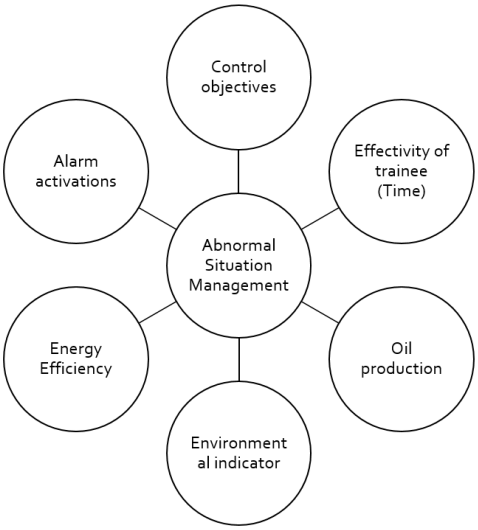

Figure 2. Main performance indicator and complementary factors.

Every abnormal situation in industrial processes is reported by an alarm. The scenarios will be designed such that the problem presented in each task will constantly activate an alarm until the student solves the problem. A record of how long the alarm is active before the problem is solved is indicative of the performance of the student. Finally, the control objectives will be evaluated by the calculation of the integral of the squared error for the controller XC, which indicates how well the problematic controller was tuned, if this is the case. The following equation will be used to determine the total evaluation of the main performance indicator ASM.

$$ASM = \frac{r_{OP} \cdot w_{OP}}{r_{OP,max}} + \sum_i \left(\frac{r_{i,max} - r_i}{r_{i,max} - r_{i,min}} \right) \cdot w_i \quad (1)$$

Where the first term of the equation is related to the oil production (OP), r_{OP}, w_{OP} and $r_{OP,max}$ correspond to the performance measure, the weight of the OP factor and the maximum value of oil production, respectively.

In the second term of the equation, the rest of the factors are evaluated, r_i corresponds to the performance measure of the i_{th} factor, w_i is the weight of the i_{th} factor and $r_{i,max}$ and $r_{i,min}$ are the maximum and minimum value of r_i, respectively.

Each factor makes a different contribution to the total evaluation of the main performance indicator ASM. The Analytic Hierarchy Process (AHP) (Saaty, 2008), was used to calculate the corresponding weight of each factor. This method consists of creating a square matrix based on a pairwise comparison of the factors. The values that indicate how many times one factor is more relevant than the other are according to Saaty's scale. Finally, the matrix entries satisfy the condition $a_{i,j}=1/a_{j,i}$.

Table 1 shows the pairwise comparison matrix for the factors that constitute the main performance indicator. The final priorities associated with each factor (Table 1) correspond to the priority vector of the pairwise comparison matrix, which is the normalized principal eigenvector of the matrix (Brunelli, 2015).

4.2 Specific example of effective evaluation methods for simulator learning

The scenarios must be related to the tasks that the students are going to develop during the first part of the simulation module. The goal is to gradually increase the difficulty of the tasks within the same contexts. In the first part of the module, the students make changes in the system themselves and evaluate the results. In the second part, they are not going to make the changes but to recognize them and solve them.

Table 1. Pairwise comparison matrix for weighing the factors that constitute the main performance indicator.

Pairwise Assessment	ET	OP	EI	EE	AA	CO	Priorities
Effectivity of Trainee (ET)	1	1/4	1/3	1/3	1/2	1/2	0.063
Oil Production (OP)	4	1	1	1	3	3	0.262
Environmental Indicator (EI)	3	1	1	1	3	3	0.251
Energy Efficiency (EE)	3	1	1	1	2	2	0.218
Alarm Activations (AA)	2	1/3	1/3	1/2	1	1/2	0.091
Control Objectives (CO)	2	1/3	1/3	1/2	2	1	0.115

For example, one of the tasks of the first part of the module consists of producing a failure in the level controller of the HP separator by changing the controller to manual mode and decreasing the controller output. As a result, the level in the separator increases and reaches the High-High level, which activates the security alarm, and a partial shutdown occurs. The corresponding assessment scenario will also be based on a controller failure, but the students will not know this in advance. The student will have to run the simulation and observe the system behavior, identify the alarm and solve the problem.

In this particular case, the level will reach the High limit, and it will then stabilize for a moment before reaching the High level again. These kinds of scenarios are also devised with the aim of developing the students' situation awareness, since they must be attentive to recognize the changes in the system.

An example is presented below to demonstrate how to apply the Analytic Hierarchy Process together with (1) to calculate the result of the main performance indicator. The results presented below correspond to a trial test executed by the authors.

As mentioned before, the scenario consists of a failure in the level controller of the HP separator. When the scenario starts, the controller mode switches from auto to manual and the controller output is decreased until the level in the separator reaches the High Level Alarm, then the controller output increases again until the level inside the tank reaches a safe value. This sequence is constantly repeated until the problem is solved, as shown in Figure 3. The solution is simply to switch the controller back to auto. Since no controller tuning is required in this scenario, and the abnormal situation does not affect any environmental aspects of the process, these two factors are not considered in the pairwise comparison matrix developed for the example, which is shown in Table 2.

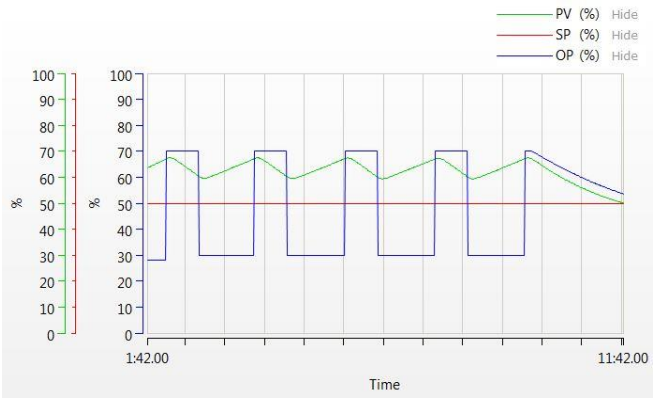

Figure 3. Level controller behavior during the simulation scenario.

Table 2. Pairwise comparison matrix for the example of the level controller failure.

Pairwise Assessment	ET	OP	AA	Priorities
ET	1	1/4	1/2	0.137
OP	4	1	3	0.625
AA	2	1/3	1	0.239

Table 3 shows the values needed for the calculation of each term of (1), and the final calculation of the main performance indicator that correspond to this example. Table 3 also shows the contribution made by each factor to the final value of the Main Performance Indicator. The example was solved in 11.7 min. The minimum time was 5 min and the maximum time was 20 min. There were five alarm activations. In this case, the minimum alarm activations was 2 and the maximum was 10. Finally, the average oil production during the total running period of the example was 908.3 m^3/h and the maximum production under normal circumstances is approximately 980.0 m^3/h. The sum of the values obtained for each factor multiplied correspondingly by their individual contribution gives a final performance of 80%.

Table 3. Calculation of the final value of the main performance indicator.

	r_i	$r_{i,min}$	$r_{i,max}$	w_i	Equation Term
ET [min]	11.7	5.0	20.0	0.137	0.076
AA [-]	5	2	10	0.239	0.149
OP [m^3/h]	908.3	-	980.0	0.625	0.579
	Main Performance Indicator				0.804

5 Conclusions

The simulator training at HiOA currently lacks quick, individual feedback for the participants, and the learning outcomes of the simulator training are not properly assessed after the simulator course. The formal final exam results from HiOA reveal that in spite of the debriefing-workshop after simulator training sessions, some misconceptions remain.

An automatic assessment method is proposed that gives immediate feedback to the students after a scenario is run. The method is based on the evaluation of a main performance indicator that consists of different factors related to the functioning of the process. This main indicator comprises an overall evaluation of the students' progress while dealing with an abnormal situation in the process. The students will receive early and individual feedback on their performance before the workshop, which means they will be able to recognize where there is room for improvement and have the opportunity to work on this before the final exam. Since the instructor will have access to the scenario results of each student, this will also provide the instructor with a clearer picture of how effective the simulator training has been.

The proposed assessment method will be tested at HiOA during the spring and fall semesters of 2017, for the undergraduate courses on chemical engineering and dynamic systems.

Acknowledgements

The authors would like to thank all the participants in the study and the industrial partner Kongsberg Oil & Gas Technologies for providing the software and guidance. Docent Finn Aakre Haugen and Professor Arne Ronny Sannerud are also greatly acknowledged for reviewing the draft paper. Last but not least, thanks to the research funder Oslo and Akershus University College of Applied Sciences, Faculty for Technology, Art and Design.

Learning Heat Dynamics using Modelling and Simulation

Merja Mäkelä Hannu Sarvelainen Timo Lyytikäinen

Energy Technology, South-Eastern Finland University of Applied Sciences, Finland, www.xamk.fi

Abstract

In the education of energy and power plant engineers, the learning of heat transfer, its dynamics and process control plays an important role. Deeper touch in dynamic process phenomena in our vibrant times may sometimes be a challenge for students and teachers. Modelling and simulation make a continuously increasing tool as a learning method, in various kinds of application fields. In engineering, using pilot or production plants, by modelling the systems, getting results from simulations and comparing the results to real life data, the intended learning outcomes can be achieved in a varying and motivating way. This paper presents a pilot heat exchanger which was mostly constructed by a few students of energy technology and supervised by their teachers. Some basic physical and identified process models of the heat exchanger are introduced, as well as their simulation results. This heat exchanger is widely used in the basic heat transfer and control system studies of higher education. Positive learning and teaching experiences were already achieved in the design and commissioning phase. As a result, the heat exchanger system offers a multifunctional learning environment with modelling and simulation activities in practice-oriented engineer studies.

Keywords: heat transfer, modelling, simulation, process control active learning, collaborative learning

1 Introduction

Learning and teaching of engineering in our times may be rather challenging. Very often also amusing elements are expected. Collaborative learning in teams and practice-oriented experimental learning may help to overcome these challenges. The need of collaborative and practice-oriented learning elements is already referred in (Schadler and Hudson, 2004). Different kinds of active learning activities, such as analyzing, modelling, simulation, visualization, problem-solving, gaming, are emphasized in many learning and teaching instructions, such as in (Centre for teaching Excellence Canada, 2016; Carleton Science Education Center USA, 2016), for example. This paper presents an educational heat exchanger system, some modelling and simulation methods for activating and successful learning and teaching experiences.

The objective educational heat exchanger describes a plate heat exchanger and comprises two water circulations. One water circulation, the hot circulation, includes a boiler unit with an electric heating element, while another circulation, the cold circulation, uses tap water leading it to a removal pipeline. Heat is transferred from the hot circulation to the cold circulation. All pipelines are isolated in order to avoid significant heat losses.

The educational heat exchanger process can be operated using both in the downstream flow and reverse flow and, and thus this system describes many common heat exchangers and heat recovery facilities. The impacts of the circulation flows and heating power can be monitored. The characteristic curve of the pump may be defined. The controllers can be optimized. This rather simple heat transfer system offers a whole set of varying learning objectives (Figure 1).

The heat exchanger process is provided with several temperature measurement sensors with Pt-100 elements: TI-1, TI-2, TI-3, TI-4 and TI-5 being in the hot circulation, and TI-11, TI-12, TI-13, TI-14, TI-15 in the cold circulation (Figure 2). The pipelines have a square-formed cross section profile, and they have a tight contact in the length of 6 meters. The effective heat transfer area totals 0.18 square meters. The dynamics of heat transfer can be experimented and monitored in several ways.

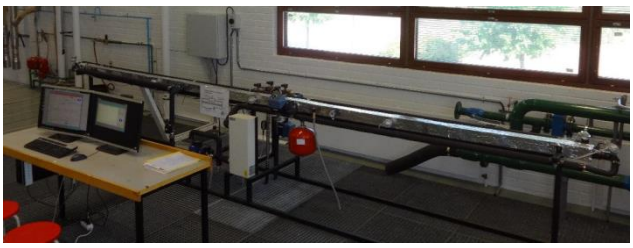

Figure 1. Educational heat exchanger system.

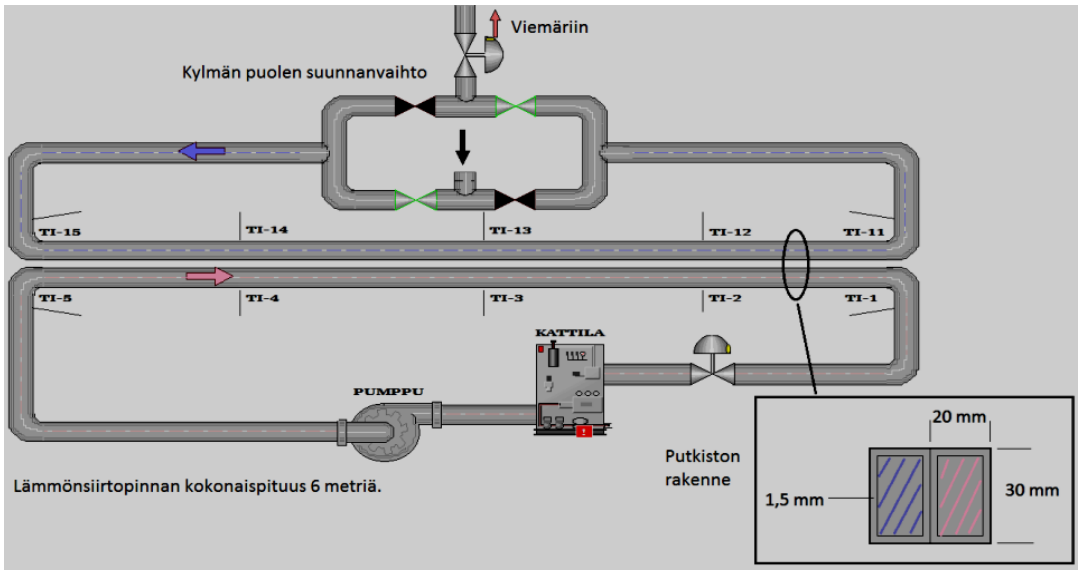

Figure 2. Structure of the educational heat exchanger system.

The temperature of the hot circulation is controlled by the power of the heating elements of the 26 kW flow type boiler (KATTILA), based on the measurement TI-1 (Figure 3). The flow of the hot circulation is controlled by the speed of a feeding pump in the control loop FIC-7. The flow of the cold circulation is controlled by the outlet valve of the control loop FIC-18. The direction of the cold circulation can be changed using a switch (SUUNTA) and related on-off valves, thus enabling the downstream and reverse flow operations.

The educational heat exchanger is provided with a programmable logic controller Siemens Simatic S7-1200 and a PC-based human machine interface (HMI) of Invensys InTouch. The HMI enables users to monitor measurement and control loops in an overview display (Figure 3) and operate them using separate loop window displays. The control system includes sampling of history data for trend curve monitoring, and for numerical tables in case of modelling and simulation.

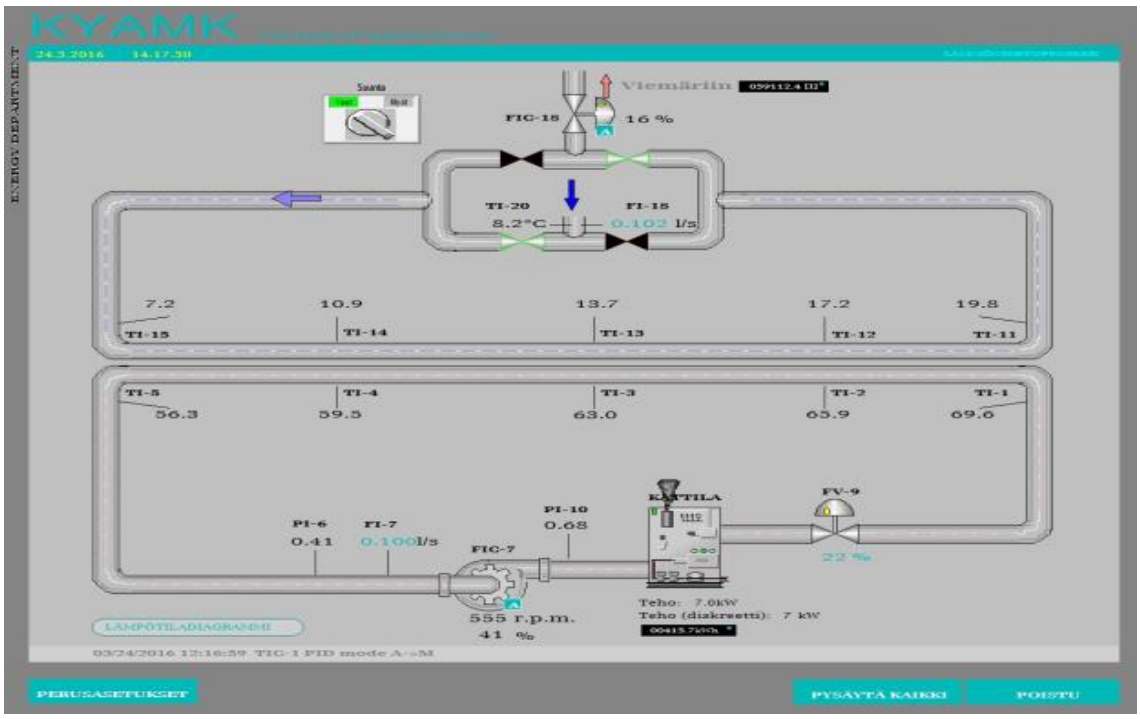

Figure 3. Overview display for monitoring.

2 Physical modelling of heat transfer

In modelling procedures we like to find relationships between interesting, interacting inputs and outputs of systems. Those systems to be modelled can be available process systems, or they may be systems to be designed. Physical models are based on well-known first principles, and they may be applied to rather simple, physically known systems. Model equations which are independent on time, describe steady state models of systems, while differential model equations, for example, present the time-dependent, dynamic behavior of systems. Steady-state models are interesting in process design, while dynamic models help to understand dynamic process phenomena from a control point of view. Modelled systems can be visualized using simulations which are needed in model validations.

We may create static or dynamic energy system models based on flow, mass and enthalpy balances, for example, as described in (Ljung and Glad, 1994). With energy systems we have different aspects. In heat transfer systems one interesting aspect comes from energy efficiency. We often like to know how much energy we do need to make a certain temperature difference in heat transfer.

2.1 First principle model of a heat exchanger

The dynamic behavior of the heat transfer in the educational heat exchanger can be described using a simplified process model of (1). Based on the dynamic heat balance, the change in the energy flow of in the releasing (or receiving) circulation can be given, based on (Ljung and Glad, 1994; Bergman et.al., 2011), as follows:

$$m * c_p * \frac{dT}{dt} = P - k * A * (T - T_n) \qquad (1)$$

m	total water mass, [kg]
c_p	specific heat capacity, [J/(kg K)]
T	water temp. of the input location, [K]
T_n	water temp. of the output loc., [K]
P	incoming heating power, [J/s]
k	average heat tr. coeff., [J/(s*K*m^2]
A	effective heat transfer area, [m^2].

Thus, the trend of temperature in the plate heat exchanger follows an exponential relationship which is dependent on the effective heat exchange area, heat transfer coefficient, mass and enthalpy of water in the circulations. In reality, the specific heat capacity c_p and heat transfer coefficient k are not constants but dependent on the temperature range. The model (1) assumes a constant temperature T_n in the output location, although the temperature T_n also changes due to operation conditions.

2.2 Simulation results based on first principle models

The first principle model of (1) of the educational heat exchanger system was used for the simulation of the temperature T (TI-1).

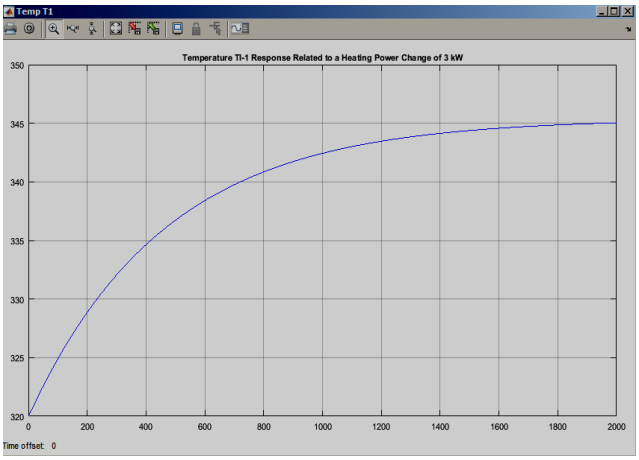

Figure 4. Simulated response of the temperature T (TI-1) related to a heating power change with time [s] in the x-axis and temperature [K] in the Y axis.

The model system was simulated using Matlab Simulink with the following heat exchanger parameters: A=0.18 m^2, T_5=312.05 K, m=10 kg, c_p=4179 J/kgK, k=500 J/sKm^2. The starting temperature T was 320 K. The response in the temperature T (TI-1) results a final increase of 25 degrees in simulations (Figure 4), and respectively in process experiments (Figure 5, red upper curve). The slowness expressed as a time constant, based on (m*cp)/(k*A), gives about 460 seconds. The time delay in the heat transfer could have been added to the simulation model but it was not known, yet.

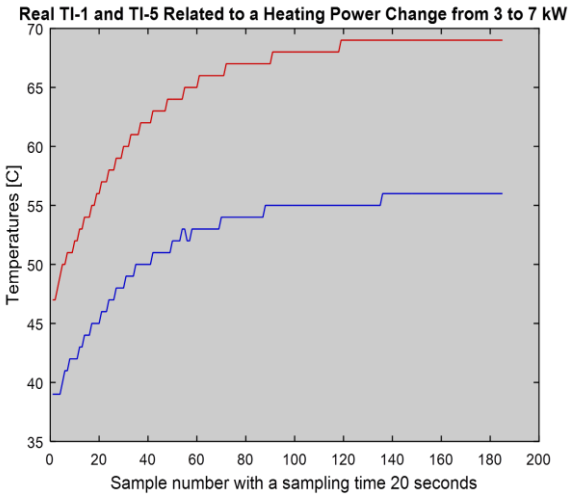

Figure 5. Temperature responses TI-1 (red upper curve), TI-5 (blue lower curve) related to heating power change in a real process experiment.

3 Identification models of heat transfer

Identified models can be achieved based on practical process experiments. Principally, it is a question of fitting sampled data to some ready-made models. These models are often mathematical, or they may even be linguistic such as fuzzy logic models (Yager, 1996; Åström and Hägglund, 1995). On one hand, the data based on simple step response tests can be fitted in time-continuous Laplace models. The most popular Laplace models, due to their physics-related parameters, are the settling first order model and the integrating model. On the other hand, the data sets based on pseudo random binary signal (PRBS) response tests can be fitted in time-discrete AutoRegressive with an eXogenous input (ARX), models, for example, according to (Ljung and Glad, 1994).

3.1 Identified Laplace model with simulation results

The first order Laplace transfer function model between the resulting output Y and excitation input U, for settling dynamics, can be given in the Laplace domain in (2), like presented in (Åström and Hägglund, 1995; Bolton, 2004; Dorf and Bishop, 2004):

$$\frac{Y}{U} = \frac{K}{T*s+1} * e^{-L*s} \qquad (2)$$

Y resulting output
U excitation input
K process gain
T time constant
L time delay
s Laplace operator.

In the first identification modelling case we liked to find out the relationship between the hot circulation temperature TI-1 and the heating power. Using the heating power of 7 kW, the heating process was taken to a steady state. Exact trend curves could be monitored (Figure 6). The heating power was changed to 11 kW, and the temperature T-1 started to increase gradually from 45.4 ºC to 63.4 ºC, after a time delay of 41 seconds. The temperature TI-1 reaches its final temperature 63.4 ºC after about 21 minutes. In the process experiment, the step response of the temperature TI-1 related to the heating power change settles down to a new level and the trend resembles a first order Laplace model response given in (2). The time constant, representing the slowness of the change can be defined to be 570 seconds. Thus, based on the step response curves, and by applying the first order Laplace model of (2), the process model between the temperature TI-1 and heating power can be stated as follows in (3):

$$\frac{Temp}{Heat\ power} = \frac{18/4}{570*s+1} * e^{-41*s}. \qquad (3)$$

The Laplace model of (3) was also constructed in the Matlab Simulink. In a simulation with a heating power change from 7 to 11 kW, the step response in the temperature TI-1 (Figure 6) gives matching results compared to the original process experiment data (Figure 7).

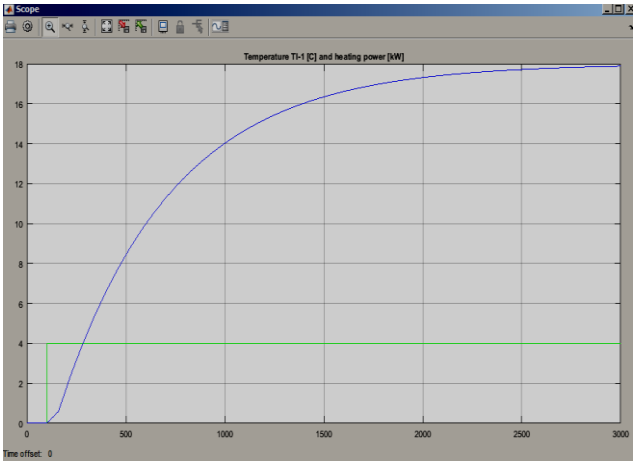

Figure 6. Simulated step response of the temperature TI-1 (blue upper curve) related to the heating power change from 7 to 11 kW (green lower curve).

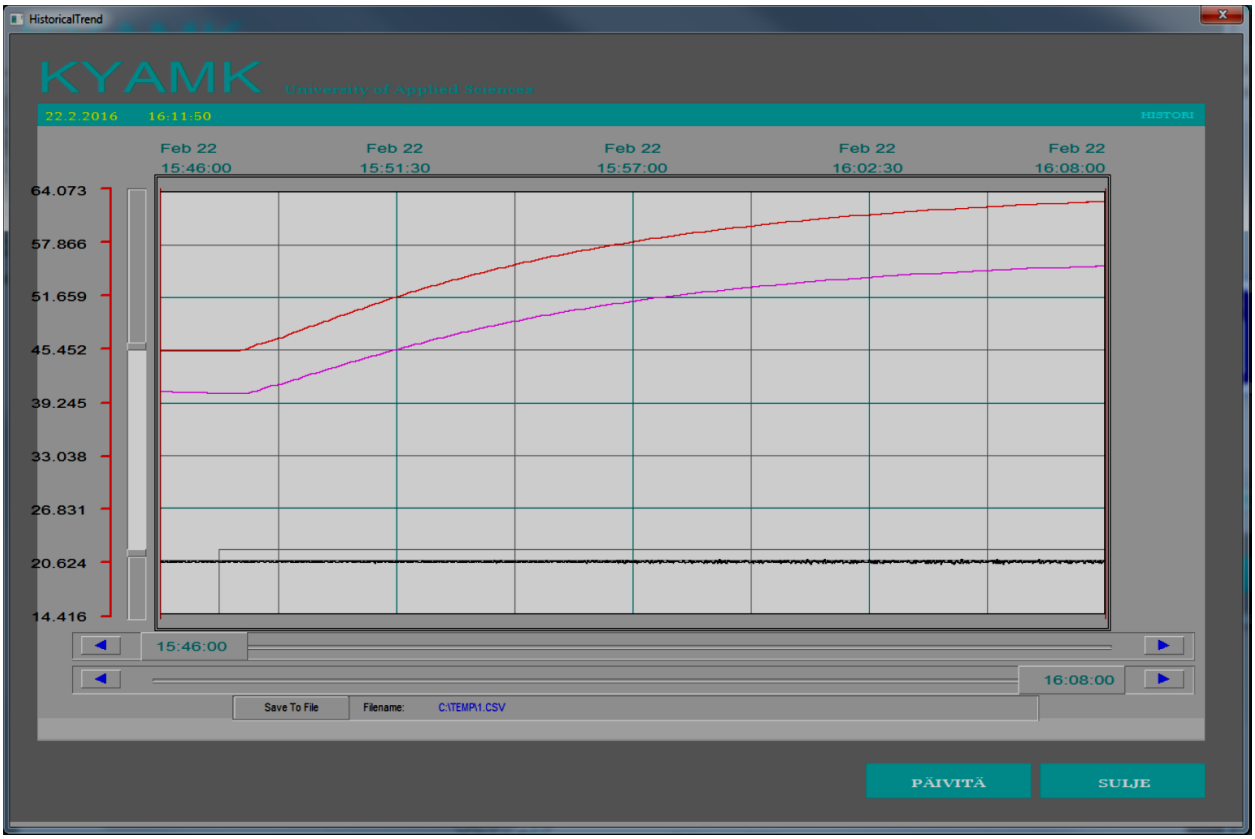

Figure 7. Real step response of the temperature TI-1 (upper red curve), TI-5 (next magenta curve) with the heating power change from 7 to 11 kW (lower stepwise gray curve) in the HMI monitoring.

3.2 ARX model with simulation results

Likewise presented in (Ljung and Glad, 1994; Åström and Wittenmark, 1997) a ready-made ARX model can be applied to practical modelling cases when data sets from process experiments with responses to pseudo random binary signal (PBRS) inputs are available. The ARX model can be given as a Z transfer function, as follows in (4):

$$\frac{Y(z)}{U(z)} = \frac{b_1 z^{-1} + b_2 z^{-2} + \cdots}{1 + a_1 z^{-1} + a_2 + \cdots} \qquad (4)$$

$a_1, a_2, \ldots$ estimated model parameters
$b_1, b_2, \ldots$ estimated model parameters
z Z domain operator.

According to (Ljung and Glad, 1994; Åström and Wittenmark) the parameter estimation of vectors' a and b in (4) can be computed using the least squares method. A process data set, comprising input-output data is fitted to the model structure, and the parameter estimation computing gives the parameters $a_1, a_2, \ldots, a_n$ and $b_1, b_2, \ldots, b_n$.

The ARX identification model was applied to a data set comprising the temperature TI-1 and heating power. The heating power was set randomly stepwise in 7 and 11 kW giving the response presented (Figure 7). Using the Matlab IDENT for the parameter estimation of an ARX model, the model parameters $a_1, a_2, \ldots, a_n$ and $b_1, b_2, \ldots, b_n$ could be estimated. The parameter estimation was based on a sampled data set with a sample time of 20 seconds. The heating power was switched to 7 and 11 kW, while the temperature TI-1 varied between 63 and 45 Celcius degrees. The first parameter estimation procedure using four a and four b parameters gave rather matching results (Figure 8), but the fitting procedure could be improved.

With eleven a, and ten b parameters the fit could be improved to be about 98 %. The modelling procedure should have been validated using another data set of the process experiment but the validation data was not available. Based on the PRBS process experiment of the pilot heat exchanger, the dynamic ARX model between the temperature TI-1 and heating power can be given using the model (4) where the estimated vectors a and b are:

a = [1.0000 -0.7586 -0.3667 -0.0649 -0.0215 -0.0870 0.1961 0.0999 -0.0810 0.1643 -0.0821]
b = [0 0.2742 0.0806 -0.0142 -0.0552 -0.0790 -0.1086 -0.0569 0.0160 -0.0528 0.0193].

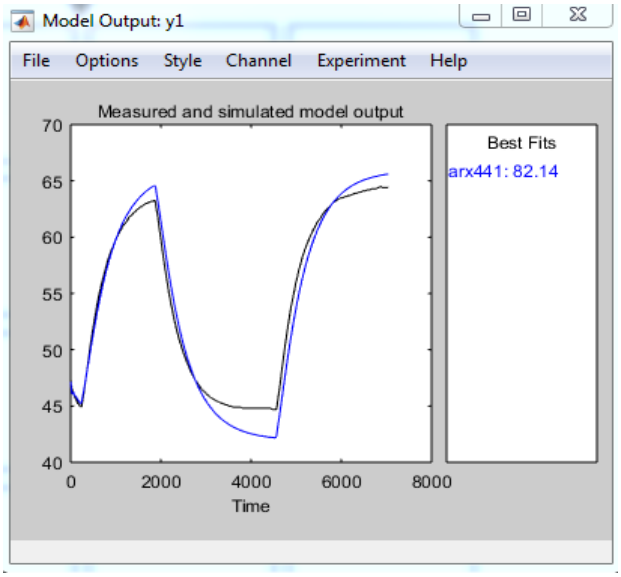

Figure 8. Simulated and ARX model responses, related to PRBS input data.

4 Conclusions

Positive - even attractive and entertaining - learning experiences are expected today also in the education of energy and power plant engineers in many countries. However, hard and some more difficult phenomena should be adapted, as well. Modelling and simulation of practical processes offer interesting learning experiences with many different aspects.

The experiences in learning the dynamics of heat transfer using an educational heat exchanger have been very positive. Combining the theory with practice has helped students to understand and analyze systems with some complexity. Firstly, first principle models based on nature laws could be modelled, constructed and simulated, and finally verified using experimental data. Secondly, based on step response tests, ready-made Laplace models could be parametrized, simulated and compared to the real data. Thirdly, based on PRBS response tests, discrete time series models could be parametrized and simulated.

Cooperative process experiments using the self-made heat exchanger system, modern control system tools, video recordings, photos and shared Moodle course materials with smartphones have been successful elements in the first learning phase. A further interactive analyzing, modelling and simulation phase using Matlab Simulink and Identification Toolbox tools deepened the learning and collaboration. It has been also encouraging to see that students don't have to manage "everything" in Matlab to be able to try basic analyzing, modelling and simulation methods. However, patience is needed in this kind of working. Several practical problems have to be overcome. This kind of a learning process offers a collaborative development environment both to students and teachers and from different disciplines, such as machinery, process technology and system engineering.

In the future, the educational heat exchanger will be provided with remote monitoring and operation in order to support flexible process experiments and data sampling. An interactive learning package based on the Moodle platform with touch-on instructions in plain language will be completed. A special attention will be paid to motivating tools and varying working procedures. Modelling and simulation aspects will be extended step by step. The dependence of specific heat capacity on temperature could be examined and included. Partial models will be collected to make an extended multivariable system model of the educational heat exchanger. The controllers could be provided by additional smart properties. Some parts and activities of this learning package could even be included in a web-based Massive Open Online Course (MOOC).

OO Modelling and Control of a Laboratory Crane for the Purpose of Control Education

Borut Zupančič Primož Vintar

Faculty of Electrical Engineering, University of Ljubljana, Slovenia, borut.zupancic@fe.uni-lj.si

Abstract

The paper deals with modelling, simulation and control of a laboratory crane for the purpose of control education. There were many similar activities in the past with realisations in causal modelling e.g. Matlab-Simulink. However we wanted to model and control the set-up also in the OO and multi-domain environment Dymola-Modelica using library components instead of mathematical equations to show all the advantages of such approach. The combination with some causal structures to solve certain problems is also discussed. The model was properly validated with some open and closed loop experiments. These results confirm the applicability of the model and the efficiency of the mentioned approach in modern control engineering courses.

Keywords: control education, modelling and simulation, OO approach, multi-domain approach, model validation

1 Introduction

It is extremely important to use miniature laboratory plants in control education. As such plants are very expensive they usually cover only a part of exercises, the basic part is realised in modelling and simulation environment. There are usually two important areas which have to be covered with education: modelling of real plants and control. Control schemes can be validated in simulation environment or on real plants.

However there are two approaches in modelling and simulation: traditional causal or block oriented or input output modelling which originates in analog simulation, in CSSL standard and is nowadays mostly covered with Matlab-Simulink environment (Moller, 2004; Simulink, 2014). However, more advanced approach is based on acausal, object oriented modelling which represents a multi-domain approach (connection of components from different fields) and giving a possibility of building libraries with reusable components. The most powerful tools are based on Modelica language (Modelica Association, 2010; Fritzson, 2004; OpenModelica, 2012), which is supported with several modelling packages. In our activities Dymola was used (Dymola, 2015). Many experiences with such tools in industrial projects and in education (Zupančič and Sodja, 2013) show, that it is possible to produce complex model in shorter periods while the models are very illustrative as they retain physical structure. However the executable models become very complex, it is usually difficult or impossible detect and solve numerical problems (Sodja, 2012). The practice shows that students are much more motivated when modelling with OO tools. This was evident when our traditional Matlab-Simulink modelling courses were expanded with Dymola-Modelica several years ago.

In our courses AMIRA 600 laboratory set-up (Amira, 2001) for basic and also more advanced courses from modelling and control was used. It enables several subprocesses, one is so called Loading bridge which actually models a crane. The mathematical model and the implementation in SIMULINK is described in (Hančič et al., 2015).

This paper describes our efforts to model the mentioned set-up without numerous mathematical equations. Instead a modeller uses prepared components from standard Modelica library. Our goal was only partly fulfilled because some modelling problems were finally solved with causal components.

2 Description of the loading bridge

AMIRA 600 (Amira, 2001) (see Figure 1) is a convenient laboratory set-up, appropriate for basic and also more advanced courses from modelling and control. It consists of an aluminium frame covered with sheets of plexiglass. The plant has different configurations, one of them is also the bridge crane. The set-up is very convenient for modelling and control. There are different control tasks such as proper positioning of the load in minimal time, small angles of the thread, avoiding obstacles, etc.

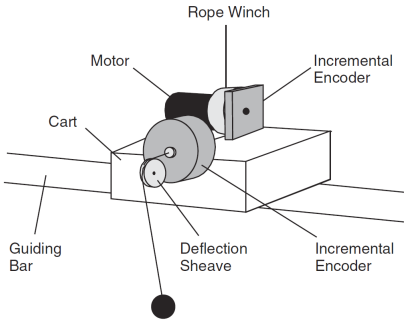

Figure 1. Laboratory set-up for control education: loading bridge.

The laboratory set-up consists of a cart which can be moved along a metal guiding bar by means of a transmission belt. Two proximity switches are mounted close to both ends of the guiding bar. They are used for limiting the position of the cart. The cart carries a rope winch that is used to change the length of the rope. A weight is fixed to another end of the thread. So the length of the thread influences the position of the weight. The lifting and descending of the weight as well as the movement of the cart is realised with two current DC motors enabling the proper positioning of the load (weight). So the DC voltages applied to these motors represent two inputs while the torques produced by both DC motors are proportional to the DC voltages. The outputs are given by three incremental encoders which measure the position of the cart, the length of the thread and the angle between the thread direction and vertical direction (φ). The thread itself together with the load is denoted as a pendulum system. The origin of the coordinate system is the cart in the very left position and the point in which the pendulum is handled to the cart. Figure 2 illustrates the described set-up with some dimensions.

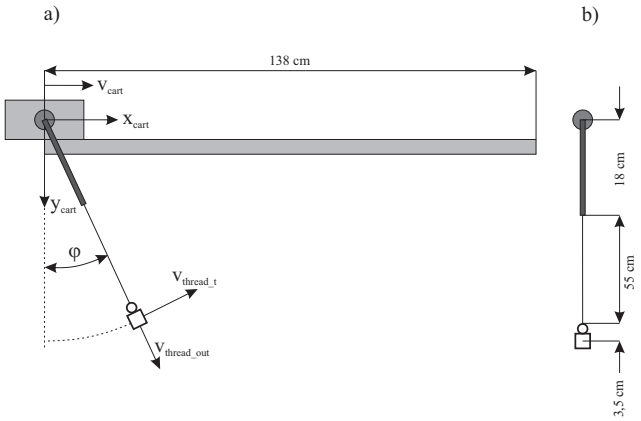

Figure 2. Part a: set-up Amira 600 working as the loading bridge. Part b: pendulum with appropriate dimensions.

Table 1. Physical parameters of the set-up.

Parameters	Values
Mass of the cart+winch	5,7 kg
Mass of the load (weight)	0,143 kg
Length of the guiding bar	1,38 m
Length of the pendulum stick	0,18 m
Distance between the centre of load gravity and the point where the load is fixed to the thread	0,035 m
Maximal length of the rope	0,55 m

Table 1 shows some important plant parameters, which were partly measured or obtained from the documentation (Amira, 2001).

3 Modelling with Modelica

The basic aim of this investigation was to show that Modelica is a convenient approach especially in the modelling of mechanical systems. We intended to use the Modelica standard library and to build an efficient model without usual mathematical modelling with equations. Of course we have to be aware that also a profound knowledge of the mathematical modelling using balance equations in modelling subjects is needed. Even very sophisticated libraries are usually not sufficient the introduction of some changes or developments of customized components in real applications is often needed.

The approach was to build the model with diagram layer (icon or graphical based modelling) and to establish some more efficient solutions using some improvements with textual model layer. Basically the components from two libraries (packages): `Mechanics` and `Blocks` were used.

3.1 Package of mechanical components `Mechanics`

The package `Mechanics` is a part of Standard Modelica library. The library consists of three sub libraries: `Multibody`, `Rotational`, `Translational`.

The library `MultiBody` is a free Modelica package providing 3-dimensional mechanical components to model in a convenient way mechanical systems, such as robots, mechanisms, vehicles. The components - the coordinate system of the world frame, the revolute joints and the rigid bodies have also animation properties.

The libraries `Translational` and `Rotational` are also free Modelica packages which enable modelling of traditional rotational and translational problems which are commonly needed especially in basic modelling courses. The basic components are mass, inertia, spring, damper etc.

It is convenient to model 3D mechanical systems with components from all three libraries, as there are property defined connectors which enable proper conections. As an example we can use two components from the sub library `Mechanics.MultiBody.Joints`, shown in Figure 3. Both components entitled `prismatic` and `revolute` are important in the loading bridge model.

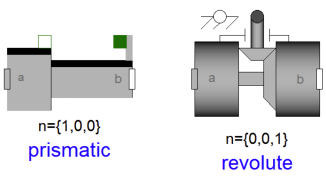

Figure 3. Two components from the sub library `Modelica.Mechanics.Joints`.

The prismatic joint has 1 translational degree-of-freedom. There are two regular connectors (frame `a` and

frame b) which enable to connect the components from the library Multibody. Optionally, two additional 1-dimensional mechanical connections can be driven with elements of the Translational library. This is especially convenient to connect a control force to the 3D mechanical system.

Revolute joint has 1 rotational degree-of-freedom where frame b rotates around axis n which is fixed in frame a. Optionally, two additional 1-dimensional mechanical connections can be driven with a component from Rotational library. This is often used to connect a control torque to 3D mechanical systems.

3.2 Package of causal components Blocks

The library Blocks contains input/output blocks to build up block diagrams. This is actually the implementation of a traditional modelling approach based in causal input/output interactions originating from analog simulation, supported later by a CSSL standard and finally implemented also in Simulink environment. The library is important for the implementation of model parts where the causality is needed, e.g. for the implementation of a control system where inputs and outputs have to be strictly defined.

With components from the library Blocks some new components were implemented and some existing were modified. These components were included into a new library AdditionalComponents, which is a part of the loading bridge model.

3.3 Structure and components of the overall model

Figure 4 shows the hierarchical structure of the loading bridge model. It is implemented with the package CraneModel on the highest hierarchical level. It consists of three sub-packages: AdditionalComponents is the library of components, developed or updated from the existing components from the Standard Modelica library. The second package PilotPlantAMIRA600 is intended to final Amira 600 models. Currently it contains only the model of the loading bridge. The third subpackage Controller is intended to implemented controllers.

3.4 Model of the loading bridge

Figure 5 depicts the top level model of the loading bridge, implemented with model class LoadingBridgeCrane. All components except CartDrive and ThreadDrive are taken from the standard Modelica library Mechanics and model the whole mechanical system with drives. The components CartDrive and ThreadDrive were placed to the library of new and appropriately modified components (AdditionalComponents).

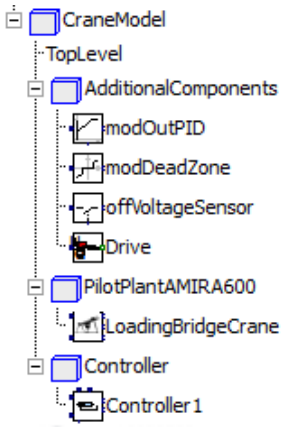

Figure 4. Hierarchical structure of the loading bridge model.

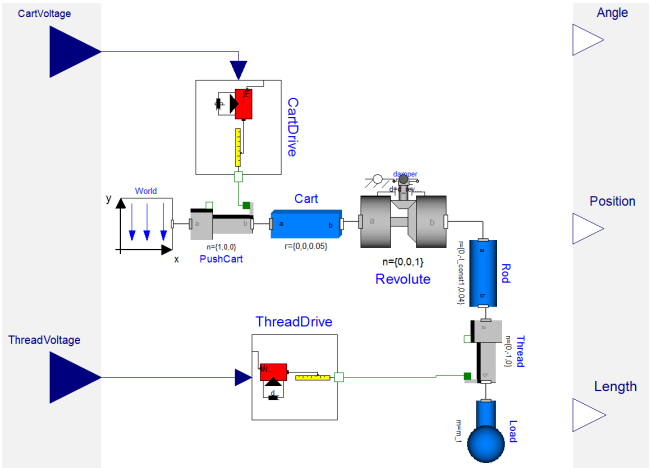

Figure 5. Model of the loading bridge in Dymola-Modelica.

3.4.1 World

Model class World is a part of the standard library Modelica.Mechanics.Multibody. It represents a global coordinate system and the gravity field.

3.4.2 Cart

The cart (model class Cart) is realised with BodyBox component from the Multibody library. The parameters are dimensions, mass, animation features etc. The cart is driven with PushCart element, which is the appropriate actuator for the movement of the cart. The information for the needed movement is calculated in the model class CartDrive.

3.4.3 Pendulum

On the connector b of the Cart the component Revolute is connected. This is a revolute joint which handles the pendulum. The pendulum is built according to the construction shown in Figure 2, b. It is a mathematical pendulum with the whole mass concentrated in a point at the end. The component Rod is a rod with no mass, with appropriate length and it handles the thread which is

realised with the class `Thread`. This prismatic actuator is the implementation of the winch. The movement of the the thread is therefore implemented in the same way as the movement of the cart. The component `ThreadDrive` is almost identical to the component `CartDrive`. So the length of the thread depends on the input DC voltage. The load of the crane is realised with the element `Load` with the whole mass concentrated in the center of gravity point. The distance between the mass point (center of gravity) and the point where the mass is connected to the thread is illustrated in Figure 2, b.

3.4.4 Drive

The model class `Drive` is used in two almost identical classes `CartDrive` and `ThreadDrive`. It transforms the input DC voltage signals into appropriate positions. It consists of causal blocks. The Modelica diagram is shown in Figure 6. This component includes many parameters,

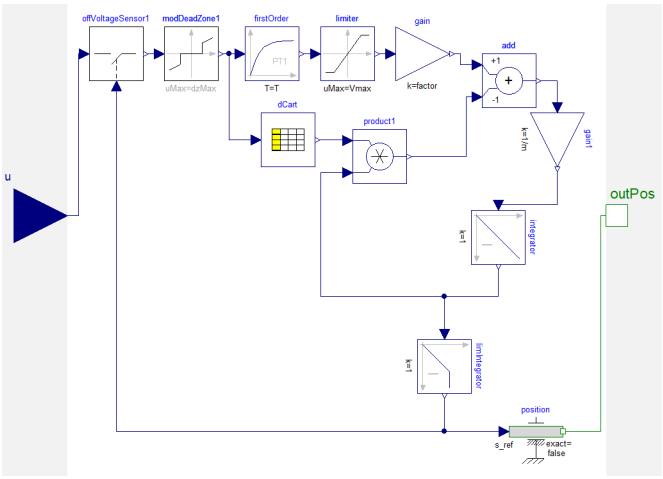

Figure 6. The diagram of model class `Drive` in the Dymola-Modelica environment.

which are needed for proper transformation. The information of the mass of the object and its initial position are also needed. The damping is also important. The experiments show that constant damping is not appropriate. Better results were achieved with the damping which depends on the input voltage. Experimentally obtained curves ware realised with look up tables.

The input to the model is a real variable, representing the DC voltage to the DC motor. This real variable feeds the model class `offVoltageSensor` which models proximity final position switches for limiting the final positions. The output of this class is connected to the input of the component `modDeadZone`, which is a modified standard block `deadZone` from the library `Modelica.Blocks.Nonlinear`. A deadzone in which the voltage is not sufficient for the movement is implemented with this model. The output of the block `modDeadZone` is connected to the lag system `firstOrder` with an appropriate time constant. With this time constant (delay) it was possible to tune the speed of the positioning of the cart and the length of the thread. At the beginning we tried to compensate a fast dynamics with the appropriate damping but it appeared that the appropriate delay, which has to be included, does not depend on the velocity. The output from the lag system goes to the limiter of the input voltage (`limiter`) and is finally in the block `gain` transformed into the appropriate force. The gains 5.17 for the cart and -0.35 for the thread were obtained experimentally. This gains actually represent very simplified models of DC motors. Additionally we improved the model by introducing a damping force. If a force F acts to a mass m, which movement is also damped (damping b), then the acceleration can be evaluated with the equation

$$F - bv = ma \tag{1}$$

where v denotes the velocity and a acceleration. However the model was improved with nonlinear damping where b depends on the DC voltage. The nonlinear function was realised with the look up table `dCart`. Finally the acceleration was obtained by dividing the left hand side of Eq. 1 with the mass m. With two integrations the velocity and the position are obtained (model classes `integrator` and `integrator1`). The calculated position was connected to the position component (`position`) which interacts the causal and acausal modelling parts and implements appropriate movement of the cart or thread.

It is clear that the described modelling is not what was intended at the beginning - to implement fully acausal model, because it introduces partly causal modelling and reduces the efficiency of Modelica language. However this was the most efficient solution of the problem appearing above all in conjunction with the pendulum. Namely we were not able to compensate gravitation and centrifugal forces of the pendulum in open loop experiments what resulted in uncontrolled and unstable movement of the thread. With the solution that the driving actuators obtain the information of the position instead of the force, the compensation forces are automatically generated inside actuators.

4 Controller in Matlab Simulink environment

Dymola-Modelica is an extremely powerful tool for true physical modelling. However for complex experimentations (e.g. optimisation, linearisation, steady state calculation, etc.), for results presentation, e.t.c. it is far from Matlab possibilities. So we decided to use Dymola-Modelica just for the 'physical' part and Matlab-Simulink for all other needs: Simulink for control systems description and Matlab with some Toolboxes for making experiments. We prepared a top level Modelica model which can be used as a Dymola (Modelica) block in the Matlab-Simulink environment. Actually the appropriate connectors which are compatible with other Simulink blocks had to be additionally prepared. Such the top level Modelica model is shown

in Figure 5. Two inputs (cart voltage, thread voltage) and three outputs (cart position, thread length and thread angle) were prepared. Then the Simulink environment to accept Dymola block was properly configured. This block had to be compiled within Simulink before the simulation is started. The control scheme in Simulink is depicted in Figure 7.

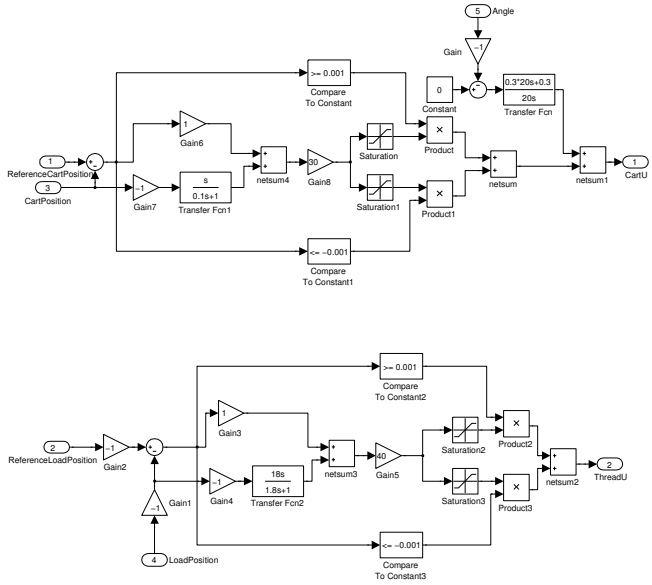

Figure 7. Control system in Simulink.

The upper part is the control scheme for cart positioning realised with PD and PI controllers

$$u_{cart}(t) = K_{Pc}\left(e_{cart}(t) + T_{Dc}\frac{de_{cart}(t)}{dt}\right) \qquad (2)$$

$$u_{angle}(t) = K_{Pa}\left(e_{angle}(t) + \frac{1}{T_{Ia}}\int e_{angle}(t)dt\right) \qquad (3)$$

where u_{cart} and u_{angle} are the appropriate control signals which influence the position of the cart in order to minimize errors between the cart reference position and actual position (e_{cart}) and thread reference and actual angle (e_{angle}). So this part of controller has 3 inputs: the reference value of the cart position (`ReferenceCartPosition`), the actual position (`CartPosition`) and the angle of the pendulum system (`Angle`). So the left part of the structure is described with Eq. 2. PD control was chosen as the process already has the integral behaviour. To realise the real behaviour the output of the PD controller was limited, so that the positive values can change at the interval $1,28V$ - $3V$ and negative values at $-1,8V$ and $-3V$. The behaviour of the model was improved by forcing the output of the controller to $0V$, when the position error was in the range of $\pm 0,001m$. At the right upper part of the scheme the PI control action (Eq.3) was superadded. Namely the influence to the cart position is the only possibility to influence the pendulum angle, which has the reference value 0°.

The lower part is the control scheme (Figure 7) handles the length of the thread. Here the PD controller was used

$$u_{thread}(t) = K_{Pth}\left(e_{thread}(t) + T_{Dth}\frac{de_{thread}(t)}{dt}\right) \qquad (4)$$

where u_{thread} is the appropriate control signal which influences the position of the length of the thread in order to minimize the error between the thread reference position and actual position (e_{thread}). Again the PD controller is used as the process itself has an integral character. The reference length of the thread is in Figure 7 signed with `ReferenceLoadPosition`), and the actual length with *CartPosition*. To match the real behaviour the output of the PD controller is limited, so that the positive values can change at the interval $3V$ - $5V$ and negative values at $-2,8V$ and $-5V$. The behaviour of the model was improved by forcing the output of the controller to $0V$, when the position error was in the range of $\pm 0,001m$.

The parameters of all three controllers are shown in Table 2.

Table 2. Controller parameters

K_{Pc}	T_{Dc}	K_{Pth}	T_{Dth}	K_{Pa}	T_{Ia}
30	1	40	18	0,3	20

Figure 8 depicts the overall Simulink scheme, where the control structure (Figure 7) was realised with a Simulink subsystem `Control system` and the physical part of the laboratory set-up with Modelica model `DymolaBlock`, which has to be compiled before simulation.

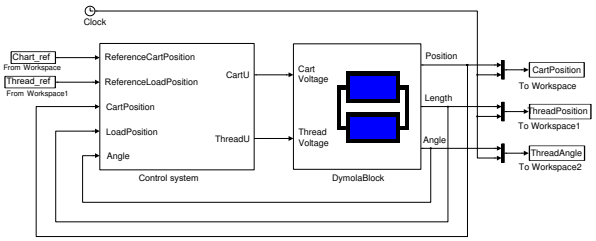

Figure 8. Overall scheme in Simulink with Modelica block.

5 Experiments

It is well known that the model validation is the most important part of each modelling procedure. It is based on comparisons between real measurements and simulation results. Many open loop and closed loop experiments were performed.

5.1 Open loop experiments

The basic validation was performed in open loop with the DC voltage inputs as shown in Figure 9. These inputs

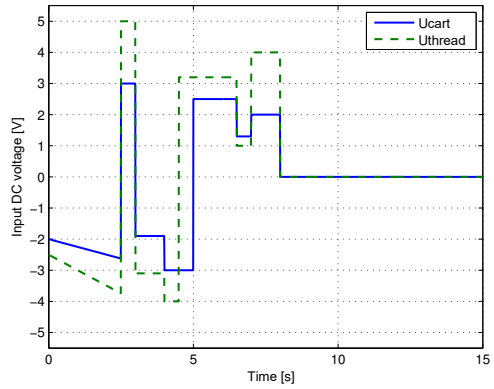

Figure 9. DC motor voltages for open loop experiments.

influenced the real loading bridge set-up and the model. According to several experiments some parameters were tuned and some procedures, which were already commented in the modelling section, were performed. The validation results presented in Figure 10 show that the model behaviour is satisfactory. It appropriately describes the movements of the cart and not so good the lowering and lifting of the weight. Especially it is difficult to tune the angle of the pendulum, where the basic frequency is properly modeled, however real measurements contain also higher frequency components.

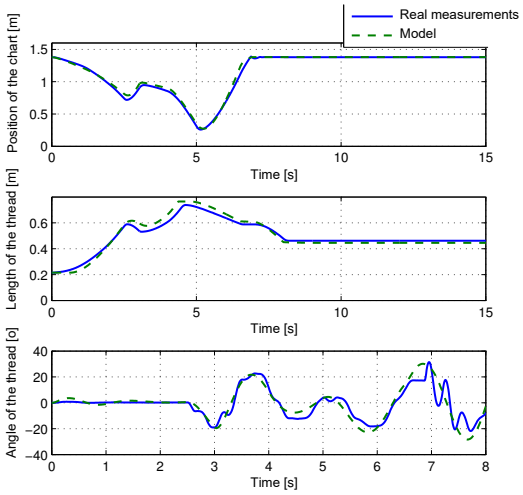

Figure 10. Open loop experiment: comparison of model outputs and corresponding real measurements.

5.2 Closed loop experiments

Figure 11 shows the position of the cart, the length of the thread and the angle of the thread in a closed loop experiment. The same reference signals were applied to the real set-up and the model and the control systems were of course identical. We can notice that the behaviour of the model is reasonable also in the closed loop. The largest deviations are again at the pendulum part, especially with its oscillations.

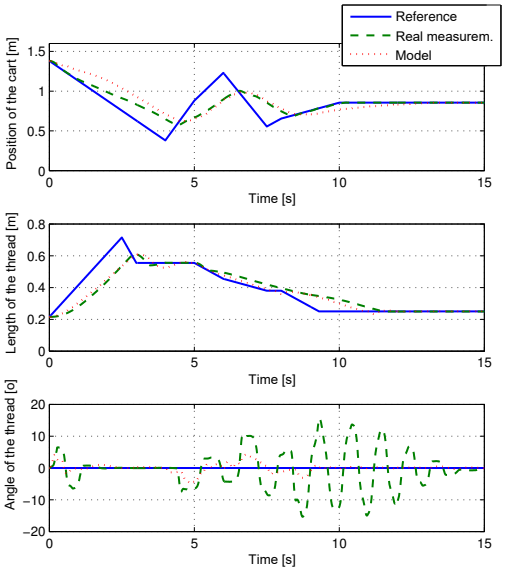

Figure 11. Closed loop experiment: reference signals, model outputs, real measurements.

As the basic goal of the control of the crane is that the load tracks the appropriate trajectory, we also present it in *xy* plane, where *x* and *y* are coordinates of the load. Figure 12 shows the reference trajectory, the trajectory of real measurements and the simulation trajectory.

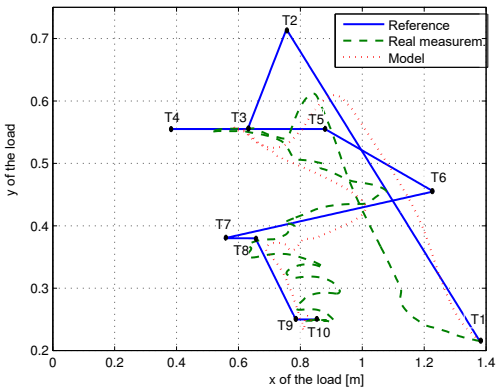

Figure 12. Presentation of trajectories in *xy* plane.

The reference trajectory is defined with points *T1* to *T10*. It has to be mentioned that controller parameters were not strictly optimised as the emphasise was given to the modelling part.

6 Conclusions

The laboratory set-up Loading bridge AMIRA 600 is a very efficient equipment for control education enabling interesting modelling and control courses. The models were previously mostly developed in Matlab-Simulink environment where all balance equations have to be precisely specified. In this investigation we tried to develop an us-

able model without equations, with OO approach using Modelica language and Standard Modelica libraries with mechanical components in Dymola environment. However some difficulties in modelling were later solved with causal approach, which was in Modelica implemented with the Block library showing that the combination of different approaches often gives better solutions. Anyway, such model much better preserves the physical modelling structure, what is important in the education but also in better understanding when model users are not modelling experts.

The experiments results confirm that the model reasonably describes the real system. The worst part of the model is the presentation of the pendulum angle where some higher frequencies also appear in real experiments. Additional efforts will be also devoted to the control system (optimisation of parameters, new control strategies, etc.).

Abstract

This paper introduces two different e-Learning environments. Both are used at the Vienna University of Technology to support the courses and exercises in mathematics. There are different level of courses. On the one hand there is a refresher course to support new students who might had some time off before starting their study as well as flatten different school levels of mathematics. On the other hand there are regular mathematical courses in the first two to three semester. Due to improved and advanced possibilities offered by the environment in the last years the system enables the integration of simulation examples. In 2006 the research group Mathematical Modelling and Simulation (MMS) developed an individual web-server to provide students with simulation examples. This server was used in the lectures as well as for practice at home. In the last year also a combination of Moodle and this web application was used to perform tests. This paper should give a short introduction in both systems and compare their advantages and disadvantages. In the outlook a new possibility is presented to combine the advantages of both presented systems.

Keywords: modelling and simulation, education, blended learning, case studies

1 Introduction

In 2004 the research group started to use online tools to improve the quality or at least the administration part of lectures. The first step was using a moodle based platform. The moodle installation was made by an group at the university and is still supervised by the same group. They are as well developing various additional plugins for the moodle based university website. The website is mainly used to organize lecture notes and additional materials. There is also another web application used for lectures dealing with modelling and simulation. This environment has been developed in 2006 and is called Mathematical, Modelling and Tools (MMT). In general it is a simple content management system but with the possibility to connect to simulation environments. This eLearning system is explained in Section 2. (Winkler et al., 2010)

Due to the fact that the research group Mathematical Modelling and Simulation (MMS) was one of the first users of the moodle based university platform, developed the MMT server and won an E-Learning award in 2007 the vice rector for academic affairs commissioned the research group to organize and administrate a refresher course using b-learning. This refresher course was initialised to help students starting their studies subsequently after school. The content of this course is a summary of mathematical knowledge students should have gained at school. The structure and the used eLearning system is explained in Section 2.

2 MMT - Mathematics, Modelling and Tools

2.1 Structure of MMT

The requirements for the website include the possibility to use modelling and simulation examples online. The students should be able to execute a certain simulation example and receive the generated output plot. Another feature is experimenting with these simulations in some kind. The realization enables students to change different parameters of the system and generate the new output to get an idea of the influence these parameters have.

In the last years there where several improvements in the environment. At the beginning the usage of simulation software was restriced to Matlab alone. The current examples show a wider field. There are examples running in Matlab, Simulink, Octave, Anylogic as well as Java. The expansion including Simulink lead to one problem. Compared to all other examples implementations in Simulink need two different m-files to work properly. In case of Matlab and Octave it is enough to simply execute one program file. The Analogic examples use so called Java Applets which represent the interface between Anylogic and webserver.(Körner et al., 2011) In Figure 1 and Figure 2 the structure of the MMT Server and the examples available is depicted. As you can see in Figure 1 on the left hand side all examples are assigned to different topics. In one topic there are more than one implementation. For example different cases of the pendulum model are available. All the pendulum examples are in the folder "'Pendulum"', as shown in Figure 1 marked with number 1. Therefore the theoretical and mathematical basics are explained on the first site of the main topic. The different model implementations explain only the current used method and the different parameters, as marked with num-

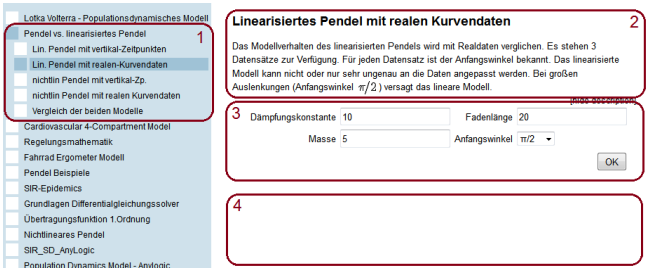

Figure 1. Structure of the MMT system.

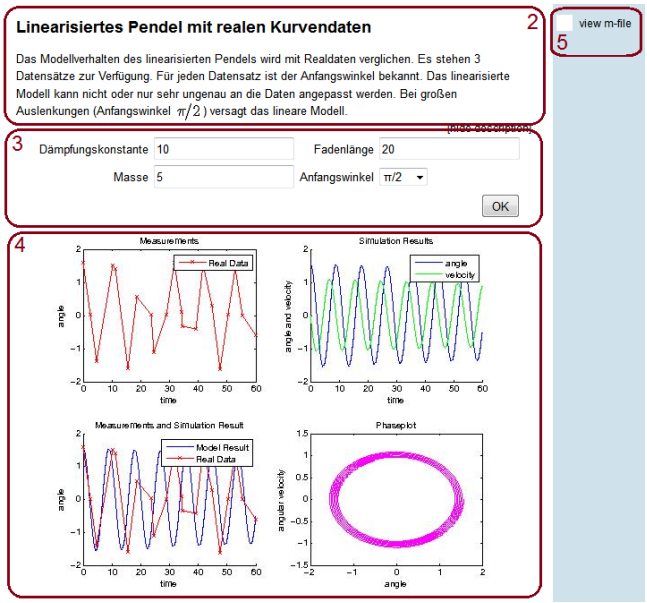

Figure 2. Structure of MMT examples.

ber 2 in Figure 1. In order to know which parameter influences the model output how the students have the possibility to change one or in most examples more than one parameter values. Section 3 shows the parameter area. After setting parameter the student has to summit the parameters by clicking *OK* which leads to the execution of the model. If the example is more complicated it might take some time but usual after some seconds the output plot appears as shown in Figure 1 and 2. Section 5 of Figure 2 offers a link to an m-file. In general this section enables lecturer to upload additional material for the different examples as well. For sure there will be the file containing the corresponding algorithm. It does not matter which simulation environment was used for the implementation. Students have the possibility to download the file and execute or adapt it on their own computer to see how such examples are structured and which commands are used to implement for example the pendulum. (Bicher et al., 2013)

2.2 Usage of MMT

At the moment there are nearly 700 examples stored on the web server. The examples cover various fields of application. Some of the topics are even implemented in different environments to show various realizations or even approaches simulating continuous and discrete models. The examples are used for different courses. The modelling and simulation courses are offered to students of electrical engineering, information technology, mechanical engineering as well as mathematicians. Due to the fact that the knowledge of these groups are not identically the courses are organized differently. Every course contains a certain selection of topics to satisfy the needs of students from different field of studies.

In most of the lectures it is also necessary to pass a test. Up to now these tests are implemented in Moodle. In general the test consists of theoretical and practical questions. The theoretical questions deal with different approaches or even mathematical basic questions. Regarding the practical part the experiments on the MMT server are slightly modified to allow such test questions. In some examples the students have to adapt the parameters of the model to gain certain information of the model behavior, e.g. the state point of a model. Then the results of the practical examples have to be inserted into the Moodle question. Due to the complex structure no randomization in the examples is possible.

3 Maple T.A. - Maple Testing and Assessment

In 2008 the research group was commissioned to initialize a refresher course. There were different requirements the course had to fulfill. The course should be held in the first two weeks of the semester and enables high participation. Additionally the course structure should provide some kind of E-learning support. Due to the fact that the topics of this course are just mathematical subjects the MMT server was not providing a suitable structure. A system called Maple T.A. was chosen.(Urbonaite and Winkler, 2013)

3.1 Structure MTA

Maple T.A. is an interface developed by Maplesoft. In 2008 the software was quite new. It provides an interface to create mathematical questions as well as theoretical questions. The main aspect of the system is the possibility to create practice and test assignments. Therefore it is not only a content management system where different questions are stored but an environment where students can exercise and improve their calculation skills. The administration of examples as well as users is quite easy. In order to create a new question one has to decide which type of question is required. There are different types available, e.g. Multiple Choice, Numeric, Algebraic, graphical questions and so on. For the algorithm the ordinary maple commands are available. The initialization of variables is different but despite of that a user of Maple won't have any problems creating a basic mathematical questions. To give an example a regular if-command in Maple looks like

if a>b then a else b end if .

If one uses Maple T.A. syntax to get the same result it can be written like

$$if(gt(a,b),a,b).$$

For using Maple T.A. to create examples, it is not necessary to know commands of Maple T.A. On the other hand it is helpful to know some of the short devices because they are develop to avoid constant use of the underlying maple kernel, leading to lower capacity requirements. In some cases it is better to use special commands of Maple T.A. Below a short code of a very easy example is given to show the difference to Maple.

$$\$a = range(1,5);$$
$$\$b = range(1,6);$$
$$\$c = range(1,3);$$
$$\$ans = maple(\text{"}if\ \$a > \$b\ and\ \$a > \$c\ then\ \$a\ elif\ \$b > \$a\ and\ \$b > \$c\ then\ \$b\ else\ \$c\ end\ if\text{"});$$

All the created questions can then be combined to assignments associated to a certain topic of the lecture. The assignments can be used during exercises as example resource and of course students can practice examples anytime at home. One advantage of the system is an easy administration of examples and course assignments. Another, even more important benefit, is the usage of a computer algebra system regarding grading of examples. The grading can be easily formalized in a mathematical algorithm ignoring equivalent transformations. On the other hand the question task can be randomized using different parameters in the formulation of even randomize functions, e.g. for calculating a derivative. The variety of the examples increases and students can practice the same assignment more often without repeating exactly the same examples.

3.2 Usage MTA

In the beginning the questions used in the refresher course were very simple. In 2010 the usage of the system was extended. Not only the refresher course but also the basic mathematical courses in the first and second semester were using the system were intense. The level and complexity of the questions increased. This lead to another problem. The grading algorithms had to be improved and get more complex as well. In order to support the acceptance of the system among students the grading provided the possibility to gain partial points if the result is partly right. Two different libraries were established to enable teachers to give partial points if a result is more complicated. On the oterhe hand the library also simplifies the process of creating examples. In Figure 3 an example using the partial grading is shown. This example also uses the second library containing commands to generate randomized matrices with defined properties. The libraries are as well used to guarantee a certain structure of the solution in order to assure similar levels despite randomized factors. The examples cover all topics of the mathematical

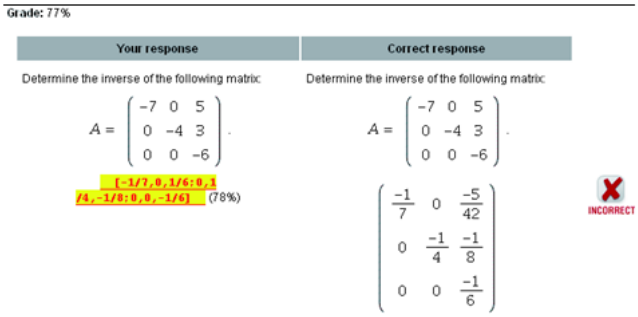

Figure 3. An example working with partial grading.

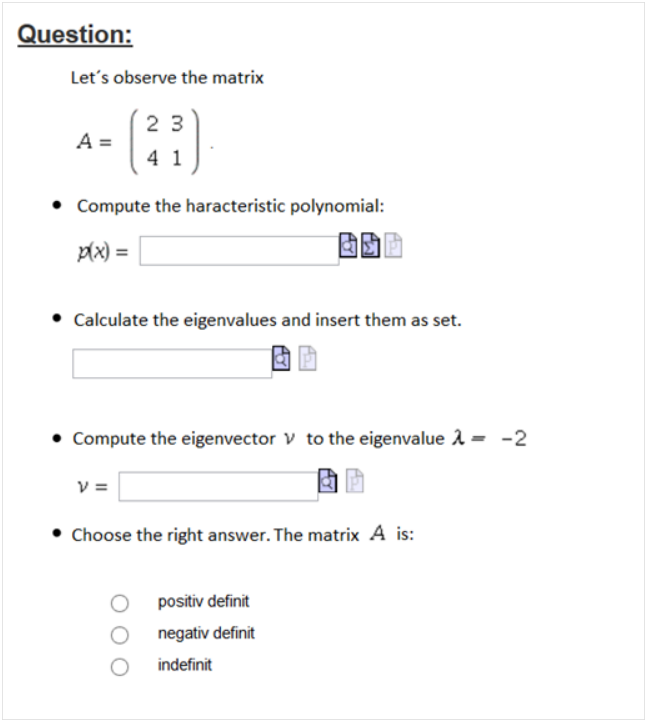

Figure 4. An example used in the written exam.

courses for students of electrical engineering. Examples dealing with Analysis in one and two dimensions, Linear Algebra as well as Vector Analysis and complex analysis are available. Figure 4 shows an example of the chapter Linear Algebra which is also using the libraries mentioned above. Since some years the system is also used to realize exams. Before then the system was used to support the exercises and perform midterm tests. Students have to pass 2 of the 4 provided tests each semester in order to pass the exercise part. For the lecture they have to pass a separate exam. Compared to the small tests during the semester, which only take 30 minutes, the exam lasts 2 hours. This exam is a written test and afterwards a short oral exam follows. Since 2012 the students can decide if they want to do the test as an ordinary written exam or on the computer system. Figure 4 shows a possible question for the exam. The examples are the same but in the online example the variables and functions are changing. Therefore it

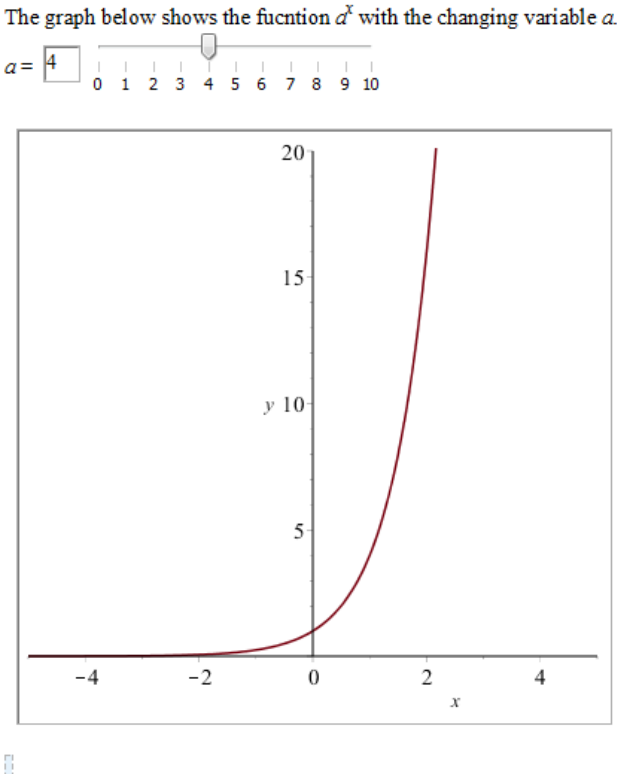

Figure 5. A simple mathapp question used to explain the basics of exponential functions.

is nearly unable to cheat at the examination.

3.3 Mathapps

Due to the fact that the system evolved over the past years there are new interesting features. As mentioned before the development of a test in the web sever MMT is not so easy. A disadvantage is the lack of flexibility regarding randomized test questions. As explained above Maple T.A. enables a wide range of possibilities to randomize parameters and functions of questions. So it would be very feasible to use Maple T.A. for the modelling and simulation courses.

In order to establish simulation examples in Maple T.A. an explanation of Mathapps is necessary. Since some years Maplesoft enables the creation of Mathapps. In general it is a certain form of Maple Worksheets. Before this invention lectures used as well Maple Worksheet to explain mathematical basics benefiting from the algebraic properties of Maple. Compared to an ordinary worksheet Mathapps additionally enable integration of sliders, figures and controllers to design an interactive area as shown in Figure 5. After that an exponential function with parameter a is given. After setting the parameter a using the slider, the graphic is loaded automatically. Such mathapps can be used to explain mathematical principles more easily using the figure of the problem. Regarding modelling and simulation this improvements enables the creation of example similar to MMT examples from above. Students have the possibility to change the parameter and after submitting the new parameter output and figure is actualized automatically.

The implementation using Mathapps can be divided into three different parts. On the one hand there is the so called Startup Code which is executed during loading the question and generates the output plot. In Section 2 it is described that in the beginning there is no output on the MMT server. Students can only see the text describing the example and the parameter area. After submitting the parameter the output appears. In Maple T.A. this can be done automatically. In order to create a efficient example the used algorithm in the Startup Code defines a procedure and therefore can be used again.

If the students submits the parameters using the button *start* the procedure defined in the Startup Code is used to update the output plot. The last part is the grading. There are two different options. On the one hand it is possible to write a grading procedure as well inside the Startup Code. This grading routine then can be used directly in Maple T.A. Another possibility is to formulate the algorithm in Maple T.A. itself. It does not matter which option is chosen. In both cases the current values of all sliders can be used to determine if the chosen input variables students chose are right or wrong.

3.4 MTA - Moodle Connector

In all mentioned cases there is a Moodle course where the lecture notes and materials are organized. A student who enrolls at Vienna University of Technology receives a unique registration number and a password for the university system for course administration. With this account the student can enter the course administration website as well as the moodle based E-Learning website. In previous times the student had to enter the number and password of the university to get an account for Maple T.A. So a student has to go through 3 different websites to get to Maple T.A. Since 2013 it is possible to integrate the Maple T.A. into the e-learning platform of the Vienna University of Technology. This connection is a data interface. If a student registers for the course on the e-learning platform from the university the student is able to get to the examples directly through a link on the course page as shown in Figure 6. There is no need for an additional account in Maple T.A. All results the students gain in the different courses are recorded in Maple T.A. and sent to moodle. This is very useful for administration because also the grade in the end of the semester is created in the moodle system. Therefore the test results can be involved in a formula to generate the over all grade.

4 Case Study

In Section 3.3 the basics of Mathapps created in Maple are explained. Using this tool it is possible to create examples similar to the examples in MMT as shown in Section 2. An implementation of a pendulum example in MMT is shown in Figure 7. Analog Figure 8 presents the realization of the same example inside Maple T.A. using a Mathapp.

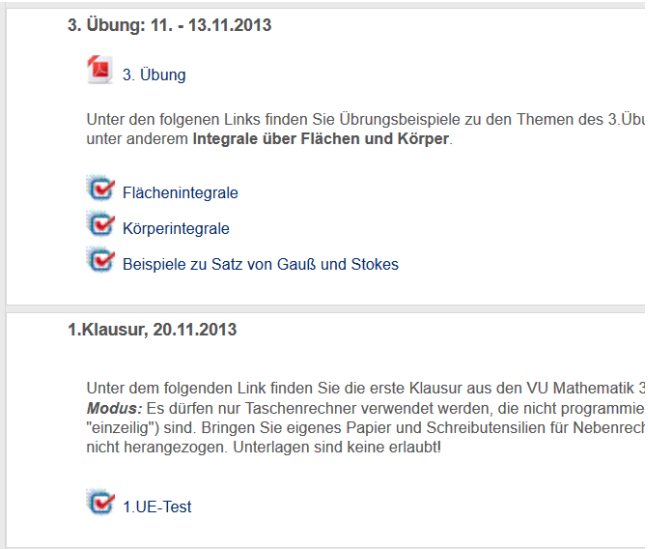

Figure 6. Usage of the moodle Connector to link Maple T.A. assignments.

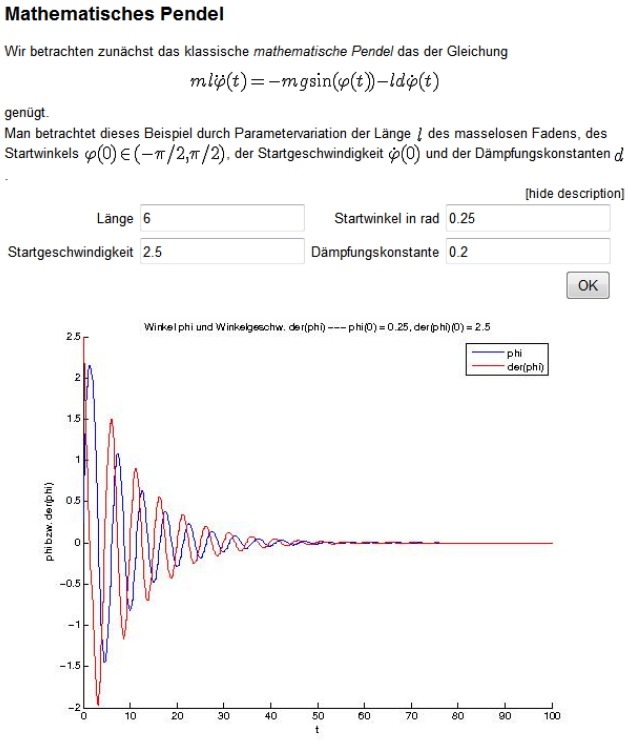

Figure 7. A pendulum example on MMT server.

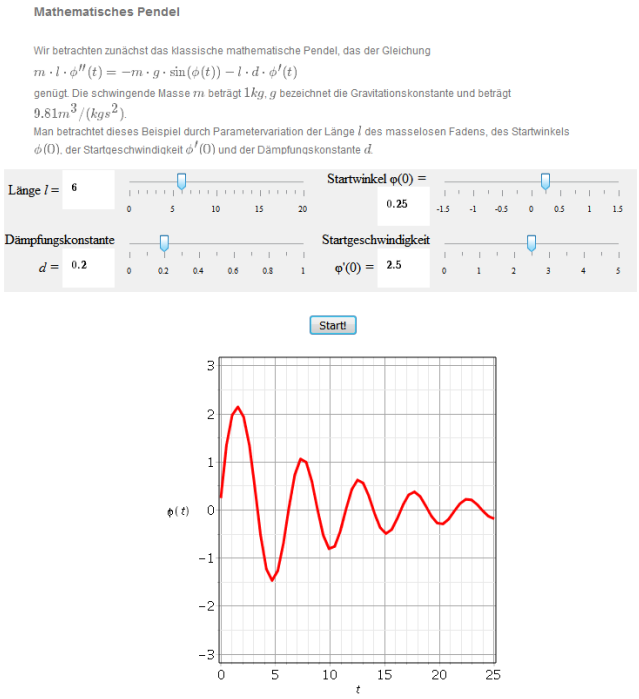

Figure 8. Implementation of a pendulum example in Maple T.A. with Mathapps.

The basic differential equation used to describe the behavior of a pendulum are simple. The implementation of this differential equations is easier done in Matlab or any other numerical environment. It is a greater challenge to implement the same behavior in Maple. In the last years also Maple made some improvements to enable the numerical calculations which are necessary for such Mathapps. Ignoring the fact that the implementation might be easier in Matlab the qualitative behavior of the model is recognizable in both realizations. Both environment allow a default setting by the model. The student can then start experimenting using the sliders to change the parameters or simply insert the parameter value. An advantage of the slider is a restriction of the parameter range. Also in MMT the range of all parameters is restricted but the student would get an error message that a certain parameter value is not possible and then change the parameter in order to execute the example again with a possible value. In case of the Mathapp this can not happen because the student can see the range of the slider. Comparing the two figures the output plot in Maple might be not used to its full potential. Further improvements are possible to enable an easy understanding.

The implementation might be easier using Matlab. The example in Maple T.A. might seem clearer for the students. The area where the parameters can be changed is neatly arranged in the Mathapp implementation. Even the symbols used for the parameter change, if it is a slider a controller or something completely different, can be adjusted to the meaning of the parameter and its variation.

As mentioned in Section 2 there is a test realized using

moodle and MMT in combination. Regarding the lack of randomization in this test as well as level of complexity of questions Mathapps offer more possibilities. One the one hand for grading Mathapps in Maple T.A. every command and library of Maple can be used. Therefore the possible issues which can be covered with the same modelling and simulation question are very variable and different from MMT. Another aspect is the very feasible administration of tests. The acronym T.A. stands for Testing and Assessment therefore the interface provides all setting such tests could need. On the MMT server it was necessary to create a separate question for the test. In Maple T.A. it is possible to use the same Mathapp for practicing and testing. But it is also possible to use the examples in the lecture to explain the basic ideas of the model and the influences of different parameters.

Up to now only some of the modelling and simulation examples are transferred to Maple T.A. Of course it is very easy to formulate all the theoretical qeustions in Maple T.A. For the simulation examples it takes some time to figure out how to implement differential equations efficient in Maple. It is not possible to use the algorithm used in Matlab because the general idea of the two software are completely different.

Despite all the new possibilities of Maple T.A. there are also disadvantages. It is not possible to transfer all the eamples to Maple T.A. because some of the examples are based on Anylogic, Simulink and Java. These Tools are not supported by Maple so we can not use these examples anymore.

5 Conclusions

The comparison of both environment shows that there is no such thing as the best choice. Both systems have their advantages and disadvantages. MMT enables examples using different software products combining them in one content management system. The output on the MMT system shows more detail and potential. But the problem might be that there are much more possibilities in Maple than used in Figure 8. The Mathapps and outputs should be implemented more carefully and then it might be possible to generate outputs as detailed as in Matlab. In Maple T.A. it is not possible to add additional materials. Instead it would be possible to but additional material into the moodle course.

Maple T.A. offers some nice features regarding testing. It is very easy to provide examples in a feasible way for testing and assessing students. Additionally the usage of the moodle Connector mentioned above enables students to connect to the system without even knowing that they changed the platform. At the MMT server every course has its own authorization code. In Maple T.A. practicing and testing is now personalized. The appearance of the examples using sliders and controllers improved. The main advantage of the system might be again the great variety using random variables and function. And as a consequence also the grading offers much more possibilities.

6 Outlook

The conclusion shows that even Maple T.A. which is developed for testing and assessment misses some features. Especially regarding using a combination of different tools. There is an additional environment developed by Maplesoft which could help to erase remaining problems regarding modelling and simulation examples. An aspect which would be nice to extend are teaching possibilities. For Testing Maple T.A. has very useable features. In order to enable more teaching aspects using Maple T.A. Maplesoft came up as well with a solution. The new software is call Möbius (Maplesoft, 2016) and combines teaching and testing aspects. It is a combination of content management system and Maple T.A. but in a more interactive way. It is possible to design something similar to a textbook site including Mathapps as well as Maple T.A. questions.

Imagine a text explaining perhaps the basics of exponential functions. Next an interactive action, e.g. Figure 5, is included. Then there are some examples with its solution step by step. Afterwards an example from Maple T.A. can be integrated. This example actualizes every time. Students can check if they understood the text in order to apply as well the method explained. If the first attempt was wrong there is the possibility to update the integrated examples using the randomized variables in Maple T.A. Using this system students can repeat the lecture in their own tempo and even try examples until the grading is correct.

Extracting Vibration Severity Time Histories from Epicyclic Gearboxes

Juhani Nissilä Esko Juuso

Control Engineering, Faculty of Technology, University of Oulu, Finland, P.O.Box 4300, FI-90014
{juhani.nissila,esko.juuso}@oulu.fi

Abstract

Monitoring epicyclic gearboxes in vital power transition situations is still a challenge. In this paper, we discuss these challenges with long time vibration measurements through two industrial examples. The first are the two gearboxes in the front axle of a load haul dumper (LHD) from Pyhäsalmi mine and the second a two stage gearbox from Kelukoski water power station (WPS). The LHD was monitored almost continuously for nearly two years until its breakdown. The data from WPS was intermittent from a five month period. We discuss how to find stable conditions for comparable measurements in these cases. For this we utilise a tacho signal from the cardan axle of the LHD and power measurements from the WPS. It is found that in both cases second derivatives of acceleration signals, called snap, respond more quickly to changes in vibration severity. In the LHD case we get clear trends for increasing norms of snap signals. The trends are extracted with nonparametric regression. The shorter measurement period of the WPS makes it impossible to say if its changes are only seasonal. Spectral analysis shows increase in high frequency vibration with time in both cases but provides almost no help for detailed diagnostics.

Keywords: epicyclic gearbox, spectral analysis, higher derivatives, MIT-indices, nonparametric regression

1 Introduction

Typical methods for vibration severity calculations are for example root mean square (rms) values of displacement, velocity or acceleration signals. These may reveal some faults in rotating machines, such as imbalance, but gear and rolling bearing faults often cause high frequency vibration which is more evident in higher derivatives of acceleration. The compact and complex structure of epicyclic gearboxes are no exception. We will present methods to extract vibration severity time histories from epicyclic gearboxes and discuss the difficulties that are encountered.

Signal processing methods are presented in Section 2. These are the Discrete Fourier Transform (DFT) and its inverse (IDFT) for spectral analysis, calculation of derivatives using these transforms, l_p-norms and *MIT*-indices for vibration severity calculations and Nadaraya-Watson nonparametric regression for estimation of *MIT*-trends and other relationships of two variables.

Vibration measurements from the LHD and WPS are described in Section 3 and we will also solve the total revolution times of the gearboxes with the help of some basic number theory. Calculations from vibration measurements are presented in Sections 4 and 5 respectively. Finally the obtained results are discussed in Section 6.

The method for obtaining vibration severity time histories presented in this study is as follows:

1. Find stable and comparable operating conditions of the machine or normalise these conditions computationally.

2. Find which values of norms and derivatives have changed the most during the measurement period and use these for *MIT*-indices.

3. Use Nadaraya-Watson regression to fill in the gaps in measurements. It also extracts the trends more clearly, since there typically still is some variance left in the calculations. Here the scaling parameter is chosen visually.

2 Signal processing

2.1 DFT and derivatives

The vibration measurements are stored as sampled sequences $\mathbf{x} = (x_0, \ldots, x_{N-1})$ of length $T = \Delta t \cdot N$, where Δt is the sampling interval. The spectrum of this sampled signal is calculated with the *Discrete Fourier transform* (DFT)

$$\mathscr{F}\{\mathbf{x}\}_k = X_k = \frac{1}{N}\sum_{n=0}^{N-1} x_n e^{-i2\pi kn/N}. \tag{1}$$

Its *inverse transform* (IDFT) is

$$\mathscr{F}^{-1}\{\mathbf{X}\}_n = x_n = \sum_{k=0}^{N-1} X_k e^{i2\pi kn/N}. \tag{2}$$

Here we have equated the inverse as x_n, because it returns the original signal at the sample points (Briggs and Henson, 1995). The DFT and IDFT pair can be used for differentiation and integration of signals. An algorithm for this consists of calculating the DFT coefficients X_k and

then forming a new sequence $\mathbf{G} = (G_0, \ldots, G_{N-1})$, with $G_0 = 0$ and

$$\begin{aligned} G_k &= \left(\frac{2\pi ki}{T}\right)^z X_k, \qquad 0 < k < N/2 \\ G_{N+k} &= \left(\frac{2\pi ki}{T}\right)^z X_{N+k}, \quad -N/2 < k < 0 \\ G_{N/2} &= \left(\frac{\pi N}{T}\right)^z \cos\left(z\frac{\pi}{2}\right) X_{N/2} \quad \text{(if } N \text{ is even)}, \end{aligned} \tag{3}$$

where z is the order of derivative (or integral when negative). Finally we get the vector $\mathbf{x}^{(z)}$ with the IDFT

$$x_n^{(z)} = \mathscr{F}^{-1}\{\mathbf{G}\}_n. \tag{4}$$

The only problematic part in deriving this algorithm is the term $G_{N/2}$ for even N, which the author has presented in (Nissilä et al, 2014). The algorithm also works with any complex z, in which case we use the principal values of $\left(\frac{2\pi ki}{T}\right)^z$ and $\left(\frac{\pi N}{T}\right)^z$. It then calculates an approximation of the Fourier or Weyl *fractional derivatives and integrals*. This operation is also sometimes called *differintegration*.

The DFT assumes the sequence periodic and thus it is practical to window the signal by multiplying it with a suitable window function to attenuate any discontinuities at the end points of the sequence. We use the window function which was introduced in (Lahdelma and Kotila, 2005)

$$w(t) = \begin{cases} 0, & \text{if } t \le 0 \\ \frac{1}{A}\int_0^t e^{\left(y(y-T/\varepsilon)\right)^{-1}}\,\mathrm{d}y, & \text{if } 0 < t < T/\varepsilon \\ 1, & \text{if } T/\varepsilon \le t \le T/2 \\ w(T-t), & \text{if } t > T/2. \end{cases} \tag{5}$$

Here $A = \int_0^{T/\varepsilon} e^{\left(y(y-T/\varepsilon)\right)^{-1}}\,\mathrm{d}y$ and ε is the portion of T for ascent and descent. Window function w is infinitely differentiable and, therefore, it preserves the continuity properties of the original signal. We use the trapezoidal rule to approximate the integrals in the definition of w.

2.2 l_p-norms and MIT-indices

The *generalised* l_p-norm or *Hölder mean* of vector $\mathbf{x}^{(z)}$ is

$$\left\|\mathbf{x}^{(z)}\right\|_{p,\frac{1}{N}} = \left(\frac{1}{N}\sum_{n=0}^{N-1}\left|x_n^{(z)}\right|^p\right)^{1/p}, \tag{6}$$

for $p \ge 1$. This is the traditional l_p-norm with equal weights $1/N$. The generalisation to cases $-\infty \le p \le \infty$ is done in (Bullen, 2003) with the limiting values

$$\left\|\mathbf{x}^{(z)}\right\|_{p,\frac{1}{N}} = \begin{cases} \left(\sum_{n=0}^{N-1}\frac{1}{N}\left|x_n^{(z)}\right|^p\right)^{1/p} & \text{if } p \in \mathbb{R}\backslash\{0\} \\ \left(\prod_{n=0}^{N-1}\left|x_n^{(z)}\right|\right)^{1/N} & \text{if } p = 0 \\ \max_{n=0,\ldots,N-1}\left|x_n^{(z)}\right| & \text{if } p = \infty \\ \min_{n=0,\ldots,N-1}\left|x_n^{(z)}\right| & \text{if } p = -\infty. \end{cases} \tag{7}$$

The Hölder mean includes many traditional features, such as *minimum value* $p = -\infty$, *harmonic mean* $p = -1$, *geometric mean* $p = 0$, *arithmetic mean* $p = 1$, *root mean square* (rms) $p = 2$ and *maximum value* $p = \infty$.

The dimensionless *MIT-index* for vibration severity evaluation was first presented in (Lahdelma, 1992) and it utilised the rms values of integer order derivatives and integrals. It has been generalised to real order differintegrals (Lahdelma and Juuso, 2011) as

$${}^{\tau}MIT^{p_1,p_2,\ldots,p_M}_{\alpha_1,\alpha_2,\ldots,\alpha_M} = \frac{1}{M}\sum_{m=1}^{M} b_{\alpha_m}\frac{\left\|\mathbf{x}^{(\alpha_m)}\right\|_{p_m,\frac{1}{N}}}{\left\|\mathbf{x}^{(\alpha_m)}_{\mathrm{ref}}\right\|_{p_m,\frac{1}{N}}}, \tag{8}$$

where $\alpha_m, p_m \in \mathbb{R}$, $\sum_{m=1}^{M} b_{\alpha_m} = 1$, τ is the length of the signal and $\mathbf{x}_{\mathrm{ref}}$ is a reference signal from the machine in good condition or low stress. Typically *MIT* increases together with decreasing machine condition. The *MIT*-index can also compare stress levels of different operating conditions.

2.3 Nadaraya-Watson nonparametric regression

Nonparametric regression of two variables using a kernel function was proposed in 1964 independently by Nadaraya and Watson (Nadaraya, 1964; Watson, 1964). Suppose that we have measured values $\boldsymbol{x}$ at the points $\boldsymbol{t}$. Then the estimated value x at t is

$$x(t) = \frac{\sum_{n=0}^{N-1} K_h(t-t_n)x_n}{\sum_{n=0}^{N-1} K_h(t-t_n)}, \tag{9}$$

where K_h is some non-negative and even kernel function for which $\int_{-\infty}^{\infty} K(t)\,\mathrm{d}t = 1$ and h is a scaling parameter so that the scaled kernel is

$$K_h(t) = \frac{1}{h}K\left(\frac{t}{h}\right). \tag{10}$$

Smaller h gives an estimate which follows individual measurements more closely whereas bigger h gives a smoother and more slowly changing function. The kernel in all the regression calculations in this study is a Gaussian (normal distribution)

$$K(t) = \frac{1}{\sqrt{2\pi}}e^{-\frac{t^2}{2}}. \tag{11}$$

3 Measurements and gearbox properties

3.1 Load haul dumper front axle

The measurement setup consisted of four SKF CMPT 2310 accelerometers which were mounted externally onto the LHD's front axle housing and a tachometer on the drive shaft. Accelerometers were located near the planetary gearboxes on either side of the axle and were positioned horizontally and vertically. Measurements were

recorded with a National Instruments CompactRIO 9024 data logger into a solid-state drive (SSD) as binary files of one minute length. Sampling frequency is 12800 Hz, and a built-in antialising filter guarantees that there are no aliases at frequencies that are less than $0.45 \cdot 12800$ Hz $= 5760$ Hz. More information on the measurements can be found from (Laukka et al, 2016).

The measurement points are called right vertical (RV), left vertical (LV), right horizontal (RH) and left horizontal (LH). During the first month of the measurements, the accelerometer cables of LV and LH broke down and were replaced. Two SSDs also broke down almost simultaneously after six months of service, which stopped the whole measurement for a month and a half. A third accelerometer at RH broke down during this stoppage and was replaced. Finally six months before the end of measurements, the accelerometer at RH was broken and after that also the accelerometer at RV. There was only one spare accelerometer left which was installed to LV and the accelerometer at RH was moved to RV (since at this point it was clear that the vertical measurements were more sensitive to the deteriorating condition of the axle.)

At the beginning, measurements were always recorded when the LHD was operating. After the stoppage caused by the broken SSDs the program was modified to record only two hours of data after the LHD starts up.

The cardan axle transfers the power first to a differential in the front axle which has a driving pinion with 9 teeth and a crown wheel with 46 teeth (spiral bewel gears). Based only on some pictures, the actual differential operation is carried out with straight bevel gears that probably have 20 teeth. These do not affect the output ratio if the LHD is not turning. Shafts in the front axle then rotate the sun gears in the epicyclic gearboxes on either side. The epicyclic gearboxes consist of a stationary ring gear (104 teeth), three planetary gears (39 teeth) and a sun gear (19 teeth). These are simple spur gears. Unfortunately, we have not yet received enough detailed information about the bearings in the system other than that they are of tapered roller type. The planet carrier provides the output to the front wheel. This is an example of an epicyclic gearbox in the planetary configuration and driven in reduction mode. Assuming then that the rotational frequency of the drive shaft is $\nu_{driveDIF} = 13.5$ Hz, we get the differential gear mesh frequency

$$\nu_{meshDIF} = 9 \cdot \nu_{driveDIF} = 121,5 \text{ Hz}.$$

If the LHD is not turning, the differential provides the same rotational frequencies to both sides of the axle and the frequencies of the epicyclic gears are (Vicuña, 2010; Immonen et al, 2012) (negative sign means opposite direction)

$$\nu_{sunLHD} = \frac{9}{46}\nu_{driveDIF} \approx 2,64 \text{ Hz},$$

$$\nu_{carrierLHD} = \frac{19}{19+104}\nu_{sunLHD} = \frac{19}{123}\nu_{sunLHD} \approx 0.408 \text{ Hz},$$

$$\nu_{planetsLHD} = -\frac{104-39}{39}\nu_{carrierLHD} = -\frac{5}{3}\nu_{carrierLHD} = -\frac{95}{369}\nu_{sunLHD} \approx -0.680 \text{ Hz},$$

and the planetary gear mesh frequency

$$\nu_{meshLHD} = 104 \cdot \nu_{carrierLHD} \approx 42.43 \text{ Hz}.$$

Gear tooth numbers are typically *relative primes*, i.e. their *greatest common divisor* is 1. This means that it takes a long time for a gearbox to mesh through all of its tooth pairs. To calculate this time for a full revolution of meshes, we seek whole number solutions for the number of revolutions N_{sunLHD}, $N_{carrierLHD}$ and $N_{planetsLHD}$. This leads to *congruence equations*

$$19 \cdot N_{sunLHD} = 0 \mod 123,$$

$$95 \cdot N_{sunLHD} = 0 \mod 369.$$

The solution method can be found in any basic number theory book (Strayer, 1994), and they can also be solved with symbolic mathematical software (such as Mathematica) and even solvers for web browsers exist. The solutions of N_{sunLHD} are $123m$ and $369m$ respectively for all $m \in \mathbb{Z}$. The smallest combined solution is the *least common multiple* of 123 and 369, which is $\text{lcm}(123,369) = 369$. Thus after 369 revolutions of the sun gear, every tooth has returned to their original position and this takes $369 \cdot 1/\nu_{sunLHD} \approx 139.70$ seconds. For most situations this means far too long a signal to analyse (if we can even find that long signals with relatively constant speed). So in practise, we analyse signals whose lengths are at least the revolution times of all the individual components.

3.2 Water power station gearboxes

The water power station at Kelukoski has a two stage epicyclic gearbox. The first (slower) is called gearbox 1 and the second (faster) will be called gearbox 2. Both were monitored with one WBS CM301 sensor (acceleration data was recorded) with sampling frequency 5000 Hz. Every 15 minutes a signal of length 7 s was recorded from both measurement points as WAV files. There were four continuous periods of data collection.

Since the WPS is connected to the Finnish power grid, its output frequency is kept at 12,5 Hz to a high precision (the frequency of the power grid is four times this, i.e. 50 Hz) Thus we can calculate the characteristic frequencies backwards starting from the output of the faster gearbox. Gearbox 2 is in the star configuration, meaning that it has a stationary planet carrier with six planet gears (25 teeth). Output is provided via the sun gear (36 teeth), $\nu_{sunWPS2} = 12,5$ Hz, and input from the gearbox 1 via the

ring gear (86 teeth). The gear teeth are double helical and the gearboxes have plain bearings. The formulas for the frequencies of these components are particularly easy in the star configuration (Vicuña, 2010)

$$\nu_{ringWPS2} = -\frac{36}{86}\nu_{sunWPS2} \approx -5.23\,\text{Hz},$$

$$\nu_{planetsWPS2} = \frac{86}{25}\nu_{ringWPS2} = -18.00\,\text{Hz},$$

and the mesh frequency $\nu_{meshWPS2} = 36 \cdot \nu_{sunWPS2} = 450.00\,\text{Hz}$. The full revolution time calculation leads to congruence equations

$$86 \cdot N_{ringWPS2} = 0 \mod 36,$$

$$86 \cdot N_{ringWPS2} = 0 \mod 25,$$

whose solutions are $18m$ and $25m$ respectively for all $m \in \mathbb{Z}$. The smallest combined solution is $\text{lcm}(18,25) = 450$ and thus 450 revolutions of the ring gear takes $450 \cdot 1/\nu_{ringWPS2} = 86.00$ seconds.

Gearbox 1 is in planetary configuration, but in contrast to the planetary gearboxes in the LHD, it is driven in the other direction (to increase the rotational speed) and the sun gear (31 teeth, output) has more teeth than the planetary gears (25 teeth). The stationary ring gear has 81 teeth. We have $\nu_{sunWPS1} = \nu_{ringWPS2}$ (this middle part of the two gearboxes is a floating installation) and the other frequencies are

$$\nu_{carrierWPS1} = \frac{31}{31+81}\nu_{sunWPS1} = \frac{31}{112}\nu_{sunWPS1} \approx -1.45\,\text{Hz},$$

$$\nu_{planetsWPS1} = -\frac{81-25}{25}\nu_{carrierWPS1} = -\frac{56}{25}\nu_{carrierWPS1} \approx 3.24\,\text{Hz},$$

and finally the mesh frequency

$$\nu_{meshWPS1} = 81 * |\nu_{carrierWPS1}| \approx 117.31\,\text{Hz}.$$

Again, to calculate the time for a full revolution we get

$$112 \cdot N_{carrierWPS1} = 0 \mod 31,$$

$$56 \cdot N_{carrierWPS1} = 0 \mod 25,$$

whose solutions are $31m$ and $25m$ respectively for all $m \in \mathbb{Z}$ and $\text{lcm}(31,25) = 775$. This takes $775 \cdot 1/\nu_{carrierWPS1} \approx 535.11$ seconds.

Before the previous breakdown of gearbox 1 several years ago, it had a slightly different set of gears with 35 teeth in the sun gear, 27 in the planetary gears and 91 in the ring gear. These give the same ratio for the output of the gearbox, but the frequency of the planetary gears was 3.45 Hz and most importantly the mesh frequency was 131.80 Hz. Unfortunately, these older tooth numbers were still thought to be valid for quite some time after the breakdown probably due to some problems with communication. Obviously the lack of such mesh frequency and the the appearance of the actual mesh frequency 117.31 Hz in the spectra was a puzzle in the analysis of vibration measurements from this gearbox. These erroneous calculations and hardly satisfying explanations of their results ended up into some publications (Immonen et al, 2012; Nikula et al, 2015). It seems that the new gearbox is an improved design, since with these older gear tooth numbers we get full revolution of the gearbox in only 135 revolutions of the carrier (which happens due to one of the congruence equations having solutions which repeat very often), which is just 93.21 seconds, considerable less than the 535.11 s of the new gearbox.

4 Calculations from the LHD measurements

For calculations signals were selected from the beginning of most measurement days, when the rotational frequency of the drive shaft was approximately 13.5 Hz. At first this was done manually but after a while with the help of an algorithm which searched for signals with constant enough tacho pulse separations to indicate the desired speed. All of these were still visually checked to select the signals for calculations. Only signals from the beginning of the workday or right after the LHD had been in its weekly maintenance were selected, because then we knew that its bucket was empty and thus the load on the axle was consistent. One could also use the tachometer signal for order tracking the signal, i.e. interpolating the signal to exact revolutions of the cardan axle. This would probably reduce variance in the calculations and make spectral analysis more exact, but because the tacho pulse was recorded badly at times, it would not have been simple to implement. From each signal a 4 s sample was multiplied with the window function (5) using $\varepsilon = 10$ and this new signal was differintegrated with the algorithm (4). Band-pass filtering was performed with an ideal filter at cut-off frequencies 3 Hz and 5000 Hz. From each end of the signal 20% was rejected and the remaining 2.4 second signal (approximately the time it takes for the carrier to rotate once) was used in the calculation of generalised l_p-norms. All the calculations were performed with Matlab.

Figure 1 shows the trend of values ${}^{2.4}\boldsymbol{MIT}_4^2$ from the point RV and a fitted regression estimate with $h = 20$. In (Nissilä et al, 2014) it was already demonstrated that the relative increase of norms of snap signals were bigger than norms of acceleration signals and that the order of norm had very little effect. The fitted regression curve is almost an increasing function with smooth steps. This could mean several different faults or faults which worsen with time.

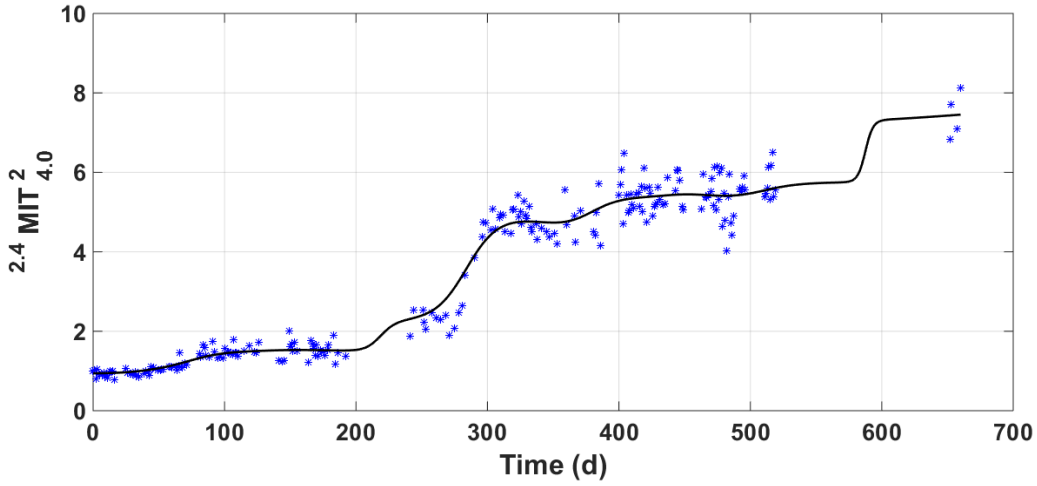

Figure 1. Trend of ${}^{2.4}\boldsymbol{MIT}_4^2$ from the point RV in the frequency range 3 - 5000 Hz and regression estimate with $h = 20$

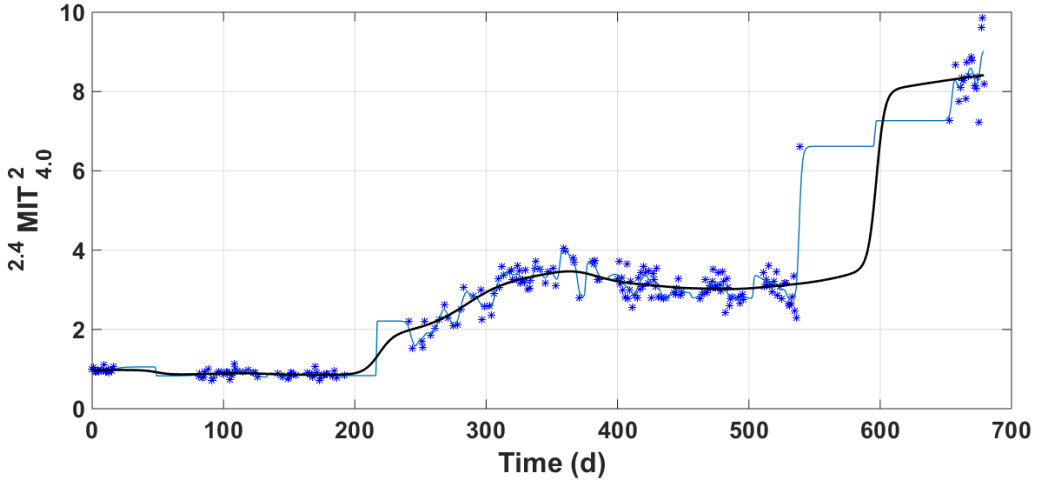

Figure 2. Trend of ${}^{2.4}\boldsymbol{MIT}_4^2$ from the point LV in the frequency range 3 - 5000 Hz and regression estimates with $h = 20$ (black) and $h = 2$ (blue)

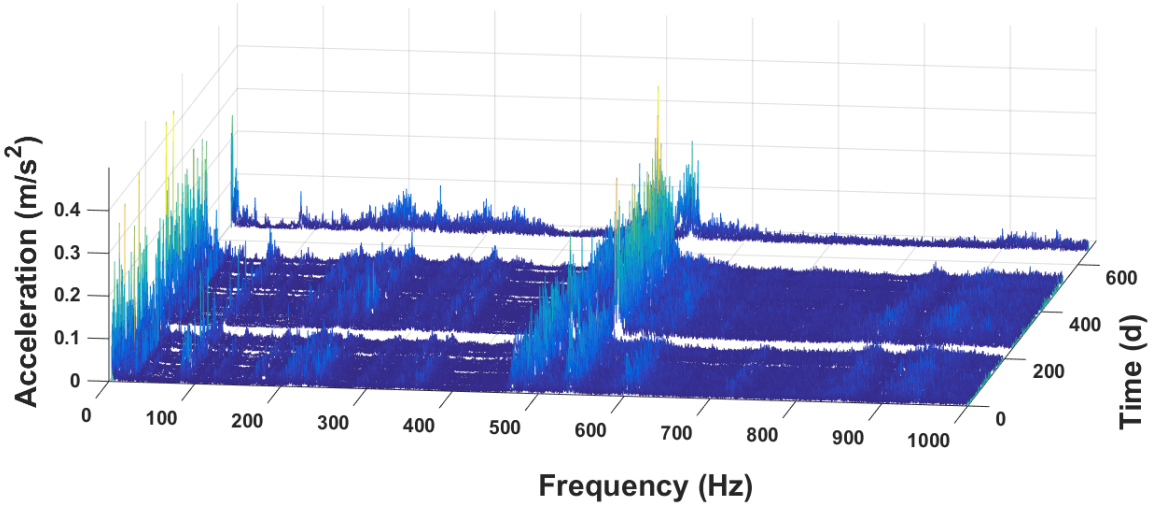

Figure 3. Waterfall plot of the spectra from the point RV in the frequency range 3 - 1000 Hz

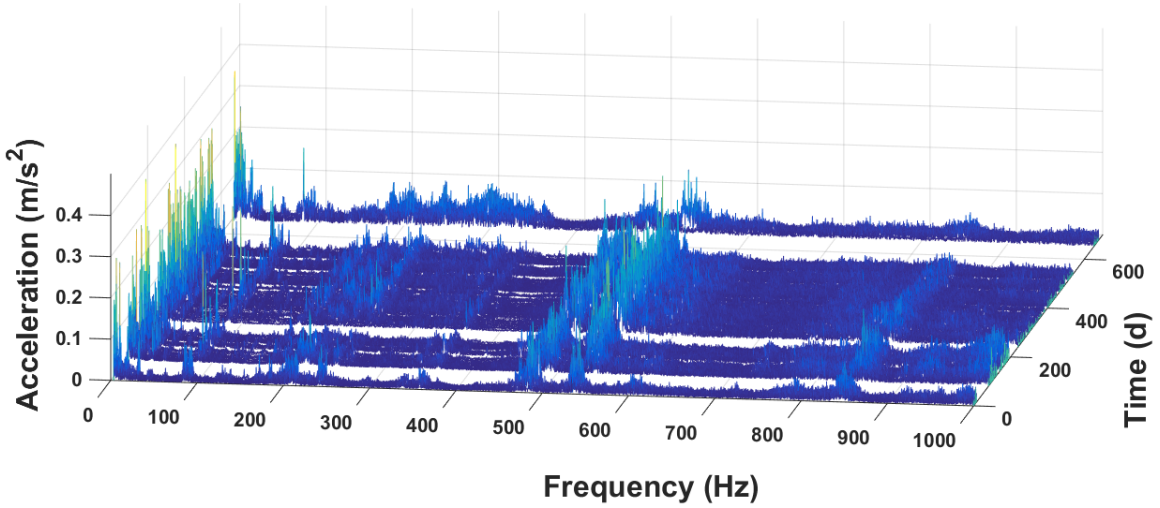

Figure 4. Waterfall plot of the spectra from the point LV in the frequency range 3 - 1000 Hz

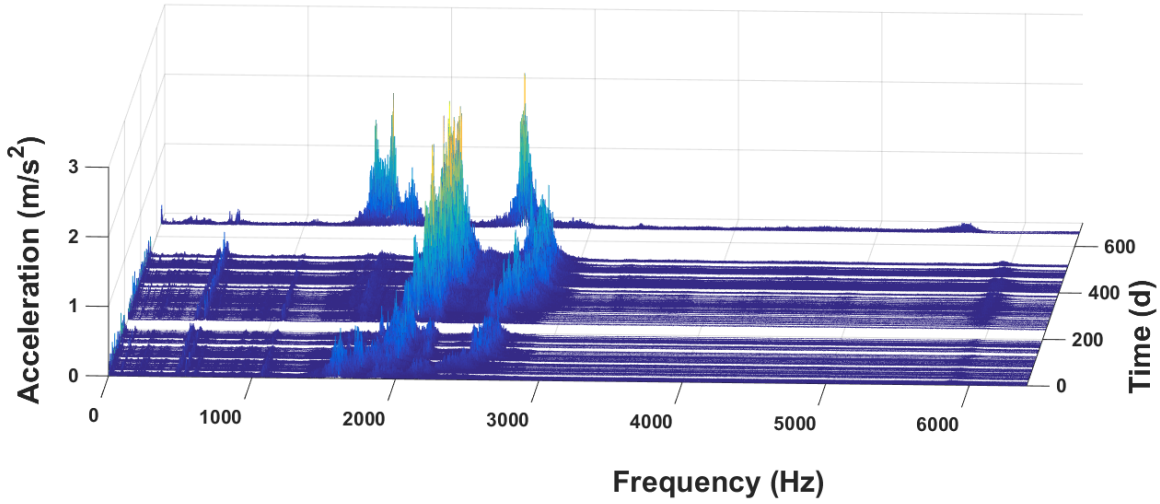

Figure 5. Waterfall plot of the spectra from the point RV in the frequency range 3 - 6400 Hz

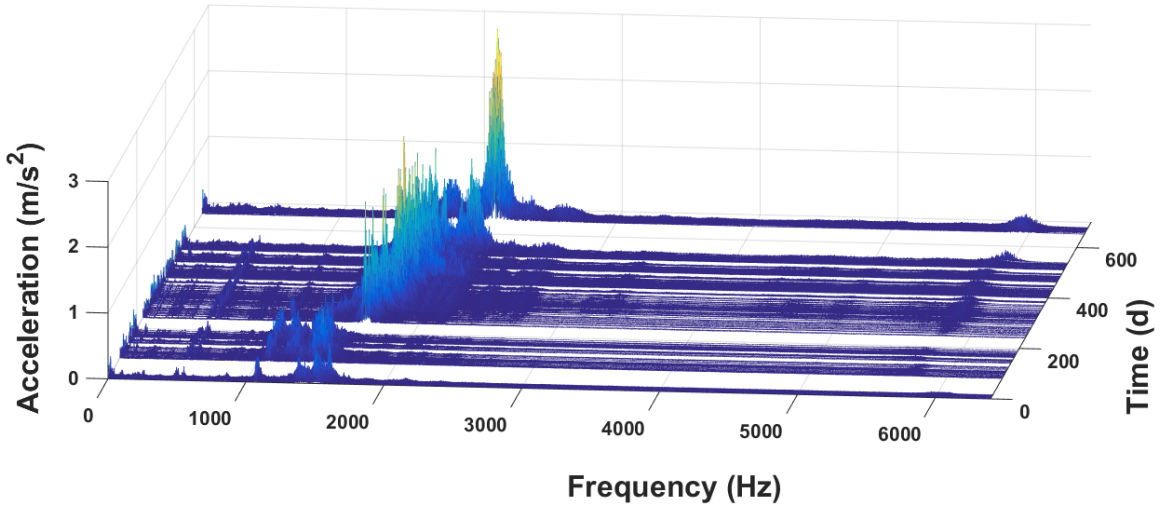

Figure 6. Waterfall plot of the spectra from the point LV in the frequency range 3 - 6400 Hz

Figure 2 shows the trend of values ${}^{2.4}\boldsymbol{MIT}_4^2$ from the point LV and fitted regression estimates with $h = 20$ and $h = 2$. After 350 days the trend starts to decrease but then makes a huge increase during the last gap in the measurements (or just before it, since there is one measurement before the gap for which ${}^{2.4}\boldsymbol{MIT}_4^2$ is almost 7). The trend estimate with $h = 2$ is shown here because it manages to estimate this last big change before the gap based on that one measurement.

Fig. 3, 4, 5 and 6 show waterfall plots of the spectra which were used in the calculation of the snap signals for the trends in the previous figures. In the frequency range 3 - 1000 Hz hardly any changes occur during the measurement period. This is interesting, since this frequency range contains the mesh frequencies (42.4 Hz and 121.5 Hz), their multiples and other gear related vibrations. In the higher frequencies we see huge increase in vibration amplitude around 2000 Hz and also a drift towards higher frequencies. These spikes are probably structural resonances and one can actually see with more in depth analysis that they are mostly very high order multiples of the cardan axle frequency 13.5 Hz. There is also increase in the 6000 Hz region with time. At the very end of the measurement period these high frequency resonances drop to smaller frequencies at the point RV (Fig. 5).

Some information on the damage in the axle after its breakdown was delivered to the university. It seems that the planetary gears had only minor wear on their surfaces. The ring gear of the differential had several pieces broken off from its teeth (probably explains the increase in the high multiples of the cardan frequency). There was also a lot of wear around the shafts in the axle and at least one cracked inner ring of a bearing.

5 Calculations from the WPS measurements

An overview of these measurements is provided in Fig. 7 where we have calculated the rms values from all of the vibration measurements together with the power data. It is clear that the WPS is operated very differently at different times. In the middle of summer the WPS is shut down during nights. The power output and vibration power seem to correlate so much that it is useful to investigate their relation in more detail.

Fig. 8 shows that the relation between acceleration rms and WPS power output is almost linear in gearbox 1. A good regression fit is achieved with parameter $h = 0.2$. Similar linear relationships between certain vibration frequency components and WPS power output were found in a previous study from the same WPS (Nikula et al, 2015). There is a tiny flatter part around 5 MW. This flat part is more defined in the similar visualisation from gearbox 2 in Fig. 9. It seems that the higher speed gearbox 2 (which also has much bigger vibration values than gearbox 1) also exhibits more nonlinearity in WPS power vs vibration power. These figures could be used to normalise vibration measurements taken during different power levels of WPS in its condition monitoring. One must be careful with such methods though, since for example if the measurements from low power situations are amplified, we will also decrease the signal to noise ratio in those cases when compared to those signals which are not amplified. In what follows we will consider only measurements from the power band 7.9 - 8.1 MW, since then we don't need such normalisation and the four continuous measurement periods all contain measurements from this power band.

From each signal from the power band 7.9 - 8.1 MW we took a 6.5536 second sample (to get 6.5536 s * 5000 Hz = 32768 samples, a power of two) and multiplied it with the window function (5) using $\varepsilon = 10$ and this new signal was differintegrated with the algorithm (4). High-pass filtering was performed with an ideal filter at cut-off frequency 3 Hz. Because the sampling frequency was relatively low, no low-pass filtering was done. From each end of the signal 20% was rejected and the remaining 3.9 second signal was used in the calculation of generalised l_p-norms.

Fig. 10 shows the trend of values ${}^{3.9}\boldsymbol{MIT}_2^8$ from gearbox 1 and a fitted regression estimate with $h = 20$. We see a 10 % increase in the last measurement period. Here and in the following trends we have a used a higher order norm just to show their effectiveness. In these calculations the norms with $p = 8$ showed a slightly more clear increase when compared to $p = 2$, but as we see in Fig. 11, the order of derivative plays a bigger role since the increase of ${}^{3.9}\boldsymbol{MIT}_4^8$ is 20 % and there is no downturn in July as there is in Fig. 10. The trend regression estimates with $h = 20$ and $h = 10$ only differ between the last two measurement periods as the smaller h shows a more rapid increase.

Same trends are calculated from the measurements from gearbox 2 and plotted in Fig. 12 and 13. Both show a 15 % increase during the measurement period, but the changes in the norm ${}^{3.9}\boldsymbol{MIT}_2^8$ are more irregular. This is especially clear in the trend regression estimate with $h = 10$ in Fig. 12. The bigger h ignores these local changes and reveals the long term trend more clearly. Even so, again the snap signals are more consistent as both trend regression estimates in Fig. 13 reveal the increasing trend better than the calculations from the acceleration signals.

Waterfall plot from gearbox 1 (Fig. 14) has increased at the very end of the measurement period at 1350, 1800 and 2250 Hz, which are multiples of $\nu_{meshWPS2}$. They also have sidebands 18 Hz apart, which is $\nu_{planetsWPS2}$. The gearbox 1 mesh frequency 117.3 Hz is also visible and it has sidebands 1.45 Hz apart (not visible in this zoom level of the figure), which is $\nu_{carrierWPS1}$. These do not change noticeably in the measurement period.

Waterfall plot from gearbox 2 (Fig. 15) shows hardly any change at all with time. It is a mystery why the increase at the frequencies 1800 and 2250 Hz are not visible here.

6 Conclusion

The long measurement period and the final breakdown of the front axle of the LHD makes it quite clear that vibration severity calculations could serve as indicator's of its condition. Snap signals are especially sensitive for deteriorating condition of the axle. Most of the critical faults occurred in the differential gearbox, which might explain why the spectral analysis only shows noticeable increase in the multiples of the cardan frequency.

Unfortunately the data from the WPS was intermittent and lasted only for one summer period, so we can not say for certain how big are for example its typical seasonal changes in vibration severity. An increasing trend was observed from both gearboxes especially when *MIT*-indices were calculated from snap signals. An increase in the multiples of the gearbox 2 mesh frequency was also observed, but interestingly from the gearbox 1 vibration measurements.

Acknowledgement

The LHD measurements were part of the "Development of production integrated condition-based maintenance model for mining industry (DEVICO)" project. The measurements at the WPS were part of the "Integrated condition-based control and maintenance (ICBCOM)" project. The first author wishes to thank Tauno Tönning foundation for their support on his doctoral studies.

Abstract

The development of steel products with various characteristics increases the need for timely and preventive maintenance and condition monitoring of the production machinery. For instance, the roller levelers at modern steel factories are exposed to a high variation of forces due to the large range of steels leveled. In this study, the vibration measured from a steel leveler used for cold steel strips is analyzed with the goal to identify the effects different operational conditions have. Features such as generalized norms, generalized norm sums and the crest factor are computed from the vibration signals. The effects of the steel strip properties and the operational parameters of the machine on these features are then analyzed. The obtained information can be utilized in the models that are used as planning tools for the preventive maintenance of the steel leveler.

Keywords: feature extraction, roller leveling, signal processing, vibration

1 Introduction

The machines and devices in the modern steel industry are exposed to a high variation of load. This is a common characteristic especially at the factories which produce special steels. The special steel strips have properties such as exceptionally high yield strength. Major stresses are therefore inflicted on the processing equipment such as roller levelers during the production. This increases the risks of damage. The major forces make the roller leveler behave in an undesirable manner which makes, e.g., the mechanical load limiters break and the work rollers slip. Other common detriments encountered in the steel levelers include bearing damage in the rollers and the breakage and abrasion of the work rollers. These factors may consequently weaken the quality of the final steel product or cause a notable production loss due to the maintenance time. Therefore, the real-time monitoring of machine condition and the prediction of the effects of a specific steel product on the leveler are important subjects of research.

In this paper, the effects of the operating conditions during the steel leveling are studied from the vibration signal measured from the bodywork of a steel leveler. The studied roller leveler is used for strips of cold steel in a sheet line. The sheets are cut from the strip next to the leveler using a flying shear. The cutting causes impacts which are conducted to the leveler and the measured signal. Figure 1 depicts two examples of the measured signal during the processing of steel strips in the steel leveler. Figure 1 indicates that the effects of the steel strip properties and the operational parameters of the leveler are divergent in these cases. Differences between the leveling events can be commonly seen in the general signal level, in the impact magnitude of the sheet cutting and in the duration of the leveling events.

The identification of changes in the behavior of the monitored system can be done by using features (Lahdelma and Juuso, 2011). In this study, derivatives are first calculated in order to magnify the effects appearing in the signal. This is done according to the definitions by (Lahdelma, 1997) for real order derivatives. The actual vibration features are then extracted from the signal using the generalized norms introduced by (Lahdelma and Juuso, 2008). These norms are also used as the basis for other features such as generalized norm sums and the crest factor.

The signal derivatives and generalized norms have been previously used to demonstrate that different steel grades inflict different stress levels on a steel leveler (Karioja *et al*, 2015). Features based on the generalized norms have been proposed also as stress indicators for the same application (Nikula *et al*, 2017). In contrast to these studies, this paper addresses the effects of the operational parameters of the machine on the measured vibration. The effects of the steel strip properties on the general signal level and on the relative peak magnitude are studied as well. The correlations of the signal features with the machine parameters and steel strip properties are studied using Pearson's correlation coefficient. This information is useful for the development of data-driven models that are used in the preventive maintenance of the roller levelers.

2 Materials and Methods

2.1 Steel Leveler

The purpose of roller leveling is the elimination of various shape defects in the material. Steel coils contain flatness defects caused by uneven stresses and defects resulting from thickness variation across the product width (Smith, 1997). The stress patterns create

transverse and longitudinal curvature. Center and edge waves are caused by difference in the length of sheet between the center and the edges (Park and Hwang, 2002). Roller leveling is done by subjecting the strip to multiple back and forth bending sequences with decreasing roll penetrations as illustrated in Figure 2. The principle of roller leveling is based on controlling the plastic deformation through the thickness of the material. The plastic deformation determines the resultant flatness and memory and it also affects the required force. The roll force is a function of material thickness, width, yield strength, roll spacing and the extent of plastic deformation (Smith, 1997). A proper combination of the operational parameters is therefore needed for the required leveling result.

A schematic representation of a roller leveler is shown in Figure 2. The leveler under investigation is a four-high leveling machine used for strips of cold steel in a sheet line. The sheet cutting is performed simultaneously with the leveling without a need to stop the strip in the leveler due to the cutting. The cutting causes impacts that are conducted to the leveler and emerge as peaks in the monitored vibration signal which is also demonstrated in the lower graph in Figure 1.

2.2 Steel Leveler Parameters

The studied operational parameters of the leveler are presented in Table 1. The leveling of one complete steel strip is considered here as a leveling event. Exact time stamps for the operational parameters were unavailable and therefore the medians of each parameter represent the whole leveling event. The median represents the general level of an operational parameter during the leveling event. To precisely identify the instantaneous effect of an operational parameter on the vibration signal, the exact synchronization of time stamps is required.

The studied steel strip properties include yield strength, strip length, strip weight, strip width and strip thickness. The properties of the studied steel strips varied extensively. The range of the yield strength was approximately 200–1600 MPa; the length range was 68–1161 m; the thickness range was 1.98–15.21 mm; and the number of cut sheets was 4–465. The vibration signals from the leveling of altogether 739 steel strips were analyzed. The most common steel grade from 53 steel grades was a cold formable steel grade with yield strength around 400 MPa. This steel grade was leveled 123 times.

2.3 Vibration Measurements

The measurements were done at the SSAB rolling mill in Raahe, Finland. The accelerometer was stud-mounted in the middle of the runway on the bodywork supporting the lower supporting rolls. The acceleration was measured horizontally in the cross direction relative to the direction of the roller track. The used accelerometer was SKF CMSS 787A-M8, which has the frequency response from 0.7 Hz to 10 kHz with ±3 dB deviation. The measurement hardware included NI 9234 data acquisition card and NI CompactRIO for the data recording. The sampling rate was 25.6 kHz and the only filter used in hardware level was the built-in antialiasing filter of the data acquisition card. The measurement system was calibrated after the completion of measurements using a hand-held calibrator.

drawing force caused by entry pinch roller	*P*9	kN

2.4 Signal Processing

The signals were processed using computational methods which are integration, derivation and filtering. The processing was done in the frequency domain by manipulating the sequence of complex numbers resulting from fast Fourier transform (FFT). Lahdelma (Lahdelma, 1997) defined real order derivative $x^{(\alpha)}$ of the function $x(t) = Xe^{i\omega t}$ in the form

$$x^{(\alpha)} = \omega^{\alpha} X e^{i\left(\omega t + \alpha\frac{\pi}{2}\right)}, \quad (1)$$

where α is the order of derivative, ω is angular frequency, X is amplitude, e is the Napierian number, i is the imaginary unit and t is the time variable. The derivative with respect to time can be calculated by multiplying every term X_k of the FFT by $(i\omega_k)^{\alpha}$ and then using the inverse of FFT. The integrals can be calculated similarly by using negative values of α. Furthermore, the value is not limited to integers but any real or complex number can be used (Lahdelma, 1997; Lahdelma and Kotila, 2005). Signals are filtered by multiplying the unwanted frequency components by zero.

In this study, the order of derivation was $\alpha = \{1, 2, 3, 4\}$. The variable $x^{(2)}$ corresponds to acceleration and x stands for displacement. The velocity signal ($\alpha = 1$) was filtered so that it included the frequencies 2–1000 Hz. The other signals were filtered only by the antialiasing filter embedded in the data acquisition card. The calculation of derivatives was done only for the leveling events that took less than 60 minutes. The events with longer duration were removed. Otherwise, the pre-processing was done according to the procedure presented in (Nikula *et al*, 2017). Five per cent of data was removed from the start and the end of each event to remove the effect of windowing in signal processing.

2.5 Vibration Features

The generalized norm is defined by

$$\left\|X^{(\alpha)}\right\|_p = \left[\frac{1}{N}\sum_{i=1}^{N}\left|x_i^{(\alpha)}\right|^p\right]^{\frac{1}{p}}. \quad (2)$$

This feature is known as the l_p norm of signal $x^{(\alpha)}$ where p is the order of the norm, α is the order of derivation and N is the number of signal values. The l_p norm has the same form as the generalized mean which is also known as the Hölder mean or power mean (Bullen, 2003). The root mean square and the peak value are special cases of the norm (2) when $p = 2$ and $p = \infty$, respectively. The large order of the norm magnifies the effect of the peaks, whereas the small order of the norm diminishes them.

The rms (l_2) was used to study the effect of the machine parameters and strip properties on the general signal level in this study. The crest factor (C) is the ratio between the absolute peak value (l_∞) and rms (l_2). The crest factor was used to study the relative magnitude of the impacts seen in the signal. These two features were computed from the segments, which had the duration of ten seconds. The mean of segments from the complete event was then used in the analysis of the effects.

The sums of $l_{0.1}$, l_2, l_4, l_{10}, and $l_1 + l_{10}$ were used to study the effects of the operational parameters of the machine only. A study concerning the correlations between the steel strip properties and the generalized norm sums is presented in (Nikula *et al*, 2017). The generalized norms were calculated using one-second samples in this case. Each sum was divided by the mean of the corresponding sums from the events, during which the most common steel grade was processed. Therefore, the value 1 corresponds to the mean of the most common steel grade in each sum. This operation was done in order to make the summation of l_1 and l_{10} practical.

2.6 Pearson's Correlation Coefficient

The correlation coefficient, R_{xy}, is defined by

$$R_{xy} = \frac{\sum_{i=1}^{n}(x_i-\bar{x})(y_i-\bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i-\bar{x})^2\sum_{i=1}^{n}(y_i-\bar{y})^2}}, \quad (3)$$

where x_i and y_i are two different variables; $\bar{x}$ and $\bar{y}$ are their corresponding sample means; and n is the total number of observations. R_{xy} close to ±1 indicates strong linear correlation whereas R_{xy} close to 0 indicates weak linear correlation between the variables.

3 Results and Discussion

3.1 Correlations of Operational Conditions

Table 2 shows the correlation coefficients between the operational parameters of the machine and the steel strip properties based on the 739 events studied. The yield strength had a rather strong negative correlation with the gap values ($P1$, $P3$, $P5$, and $P7$), a strong negative correlation with the plastic deformation ($P4$) and a strong positive correlation with the drawing force caused by the machine ($P8$). The strip length had rather similar relationships with these operational parameters. The negative correlations with gap values were even stronger, but the correlations with the plastic deformation and the drawing force caused by the machine were slightly weaker. The correlations of strip weight and width with the operational parameters were generally weaker. The strong correlation of the strip width with the drawing force caused by the entry pinch roller ($P9$) is an exception. The correlations of the strip thickness were the opposite to the correlations of the yield strength or the length with the same operational parameters. This means that the thickness has a strong positive correlation with the gap values and the plastic deformation but quite strong negative correlation with the drawing force caused by the machine.

Table 2 roughly illustrates how the properties of the steel strips influence the operation of the roller leveler. In practice, the operational parameters are set based on the steel properties and then manipulated during the

leveling by the operator in the steelworks. Moreover, the strong correlations in Table 2 indicate that the medians of the operational parameters represent the operation sufficiently for the analysis purpose.

3.2 Correlations of Steel Strip Properties with Vibration Features

Table 3 shows the correlation coefficients of rms and crest factor with the steel strip properties. The rms calculated from the acceleration signal $x^{(2)}$ correlated the strongest with the yield strength, whereas the other steel strip properties had weak correlation. The rms values from the higher order derivatives of the signal indicated similar behavior. In the case of the velocity signal $x^{(1)}$, the correlation with the yield strength was slightly lower. The results indicate that the general signal level correlates the strongest with the yield strength considering the studied steel strip properties.

Figure 3 shows the rms of the $x^{(2)}$ signal together with two steel strip properties that had the strongest correlation. This 3D scatter plot illustrates that the strips with high yield strength are relatively thin. The thickness seems to have a positive correlation with rms if the yield strength is fixed although the general correlation is negative as shown in Table 3.

The crest factor had negative correlation with the strip length and positive correlation with the thickness according to Table 3. This result indicates that a thick steel strip results in relatively large impacts appearing in the signal. These impacts are mostly resulting from the sheet cutting using the flying shear. The weight and the width of the strip had low correlations in general. The effect of the yield strength varied based on the order of derivation. When the strip is thick, the yield strength and the strip length are relatively low, which explains the negative correlations of these two variables with the crest factor. When the velocity signal was used, the effect of weak impacts reduced on the crest factor. On the other hand, the strong impacts clearly stood out. This effect is shown in Figure 4. When the other signal derivatives were used, also the weaker impacts were magnified. This behavior is illustrated in the lower part of Figure 4. The level of the crest factor was lower in the case of $x^{(1)}$ signal compared with the higher order derivatives of the signal.

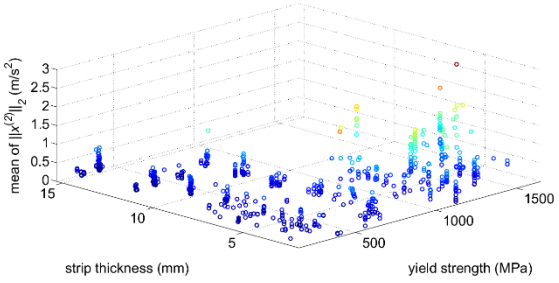

Figure 3. The effect of yield strength and thickness on the rms calculated from the acceleration signals.

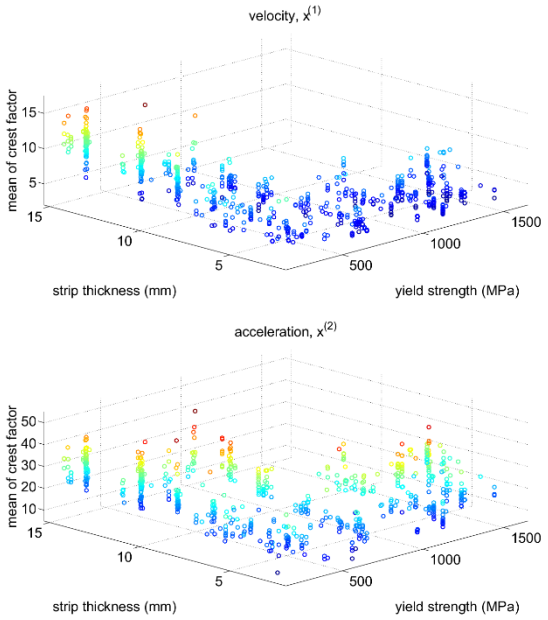

Figure 4. The effect of yield strength and thickness on the crest factor using $x^{(1)}$ and $x^{(2)}$ signals.

3.3 Correlations of Operational Parameters with Vibration Features

Table 4 shows the correlation coefficients of rms and crest factor with the operational parameters of the machine. The correlations of rms are shown using only $x^{(1)}$ and $x^{(2)}$ signals. The rms of $x^{(3)}$ and $x^{(4)}$ signals had almost the same correlations as the rms of $x^{(2)}$ signal. In general, the linear correlations between the operational parameters and rms were rather low. The drawing force caused by the leveler ($P8$) had the strongest correlation. As shown in Table 2, this parameter also had a strong correlation with the yield strength, which has a large influence on the rms level as shown in the previous Section.

The crest factor had a strong positive correlation with the roller gap values and the degree of plastic deformation when calculated from the $x^{(1)}$ signal. These correlations were weaker using the higher order derivatives of the signal. The drawing force caused by the roller leveler ($P8$) had a stronger negative correlation with the crest factor of $x^{(1)}$ signal compared with the crest factor of the other signals. The correlations between the yield strength and the crest factor of different signal derivatives indicated a similar behavior which is shown in Table 3.

Table 5 shows the correlations between the operational parameters of the machine and the generalized norm sums calculated from the $x^{(2)}$ signal. The generalized norm sums correlated the strongest with the drawing force caused by the roller leveler. The gap values and the degree of plastic deformation had substantially strong negative correlations. The results indicate that the correlations were the highest when the order of the norm was the lowest in these cases. In most cases, the second highest correlation was observed with the norm combination l_1+l_{10}.

The effects of operational parameters $P1$, $P4$, $P5$, and $P8$ on $l_{0.1}$ sum are depicted in Figure 5. According to the presented gap values, a thick steel strip causes a low accumulation of norm values. When the gap is reduced, the norm sums increase and an increasing variation in the sums is observed. This effect is seen in the graphs illustrating the effects of gap values and the degree of plastic deformation. The norm sums seem to increase together with the drawing force caused by the roller leveler. When the operational parameters are considered fixed, the variation in the norm sums can be explained by the effects of other variables. After all, the effects seen in the vibration are the result of the behavior of a multivariate system.

3.4 Discussion

The effects of the operational parameters of the steel leveler on the vibration signals were demonstrated in this study. Moreover, the results indicated that the operational parameters have strong correlations with the different steel strip properties. This implies that the characteristics of the vibration could be predicted with an approximate precision before the leveling is done based solely on the steel strip properties.

The results indicated that the steel strips with high yield strength inflict relatively high vibration level, which is seen in the rms values. According to the results in Table 4, the drawing force caused by the leveler apparently had an effect on this as well. Figure 3 also indicates that the steel thickness affects the rms value when the yield strength is kept fixed. This implies that the strip thickness could be used to predict the rms level during the processing of a specific steel grade because the yield strength is fixed in that case. The high level of rms may be an indication of the potential risks of slipping in the work rollers or abrasion, for instance.

The impacts caused by the sheet cutting manifested themselves in the crest factor especially with thick strips as shown in Figure 4. In addition, other variables such as the yield strength had an influence especially in the case of relatively thin strips. The roller gap values indicated a positive correlation with the crest factor as well. The impacts presumably stress the bearings of the work rollers and supporting rollers, which are under a major load during the leveling.

The roller gap values had quite strong negative correlation with the generalized norm sums. This indicates that the thin strips, which are also long, accumulate higher sums compared with the thick strips. This means that the leveler is stressed a relatively long duration. The generalized norm sums could be used for the general machine stress evaluation.

The roller gap differences between the sides ($P2$ and $P6$) had low correlations with the vibration features. These parameters had low correlations with the studied steel strip properties as well. The entry pinch roller ($P9$) had weak correlations with the vibration features, but a strong correlation with the strip width. The strip weight and the width had low correlations with the studied vibration features as well. These parameters apparently have poor applicability to the prediction of the studied effects appearing in the vibration signal. The effects of the positions of the supporting rollers were rejected in this study because information on the possible steel strip shape flaws was unavailable. In general, the supporting rollers are adjusted to correct flatness defects (Smith, 1997).

4 Conclusions

The effects of steel leveler parameters on vibration features were studied based on the observed linear correlations. Signal derivatives were calculated to magnify the effects. Crest factor, rms and generalized norm sums were used as the vibration features. The crest factor, which shows the ratio of the peak amplitude and rms, had strong correlation especially with strip thickness and the roller gap parameters. The general magnitude of a signal, defined by rms, had the strongest correlations with the yield strength of strip and the drawing force caused by the roller leveler. The generalized norm sums, which can be used to indicate stress accumulation, had the strongest correlations with the drawing force caused by the roller leveler, the roller gap values and the degree of plastic deformation. The strong correlations between the steel strip properties and the operational parameters of the leveler suggest that the characteristics of the vibration signal could be predicted based on the strip properties solely. This implies that the steel strip properties could be used as input variables in models, which predict different effects on the vibration. These models could then be used in the preventive maintenance of the steel leveler.

Abstract

We consider a problem of trajectory planning for path with piecewise linear boundaries. The trajectory is constructed as smoothing splines using normalized uniform B-splines as the basis functions. The boundary constraints are treated as a collection of inequality pairs by right and left boundary lines, and are formulated as linear inequality constraints on the so-called control point vector. Smoothing splines are constructed as an approximation of a piecewise linear centerline of the given path, where the given entire time interval is divided into subintervals according to the centripetal distribution rule. Other constraints as initial and terminal conditions on the trajectory can be included easily, and the problem reduces to convex quadratic programming problem where very efficient numerical solvers are available. The effectiveness of the proposed method is confirmed by an example of fairly complex path with piecewise linear boundaries. Also an example is included to demonstrate its usefulness for trajectory planning in an environment with obstacles.

Keywords: trajectory planning, smoothing spline, B-spline, boundary constraint, quadratic programming problem

1 Introduction

Splines have been used frequently in robotics as in the problems of trajectory planning of robotic arms and mobile robots (Biagiotti and Melchiorri, 2008; Egerstedt and Martin, 2010; Khalil and Dombre, 2002). A typical problem of trajectory planning consists of constructing a function of time that satisfies initial and terminal conditions together with other requirements such as via points and obstacle avoidance.

When via points are specified, trajectories may be constructed as interpolating splines to pass the via points or as approximating splines to pass near the points (Crouch and Jackson, 1991; Egerstedt and Martin, 2001). The problems of obstacle avoidance trajectory planning are often treated by introducing a cost function consisting of distance to obstacles together with e.g. the trajectory length, which are expressed as nonlinear function of some parameters representing the trajectories. Cubic splines are frequently used to construct trajectories (Kolter and Ng, 2009; Saska et al., 2006; Piazzi and Visioli, 2000), and an optimization problem is solved numerically for trajectory planning. Particle swarm optimization method is employed in (Saska et al., 2006).

In (Gallina and Gasparetto, 2000), representing trajectories by sums of harmonics, the trajectory planning problem is formulated as constrained nonlinear programming problem, where the obstacles are treated as inequality constraints by assuming their parametric representation as polygons and ellipses. Also, treating obstacles as linear inequality constraints in (Berglund et al., 2010), nonlinear programming problem is solved for quartic B-spline curves with minimum curvature. Only B-splines of degrees two to four are allowed.

In this paper, we consider a problem of trajectory planning for road-like path with the right and left boundaries in a 2-dimensional plane. The boundaries are assumed to be given as piecewise linear functions, and the problem is to construct a trajectory from given start point to goal point without exceeding the boundaries. Although such a problem of planning trajectories for path with boundaries naturally arises, the treatment as in this study seems novel to the authors' knowledge.

To be more specific, we construct trajectories as smoothing splines using B-splines as the basis functions (Kano et al., 2005). This approach is very suitable to the present problem, since we can construct trajectories piecewise in accordance with each piece of boundaries. Also, by dividing the entire time interval into subintervals, the problem is to construct the trajectory bounded by two lines for each time interval.

In such problems, our approach by constrained splines (Kano et al., 2011; Fujioka and Kano, 2012; Kano et al., 2014) is very effective. The studies on constrained splines include constraints at isolated time instants, those over an interval of time, constraints on function values, on time derivatives of arbitrary degrees, or on integral values, and so forth. The constraints can be equality and/or inequality, and are systematically included in the formulation by B-spline based smoothing splines.

We show that the problem is formulated as a convex QP (quadratic programming) problem. The description of the problem is easy since the boundaries can be defined by simply providing a series of pairs of right and left cor-

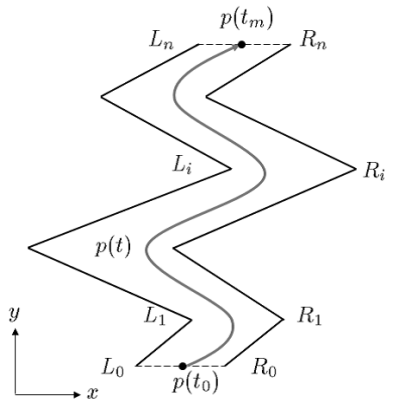

Figure 1. A path with piecewise linear boundaries.

ners, and the resulting QP problem is solved efficiently numerically by existing QP solver. The usefulness of the proposed method is confirmed by two examples: first, for relatively complex path with piecewise linear boundaries, and, second, for application to obstacle avoidance trajectory planning problem.

This paper is organized as follows. In Section 2, we present problem statement and describe 2-dimensional vector smoothing splines based on B-splines. Then in Section 3, the trajectory planning problem is formulated and solved. Two numerical exampled are considered in Section 4. Concluding remarks are given in Section 5.

Throughout the paper, the symbol $\otimes$ denotes the Kronecker product, and 'vec' the vec-function (see e.g. (Lancaster and Tismenetsky, 1985)).

2 Preliminaries

2.1 Problem Statement

As shown in Fig. 1, let a path with piecewise linear boundaries be defined by a pair of corner points (R_i, L_i), $i = 0, 1, \cdots, n$ on xy-plane. Then we consider to design a trajectory $p(t) \in \mathbf{R}^2$

$$p(t) = \begin{bmatrix} x(t) \\ y(t) \end{bmatrix} \tag{1}$$

for given time interval $[t_0, t_m]$ and for given initial position $p(t_0)$ and final position $p(t_m)$. Our particular interest is to construct a smooth trajectory $p(t)$ that is guaranteed to stay within the path specified by the piecewise linear right boundary $R_0R_1\cdots R_n$ and the left boundary $L_0L_1\cdots L_n$. It is noted that the initial and terminal conditions can be specified as equality and/or inequality conditions on $p(t)$ and its derivatives.

We construct the trajectory $p(t)$ for $t \in [t_0, t_m]$ by splines using normalized uniform B-spline $B_k(t)$ of degree $k(\geq 1)$,

$$p(t) = \sum_{i=-k}^{m-1} \tau_i B_k(\alpha(t - t_i)). \tag{2}$$

Table 1. $N_{j,3}(t)$ $(j = 0, 1, 2, 3)$ and its derivatives

j	$3!N_{j,3}(t)$	$2!N^{(1)}_{j,3}(t)$	$N^{(2)}_{j,3}(t)$	$N^{(3)}_{j,3}(t)$
0	$(1-t)^3$	$-(1-t)^2$	$1-t$	-1
1	$4-6t^2+3t^3$	$-4t+3t^2$	$-2+3t$	3
2	$1+3t+3t^2-3t^3$	$1+2t-3t^2$	$1-3t$	-3
3	t^3	t^2	t	1

Here $\tau_i \in \mathbf{R}^2$ are weighting coefficients called control points, and $\alpha(>0)$ is a constant for scaling the interval between equally-spaced knot points t_i with

$$t_{i+1} - t_i = \frac{1}{\alpha}. \tag{3}$$

Moreover, $B_k(t)$ is defined by

$$B_k(t) = \begin{cases} N_{k-j,k}(t-j) & j \leq t < j+1, \\ & j = 0, 1, \cdots, k \\ 0 & t < 0 \ \text{ or } \ t \geq k+1, \end{cases} \tag{4}$$

where the basis elements $N_{j,k}(t)$ $(j = 0, 1, \cdots, k)$, $0 \leq t \leq 1$ can be derived recursively by de Boor's algorithm (de Boor, 2001) for any $k \geq 1$. Note that this basis elements satisfies $N_{j,k}(t) \geq 0 \ \forall t \in [0, 1]$ and

$$\sum_{j=0}^{k} N_{j,k}(t) = 1, \ \ \forall t \in [0, 1]. \tag{5}$$

Since cubic splines are most frequently used, for reference, we show $N_{j,3}(t)$ together with its derivatives in Table 1. Smoothing splines are used to determine the control points τ_i, or the control point matrix $\tau \in \mathbf{R}^{2\times M}$ $(M = m + k)$

$$\tau = \begin{bmatrix} \tau_{-k} & \tau_{-k+1} & \cdots & \tau_{m-1} \end{bmatrix} \tag{6}$$

as we see in the sequel.

2.2 Vector Smoothing Splines

In this particular problem, we consider smoothing splines for continuous-time data $f(t) \in \mathbf{R}^2$, where the following cost function is minimized.

$$J(\tau) = \lambda \int_{t_0}^{t_m} \left\| p^{(l)}(t) \right\|_\Lambda^2 dt + \int_{t_0}^{t_m} \| p(t) - f(t) \|^2 dt. \tag{7}$$

Here $\lambda(>0)$ is a smoothing parameter, $\Lambda \in \mathbf{R}^{2\times 2}$ is a positive-definite weight matrix, $\|u\|^2 = u^T u$, and $\|u\|_\Lambda^2 = u^T \Lambda u$. We take the integer l as $l = 2$ for cubic spline $(k = 3)$ and $l = 3$ for quintic spline $(k = 5)$. Thus the problem is to construct a smooth spline $p(t)$ that approximate the function $f(t)$, which is given, typically so as to represent the center line of the path.

It is noted that usual smoothing spline problem (Wahba, 1990) employs discrete-time set of data (s_i, f_i) in which case the second term in (7) is set as $\sum_{i=1}^{N} \| p(s_i) - f_i \|_{W_i}^2$.

Now, let $\hat{\tau} \in \mathbf{R}^{2M}$ be the vec-function (Lancaster and Tismenetsky, 1985) of τ, i.e.

$$\hat{\tau} = \text{vec } \tau. \tag{8}$$

Then, following the similar procedure as in (Kano et al., 2005), $J(\tau)$ in (7) is expressed as a quadratic function $J(\hat{\tau})$ in $\hat{\tau}$,

$$J(\hat{\tau}) = \hat{\tau}^T G \hat{\tau} - 2\hat{\tau}^T g + g_c \tag{9}$$

where $G \in \mathbf{R}^{2M\times 2M}$, $g \in \mathbf{R}^{2M}$ and $g_c \in \mathbf{R}$ are given by

$$G = Q \otimes \Lambda + Q_0 \otimes I_2 \tag{10}$$

$$g = \int_{t_0}^{t_m} b(t) \otimes f(t) dt \tag{11}$$

$$g_c = \int_{t_0}^{t_m} \|f(t)\|^2 dt. \tag{12}$$

Here $b(t) \in \mathbf{R}^M$ is a vector of shifted B-splines defined by

$$b(t) = \left[\begin{array}{cc} B_k(\alpha(t-t_{-k})) & B_k(\alpha(t-t_{-k+1})) \\ \cdots & B_k(\alpha(t-t_{m-1})) \end{array} \right]^T, \tag{13}$$

and $Q, Q_0 \in \mathbf{R}^{M\times M}$ are Gram matrices defined by

$$Q = \int_{t_0}^{t_m} \frac{d^l b(t)}{dt^l} \frac{d^l b^T(t)}{dt^l} dt \tag{14}$$

$$Q_0 = \int_{t_0}^{t_m} b(t) b^T(t) dt \tag{15}$$

3 Trajectory Planning

Recalling that the path is constrained by piecewise linear boundaries as in Fig. 1, it is convenient to plan the trajectory $p(t)$ for each piece of the path constrained by a pair of right and left boundary line segments, R_iR_{i+1} and L_iL_{i+1}. The construction of $p(t)$ in (2) is very suitable for this purpose since it is a piecewise polynomial with the knot points t_i.

For this purpose, we divide the time interval $[t_0, t_m]$ into n subintervals $[s_i, s_{i+1}]$, $i = 0, 1, \cdots, n-1$ in accordance with n pairs of boundary segments R_iR_{i+1} and L_iL_{i+1}. Here we take $[s_i, s_{i+1}]$ to be a knot point interval, namely each s_i is taken as one of the knot point t_j with $s_0 = t_0$ and $s_n = t_m$.

Now denote the straight line passing two points R_i and R_{i+1} by l_i, and the one for points L_i and L_{i+1} by l'_i (see Fig. 2). Then we plan the trajectory $p(t)$ so that, for each $i = 0, 1, \cdots, n-1$, it lies between the two boundary lines l_i and l'_i for all t in $[s_i, s_{i+1}]$.

This condition is described in Section 3.1, a method of assigning s_i as a knot point in Section 3.2, and the spline construction procedure will be given in Section 3.3, e.g. taking initial and final conditions into account.

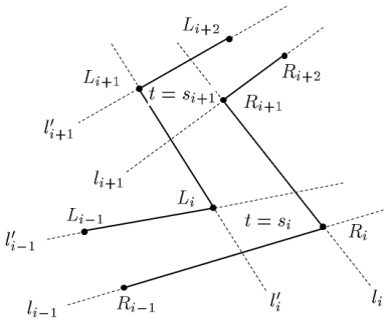

Figure 2. Corner points (R_i, L_i) and boundary lines (l_i, l'_i).

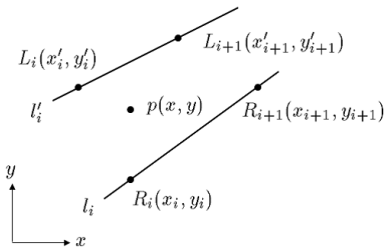

Figure 3. Right and left boundary lines l_i, l'_i and a point p.

3.1 Trajectory between Two Lines

For the present problem, it is natural to introduce the following assumptions (see Figs. 1 and 2).

(A1) The polygon $\mathscr{P}_i = R_iR_{i+1}L_{i+1}L_i$ is a convex quadrangle for all i.

(A2) In $\mathscr{P}_i$, the vertices $R_i, R_{i+1}, L_{i+1}, L_i$ are located counterclockwise.

By (A1), all the four points are distinct and the line segment R_iR_{i+1} does not intersect with L_iL_{i+1}. By (A2), the quadrangle $\mathscr{P}_i$ constitutes part of the path with piecewise linear boundaries, or the path is the union of the quadrangles.

Now we derive a condition such that $p(t)$ remains in a region between the two lines l_i and l'_i for all t in a knot point interval $[s_i, s_{i+1}]$, where we let $[s_i, s_{i+1}] = [t_\kappa, t_\mu]$with $\kappa < \mu$. Here and hereafter, by the term 'region between the two lines l_i and l'_i', we mean the region between the two lines including the quadrangle $\mathscr{P}_i$. Thus if lines l_i and l'_i intersect, then among the two wedge-shaped regions, the one including $\mathscr{P}_i$ is meant.

Since the lines l_i and l'_i respectively play the roles of right and left boundaries of the path, we require the point $p(t)$ to lie to the left of l_i when viewed from R_i toward R_{i+1} along l_i, and moreover, $p(t)$ to lie to the right of l'_i when viewed from L_i toward L_{i+1} along l'_i.

In view of Fig. 3, the above conditions for a point $p(x, y)$ to lie between the two lines can be written as

$$\left\{ \begin{array}{ll} \overrightarrow{R_ip} \times \overrightarrow{R_iR_{i+1}} & \leq 0 \\ \overrightarrow{L_ip} \times \overrightarrow{L_iL_{i+1}} & \geq 0. \end{array} \right. \tag{16}$$

Here $\times$ denotes cross product of 2-dimensional vectors, and it holds that, for $u = [u_1\ u_2]^T$ and $v = [v_1\ v_2]^T$

$$u \times v = \begin{vmatrix} u_1 & v_1 \\ u_2 & v_2 \end{vmatrix} = u_1 v_2 - u_2 v_1 \tag{17}$$

Applying this relation to the vectors in (16), for example $\overrightarrow{R_i p} = [x - x_i\ y - y_i]^T$, (16) can be rewritten as linear inequalities in $p = [x\ y]^T$ as follows.

$$Ap \le d, \tag{18}$$

where

$$A = \begin{bmatrix} -y_i + y_{i+1} & x_i - x_{i+1} \\ y'_i - y'_{i+1} & -x'_i + x'_{i+1} \end{bmatrix}, \tag{19}$$

$$d = \begin{bmatrix} x_i y_{i+1} - x_{i+1} y_i \\ -x'_i y'_{i+1} + x'_{i+1} y'_i \end{bmatrix}. \tag{20}$$

Next we consider the condition such that $p(t)$ given by (2) stays between the two lines l_i and l'_i for all t in the knot point interval $[t_\kappa, t_\mu]$. By (18), it suffices to derive the condition for $Ap(t) \le d\ \forall t \in [t_\kappa, t_\mu]$.

First note that, by the definition of $B_k(t)$ in (4), $p(t)$ is written for unit knot point interval $[t_j, t_{j+1})$ as

$$p(t) = \sum_{i=0}^{k} \tau_{j-k+i} N_{i,k}(\alpha(t - t_j)),\ \ t \in [t_j, t_{j+1}), \tag{21}$$

and it depends on only the $k+1$ weights τ_{j-k}, τ_{j-k+1}, $\cdots$, τ_j. Introducing a new variable $u = \alpha(t - t_j)$, we see that $p(t)$ is written as $\hat{p}(u)$,

$$\hat{p}(u) = \sum_{i=0}^{k} \tau_{j-k+i} N_{i,k}(u),\ \ u \in [0, 1). \tag{22}$$

Thus if $A\tau_{j-k+i} \le d$ holds for $i = 0, 1, \cdots, k$, then using (5), we get

$$A\hat{p}(u) = \sum_{i=0}^{k} A\tau_{j-k+i} N_{i,k}(u) \le d \sum_{i=0}^{k} N_{i,k}(u) = d \tag{23}$$

or $Ap(t) \le d$ for all $t \in [t_j, t_{j+1})$. This interval can be readily extended to $[t_\kappa, t_\mu]$ by imposing the following condition,

$$A\tau_i \le d,\ i = \kappa - k, \kappa - k + 1, \cdots, \mu - 1. \tag{24}$$

Namely if (24) is satisfied, then it holds that

$$Ap(t) \le d\ \forall t \in [t_\kappa, t_\mu]. \tag{25}$$

Now the remaining task is to express the inequality condition (24) in terms of the control point vector $\hat{\tau}$ defined in (8). First rewrite (24) as

$$AT_{\kappa,\mu} \le \mathbf{1}^T_{\mu-\kappa+k} \otimes d \tag{26}$$

with $T_{\kappa,\mu} = [\ \tau_{\kappa-k}\ \tau_{\kappa-k+1}\ \cdots\ \tau_{\mu-1}]$ and $\mathbf{1}_i = [1\ 1\ \cdots\ 1]^T \in \mathbf{R}^i$. Then noting that $T_{\kappa,\mu}$ is a submatrix of τ consisting of its columns from $\kappa + 1$ through $\mu + k$, it can be expressed as

$$T_{\kappa,\mu} = \tau E_{\kappa,\mu}, \tag{27}$$

where $E_{\kappa,\mu} \in \mathbf{R}^{M \times (\mu-\kappa+k)}$ is defined by

$$E_{\kappa,\mu} = \begin{bmatrix} 0_{\mu-\kappa+k,\kappa} & I_{\mu-\kappa+k} & 0_{\mu-\kappa+k,M-\mu-k} \end{bmatrix}^T. \tag{28}$$

Thus (26) is written in τ as

$$A\tau E_{\kappa,\mu} \le \mathbf{1}^T_{\mu-\kappa+k} \otimes d. \tag{29}$$

Using a formula $\mathrm{vec}(AXB) = (B^T \otimes A)\mathrm{vec}X$ for matrices A, B, X of compatible dimensions (see e.g. (Lancaster and Tismenetsky, 1985)), and noting vec $\tau = \hat{\tau}$, (29) yields

$$(E^T_{\kappa,\mu} \otimes A)\hat{\tau} \le \mathbf{1}_{\mu-\kappa+k} \otimes d, \tag{30}$$

which is the desired expression.

For convenience we summarize the above developments as follows.

Proposition 1 *The trajectory $p(t)$ lies for all $t \in [s_i, s_{i+1}] = [t_\kappa, t_\mu]$ between the two lines l_i and l'_i if the control point vector $\hat{\tau}$ satisfies the following inequality.*

$$F_i \hat{\tau} \le h_i \tag{31}$$

where $F_i \in \mathbf{R}^{2(\mu-\kappa+k) \times 2M}$ and $h_i \in \mathbf{R}^{2(\mu-\kappa+k)}$ are given by $F_i = E^T_{\kappa,\mu} \otimes A$ and $h_i = \mathbf{1}_{\mu-\kappa+k} \otimes d$.

3.2 Centerline and Intermediate Time Instants

Recall that it is necessary to allocate the given time interval $[t_0, t_m]$ to n intervals $[s_i, s_{i+1}]$ with s_i being some knot point t_j for each $i = 0, 1, \cdots, n-1$. A natural way is to take the length of center line $C_i C_{i+1}$ (see Fig. 4) into account.

Let $C_i,\ i = 0, 1, \cdots, n$ be defined by

$$C_i = \gamma_i R_i + (1 - \gamma_i) L_i \tag{32}$$

for some γ_i ($0 \le \gamma_i \le 1$). Then for determining the time instants s_i in $[t_0, t_m]$, we employ the so-called centripetal distribution (Biagiotti and Melchiorri, 2008). Namely each s_i is determined so that the whole interval $[t_0, t_m]$ is divided into subintervals $[s_i, s_{i+1}]$ in proportion to the following value ζ_i,

$$\zeta_i = \|C_{i+1} - C_i\|^\nu \tag{33}$$

for $i = 0, 1, \cdots, n-1$, where $\nu (0 < \nu < 1)$ is usually taken as $\nu = 1/2$. Actually, each s_i is determined as a knot point t_j based on ζ_i. Also it is noted that the centripetal distribution method in above requires less accelerations than other method e.g. cord length distribution, distributed proportionally to $\|C_{i+1} - C_i\|$.

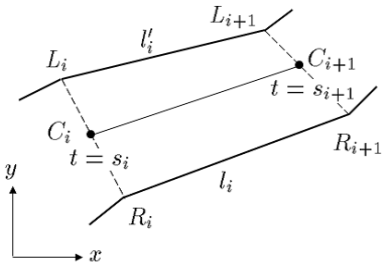

Figure 4. Centerline in the i-th quadrangle.

3.3 Smoothing Spline Trajectory

Obviously we require that, for all $i = 0, 1, \cdots, n-1$, the trajectory $p(t)$ lies between the two lines l_i and l_i' for all $t \in [s_i, s_{i+1}] = [t_\kappa, t_\mu]$. Thus by Proposition 1, we impose

$$F_i \hat{\tau} \le h_i,\ i = 0, 1, \cdots, n-1. \tag{34}$$

Usually an initial and terminal conditions of $p(t)$ are given, and typical examples are

$$p(t_0) = p_0,\ p^{(1)}(t_0) = 0,\ p^{(2)}(t_0) = 0 \tag{35}$$

$$p(t_m) = p_m,\ p^{(1)}(t_m) = 0,\ p^{(2)}(t_m) = 0 \tag{36}$$

with p_0 and p_m lying on the line segments R_0L_0 and R_nL_n respectively. Noting that $p(t)$ in (2) is written as $p(t) = \tau b(t)$ and hence $p(t) = \text{vec}\, p(t) = \text{vec}\,(\tau b(t)) = (b(t)^T \otimes I_2)\hat{\tau}$, the above initial and final conditions can be written in terms of $\hat{\tau}$ as follows.

$$H(t_0)\hat{\tau} = \bar{h}_0,\ H(t_m)\hat{\tau} = \bar{h}_m \tag{37}$$

where $H(t) \in \mathbf{R}^{6\times 2M}$, $\bar{h}_0 \in \mathbf{R}^6$ and $\bar{h}_m \in \mathbf{R}^6$ are

$$H(t) = \begin{bmatrix} b(t)^T \otimes I_2 \\ b^{(1)}(t)^T \otimes I_2 \\ b^{(2)}(t)^T \otimes I_2 \end{bmatrix}, \bar{h}_0 = \begin{bmatrix} p_0 \\ 0_2 \\ 0_2 \end{bmatrix}, \bar{h}_m = \begin{bmatrix} p_m \\ 0_2 \\ 0_2 \end{bmatrix}. \tag{38}$$

The matrices $H(t_0)$ and $H(t_m)$ can be easily set up, for example by using Table 1 when $k = 3$.

Finally in this section we consider the function $f(t)$ used for approximation of smoothing splines in (7). A natural choice will be a function constructed from the piecewise linear centerline $C_0C_1\cdots C_n$ introduced by (32). Specifically we employ a linear function of t in each section as shown in Fig. 4 as

$$f_i(t) = q_i t + r_i,\ t \in [s_i, s_{i+1}]. \tag{39}$$

Here $q_i, r_i \in \mathbf{R}^2$ are determined so as to satisfy $f_i(s_i) = C_i$ and $f_i(s_{i+1}) = C_{i+1}$. Thus the vector g in (11) is computed from

$$g = \sum_{i=0}^{n-1} \int_{s_i}^{s_{i+1}} b(t) \otimes f_i(t) dt \tag{40}$$

Now we are ready to formulate the trajectory planning problem by constrained smoothing splines with $J(\hat{\tau})$ in (9), the boundary inequality conditions in (34) and initial and terminal conditions in (37). Namely the problem is to minimize the cost function,

$$\min_{\hat{\tau}\in\mathbf{R}^{2M}} J(\hat{\tau}) = \frac{1}{2}\hat{\tau}^T G \hat{\tau} - g^T \hat{\tau} \tag{41}$$

subject to the constraints of the form

$$A_{eq}\hat{\tau} = d_{eq},\ A_{in}\hat{\tau} \le d_{in}, \tag{42}$$

where G and g are given in (10) and (11) respectively, A_{eq} and d_{eq} are formed as the collection of equalities (37), and A_{in} and d_{in} as collection of inequalities in (34).

Note that, in the case of (37), $A_{eq}\hat{\tau} = d_{eq}$ consists of 12 equality constraints in $2M$ unknowns $\hat{\tau}$. On the other hand, the total number of inequality constraints resulting from (34) is computed as $2M + 2(n-1)k$, with $2(n-1)k$ more than the number of unknowns.

This is a convex quadratic programing problem and can be solved numerically by using software tool as the function 'quadprog' in MATLAB. If necessary, other constraints may be introduced such as constraints on the magnitude of velocity or acceleration as long as all the constraints are consistent.

Finally, it is noted that, by our construction, the planned trajectory satisfies the following proposition.

Proposition 2 *The planned spline trajectory $p(t)$ is guaranteed to stay, for each $i = 0, 1, \cdots, n-1$, between the two lines l_i and l_i' as the right and left boundaries for all time $t \in [s_i, s_{i+1}]$. In particular, $p(t)$ is in the corner quadrangle formed from the four lines $l_i, l_i', l_{i-1}, l_{i-1}'$ at time $t = s_i$ for $i = 1, 2, \cdots, n-1$.*

4 Numerical Examples

Two examples of trajectory planning are considered, where we use cubic splines, namely we set $k = 3$ and $l = 2$ in (2) and (7). MATLAB function 'quadprog' is used for numerical solution of quadratic programming problems.

4.1 Path with Piecewise Linear Boundaries

We consider a path with the right and left corners R_i and L_i given as in Table 2.

Table 2. The coordinates R_i and L_i of right and left corners for $i = 0, 1, \cdots, n$ with $n = 9$.

	0	1	2	3	4	5	6	7	8	9
R_i	1	2	2	8	3	8	2	13	13	14
	0	2	9	9	6	4	0	0	8	9
L_i	0	1	1	12	6	11	6	12	12	14
	0	2	10	10	6	4	1	1	8	10

For this path, we construct a smoothing spline trajectory $p(t)$ in time interval $[t_0, t_m] = [0, 10]$. The initial and final conditions are as given in (35) and (36) with $p_0 = (R_0 +$

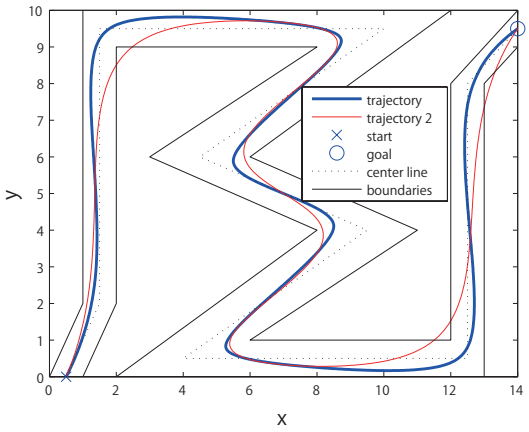

Figure 5. Constructed spline trajectories plotted in xy plane with and without the boundary constraints in (34).

$L_0)/2$ and $p_m = (R_9 + L_9)/2$. We set $\gamma_i = 1/2\ \forall i$ in (32) for centerline of the path, which together with (39) is used to set $f(t)$ in (7). The number of knot points $m = 80$, and hence the knot point interval is $t_{i+1} - t_i = 10/80 = 0.125$. The smoothing parameter is set as $\lambda = 0.01$ in (7).

Fig. 5 shows the given path with the boundaries denoted by black lines and the constructed trajectory $p(t) = [x(t),\ y(t)]^T$ on the xy plane in thick blue line. The start and goal positions are denoted by $\times$ and $\circ$ respectively, and the center line is shown in dotted lines. We observe that the trajectory satisfies the boundary constraints in addition to initial and final conditions. The red line is a smoothing spline trajectory $p2(t) = [x2(t),\ y2(t)]^T$ constructed similarly as $p(t)$ but without the inequality boundary constraints (34). It exceeds the boundaries at three corners, and the effect of introducing the inequality constraints is apparent.

4.2 Path in Obstacle Avoidance Problem

The proposed method can be used for planning trajectories of mobile robots in an environment with obstacles. As shown in Fig. 6, let us consider an environment with three 'obstacles', denoted by yellow rectangles, and the start and goal denoted by $\times$ and $\circ$ respectively. If we decide to take the upper route of the table-like obstacle in the figure, which will be shorter than taking the lower route, the path with piecewise linear boundaries can be defined, for example by setting the right and left corners (R_i, L_i) as shown in Table 3. These boundaries are shown in Fig. 6 in black dotted lines with the sign $\triangle$ and $\triangledown$ for right and left boundaries respectively.

We plan trajectories for this path with the time interval $[t_0, t_m] = [0, 10]$, initial and final conditions are as given in (35) and (36), $m = 50$ and the smoothing parameter $\lambda = 0.1$. Two cases of the parameters γ_i in (32) are considered for the centerline of the path as shown in Table 3. The first case (i) sets the line in the middle of the path, whereas the second case (ii) sets the line closer to the inner corner of the path. The planned trajectories are shown in the xy plane in thick blue line for Case (i) and thick red line for Case (ii). We see that reasonable trajectories have been generated where the second case seems more desirable, and that the parameters γ_i for the center line could be effectively used to adjust the trajectory. Note that the path is defined by only six pairs of right and left corners.

Table 3. The coordinates R_i and L_i of right and left corners and the parameter γ_i for centerline for $i = 0, 1, \cdots, n$ with $n = 5$.

	0	1	2	3	4	5
R_i	3 0	3 8	4 8	4 7	13 7	13 5
L_i	0 0	0 12	6 12	6 10	16 10	16 5
γ_i : Case (i)	1/2	1/2	1/2	1/2	1/2	1/2
γ_i : Case (ii)	1/2	2/3	2/3	1/3	2/3	1/2

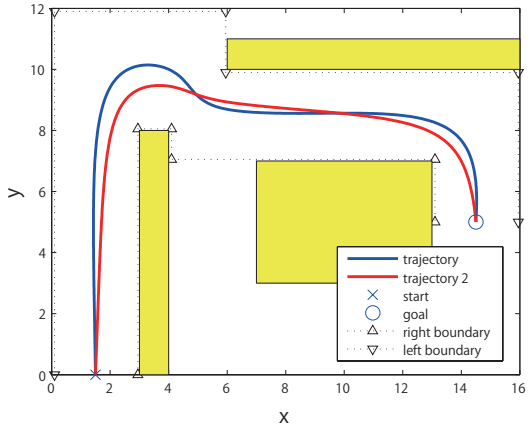

Figure 6. Constructed spline trajectories plotted in xy plane for two Cases (i) and (ii) of the centerline (see Table 3).

5 Concluding Remarks

We presented a method of trajectory planning for path with piecewise linear right and left boundaries. The trajectory is constructed as smoothing splines employing normalized uniform B-splines as the basis functions. Obviously, such boundaries can be described by simply providing a series of pairs of right and left corners (R_i, L_i), and the problem can be readily defined.

The boundary constraints could be expressed as linear inequality constraints on the control point vector $\hat{\tau}$. For constructing smoothing splines, we introduced a piecewise linear centerline of the path in accordance with each pair of right and left boundaries. An appropriate time interval for each piece of the centerline is given based on the centripetal distribution rule. It is shown that the problem is formulated as convex quadratic programming problem. We confirmed the effectiveness of the proposed method by two numerical examples.

One of the future issues is to relax the assumption (A1) in Section 3.1 to allow the multiple corner points as $R_i = R_{i+1}$. Extensions of present method are also important, e.g. to the cases of higher order boundary curves and to the planning in 3-dimensional space.

A Harvest Vehicle with Pneumatic Servo System for gathering a Harvest and its Simulation Study

Katsumi Moriwaki

Department of Mechanical Engineering, Daido University, Japan, moriwaki@daido-it.ac.jp

Abstract

A series of works such as harvesting and transporting in a farm is one of such works with so care as not to damage the harvest in order to maintain the value of harvests. We are developing an autonomous cart for gathering a harvest with the bed to be controlled to keep in horizontal level at work and in transit, in order to avoid harvests gathered in particular area of the bed and to keep away from being damaged in harvests. It is proposed a method of autonomous steering control of a harvest vehicle with maintaining the horizontal level of the bed of the cart with air cylinder suspension systems. It is shown that the problem of a level control of vehicle's bed can be formulated as one of optimal control problems. Finally, its simulation study is considered.

Keywords: level control of vehicle's bed, pneumatic servo control, autonomous vehicle, terrain farm, harvesting

1 Introduction

The work of harvesting of the fields is one of tough works which need the efficiency of materials handling, while it is necessary for guarantee of commodity value to treat crops carefully so that a crack may not be attached to crops. A harvest cart is, therefore, one of necessary apparatuses for both a professional farmer and a urban farmer to lighten their work load to harvest the fields. There are many harvest carts developed and sold in various size, from smalled-sized to mega-sized. In this research, it aims at development of the conveyance cart which can carry a harvest without swaying of the loading bed by performing level surface maintaining control, in order for the crops not to be damaged. We proposed the basic structure for level control of a harvest bed using pneumatic system (Moriwaki, 2012). It was proposed the harvest vehicle with a level-controlled harvest bed and considered the optimal control problem of a level control of a harvest bed (Moriwaki, 2013, 2016). We, furthermore, consider to realize the system of intelligent harvesting which performs autonomous collection of crops in a cultivated land and autonomous carrying them to the crops shed without deterioration of the commodity value of them. Figure 1 shows an examples of harvest vehicle, which carries crops from the cultivated land to the harvest gathering place. The harvest cart often jolts over the rough cultivated land, and crops vibrate on the loading bed of the harvest cart. Crops collide together or with the wall of a harvest stand, It damages the surface of crops and reduces the commodity value of crops. If crops without cracks can be harvested and shipped, they can be sold for a high price at a market. We have started a development program of a harvest vehicle which can perform harvesting operation and maintain the level surface of its loading bed, and can autonomously go to a harvest collection place.

The suspension model of a vehicle is considered in Section 2. After considering the structure of the loading bed of a harvest vehicle in Section 3, A model of level controlled bed by a pneumatic servo system is proposed in Section 4. The control system of a harvest bed with a pair of pneumatic cylinder is proposed in Section 5, where is also shown some numerical simulations and experimental study. Finally, it is considered the problem of level control of harvest's bed on the terrain farm land in Section 6.

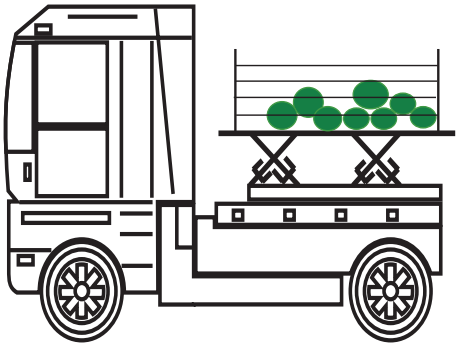

Figure 1. A harvest vehicle with active pneumatic suspension bed.

2 Suspension model of a vehicle dynamics

The control problem of leveling the load bed of a harvest vehicle is deeply relation to the vertical dynamics of a vehicle, its suspension dynamics. The features of car vertical dynamics in (X-Z)-plane are described by Figure 2 (Abe, 1992; Andrezejewski and Awrejcewicz, 2005) with active suspension system in which the external control forces is used to suppress the uncomfortable bouncing motion and pitching motion.

The equations of motions for two degrees of freedom in (X-Z)-plane with the constant velocity V are

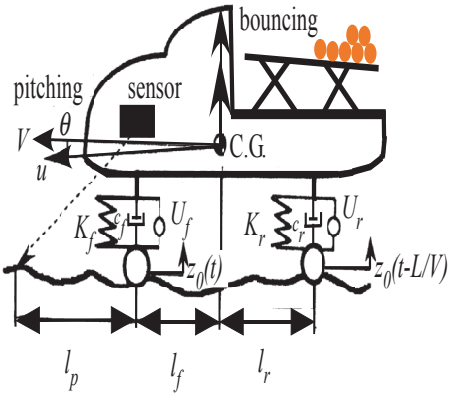

Figure 2. Active suspension control of a harvest vehicle.

$$\text{bouncing motion} : m\ddot{z} = F_f + F_r \tag{1}$$

$$\text{pitching motion} : I_y\ddot{\theta} = -l_f F_f + l_r F_r \tag{2}$$

where m is the mass of a vehicle, z is the vertical displacement of the center of gravity (CG) of a car(Figure 2), I_y is the moment of inertia around y-axis, θ is the pitching angle of the center of gravity (CG) of a car and the external forces acting on a front wheel and the rear wheel from the road surface are written by F_f and F_r, respectively. The state space model of the vertical dynamics is derived from (1) and (2), where it is assumed that the vehicle is affected from the terrain of the farm land as the unknown input U_f, U_r and the surface roughness $z_{0f} = z_0(t)$, $z_{0r} = z_0(t - L/V)$, where $L = l_f + l_r$.

$$\begin{bmatrix} \dot{z} \\ \dot{\theta} \\ \dot{w} \\ \dot{q} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ \tilde{a}_{31} & \tilde{a}_{32} & \tilde{a}_{33} & \tilde{a}_{34} \\ \tilde{a}_{41} & \tilde{a}_{42} & \tilde{a}_{43} & \tilde{a}_{44} \end{bmatrix} \begin{bmatrix} z \\ \theta \\ w \\ q \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ \tilde{b}_{31} & \tilde{b}_{32} \\ \tilde{b}_{41} & \tilde{b}_{42} \end{bmatrix} \begin{bmatrix} U_f \\ U_r \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ \tilde{h}_{31} & \tilde{h}_{32} \\ \tilde{h}_{41} & \tilde{h}_{42} \end{bmatrix} \begin{bmatrix} z_{0f} \\ z_{0r} \end{bmatrix} \tag{3}$$

where $w := \dot{z}$, $q := \dot{\theta}$ and

$$\left.\begin{aligned} \tilde{a}_{31} &= -\tfrac{K_f + K_r}{m}, \quad \tilde{a}_{32} = \tfrac{K_f l_f - K_r l_r}{m} \\ \tilde{a}_{33} &= -\tfrac{C_f + C_r}{m}, \quad \tilde{a}_{34} = \tfrac{C_f l_f - C_r l_r}{m} \\ \tilde{a}_{41} &= \tfrac{K_f l_f - K_r l_r}{I_y}, \quad \tilde{a}_{42} = -\tfrac{K_f l_f^2 + K_r l_r^2}{I_y} \\ \tilde{a}_{43} &= \tfrac{C_f l_f - C_r l_r}{I_y}, \quad \tilde{a}_{42} = -\tfrac{C_f l_f^2 + C_r l_r^2}{I_y} \end{aligned}\right\} \tag{4}$$

$$\left.\begin{aligned} \tilde{b}_{31} &= \tfrac{1}{m}, \quad \tilde{b}_{32} = \tfrac{1}{m} \\ \tilde{b}_{41} &= -\tfrac{l_f}{I_y}, \quad \tilde{b}_{42} = \tfrac{l_r}{I_y} \end{aligned}\right\} \tag{5}$$

$$\left.\begin{aligned} \tilde{h}_{31} &= \tfrac{K_f}{m}, \quad \tilde{h}_{32} = \tfrac{K_r}{m} \\ \tilde{h}_{41} &= -\tfrac{K_f l_f}{I_y}, \quad \tilde{b}_{42} = \tfrac{K_r l_r}{I_y} \end{aligned}\right\} \tag{6}$$

C_r : damping coefficient for rear suspension

3 Structure of the loading bed of a harvest vehicle

It is considered that the structure of the loading platform with the level control mechanism using pneumatic cylinders of an autonomous harvest cart in this section. We propose a control system which maintains a loading platform horizontally while harvested crops is gathered on the loading platform. When crops are taken in and it is stored by the loading platform, there are often for crops to be thrown into the harvest cart and stored randomly on a loading-platform. If the level maintaining of a loading-platform becomes difficult according to the random loading of crops, a loading-platform inclines and crops may roll in the direction of a lower side, then the damage to the crops caused by collision with other crops or with the wall of the loading-platform may occur, and it may produce deterioration of the commodity value of crops. Moreover, if crops are loaded to the specific side of a loading platform and a loading-platform inclines, the efficiency carrying crops will be affected. In order to prevent such a bad influence to an agricultural harvest work, this research considers a method of the level control of the loading bed of an autonomous harvest cart.

There are many cases in position the load bed with crops (Figure 3). Cases (a) and (b) are situations of the bed on flat field, the bed in (a) is maintained horizontally with the harvest orderly, on the other hand, the bed (b) leans with gathered crops on one side. Case (c) and (d) are situations of the bed on terrain field, the bed in (c) leans because of gathered harvest and uneven surface of the field, our aim is to propose the controlled bed to maintain horizontally, whether on uneven field or with gathered crops in ether side. In this paper, it aims at realizing the level control of a loading-platform by using position control of pneumatic cylinders with electromagnetic pressure proportional valves and a computer (Figure 4). In Figure 4, the load f_L, which is induced for crops to drop on the load platform, presses down the cylinder head, whose mass is denoted by M, and the loading platform leans down to either side. The deviation is detected by a height sensor and

is put into a computer as the reference. The computer calculates the control input e, with which a pressure valve controls the cylinder pressure so that the loading platform move back to the horizontally.

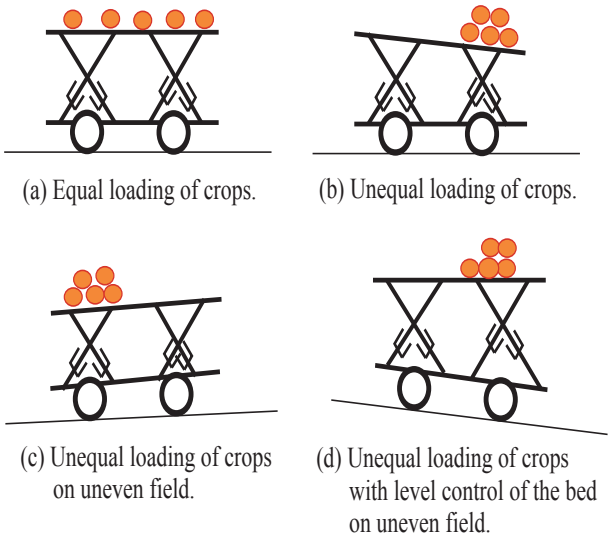

Figure 3. Harvest quality managing cart.

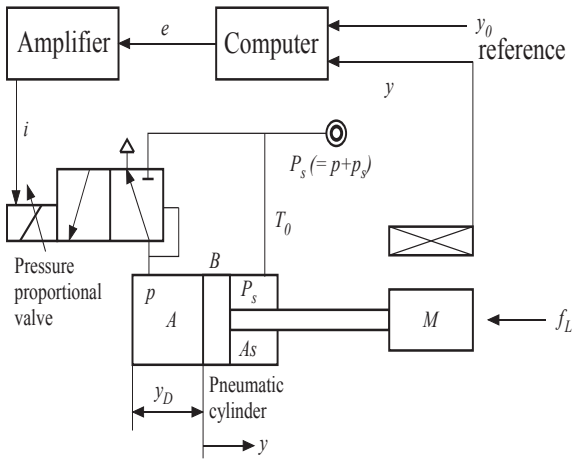

Figure 4. Position control of a pneumatic cylinder with a pressure proportional valve.

4 Modeling of a pneumatic cylinder with a pressure proportional valve

A pneumatic cylinder servo control system is expected to be applied to various automation systems, because it has some advantages such as high power/weight ratio, functions of impact absorption and rigorous force control owing to air compressibility. However, the compressibility makes it a high order and nonlinear system, its exact modeling and parameter estimation are not easy (Noritsugu and Takaiwa, 1993; Song, et al., 1997). There are many paper published about pnematic servo system up to now, almost all of them are, however, dealed with the problem of the position control or force control of a simple pneumatic cylinder. There is few study about the practical control system with the pneumatic servo system (Moriwaki, 2012, 2013, 2016).

4.1 A model for a pneumatic cylinder

The air mass flow rate W [kg/s] which flows into a cylinder can be expressed as follows.

$$W = \frac{1}{RT_0}\{p\dot{V} + (\frac{V}{\kappa})\dot{p}\} \tag{7}$$

where

$$V = A(y_D + y) \tag{8}$$

and A is a area of the cylinder $[m^2]$, T_0 is an absolute temperature $[K]$, κ is the ratio of specific heat of the air (≈ 1.4) and R is the gas constant $(= 287m^2/s^2K)$.

The motion of a rod of the pneumatic cylinder is described by the following equation:

$$M\ddot{y} + B\dot{y} = Ap - A_s p_s + f_L \tag{9}$$

where $y, A_s, p, p_s, M, B, f_L$ are the position of rod in a cylinder, a area of rod-side, a nominal portion of the supply pressure P_s, a fluctuation portion of the supply pressure P_s, a inertial mass of the cylinder, a viscous coefficient of friction of the cylinder and a external force, respectively. It is usually assumed that a fluctuation portion of the supply pressure is sufficiently small, then we can put $p_s = 0$ in (9). Therefore, we obtain the following equation from (9).

$$M\ddot{y} + B\dot{y} = Ap + f_L \tag{10}$$

4.2 A model for a pressure proportional valve

It is well known that the transient characteristics of a pneumatic cylinder is remarkably affected to a control flow, inertial mass, death volume of a valve (Tanaka, 1987; Kagawa and Cai, 2010). The servomechanism which controls the cylinder of a single rod type by the three direction type of a pressure proportional valve is used in the proposed system.

The mass flow rate W_v may be linearized with respect to the displacement x_v of a valve, then we obtain the following equation (Tanaka, 1987; Kagawa and Cai, 2010):

$$W_v = (\frac{\partial W_v}{\partial x_v})x_v + (\frac{\partial W_v}{\partial p})p = k_v x_v - k_p p \tag{11}$$

where $k_v, k_p,$ are a flow gain, a pressure flow coefficient $(k_p > 0)$, respectively. Accompanying the motion of a cylinder to the mass flow rate W_v given by (11), the energy equilibrium equation is given by

$$W_v + \frac{1}{RT_0}A_v p\dot{x_v} = W \tag{12}$$

Equation (12) is transformed and the following (13) is obtained.

$$W_v = \frac{1}{RT_0}(pA\dot{y} + \frac{V}{\kappa}\dot{p} - A_v p\dot{x_v}) \tag{13}$$

where A_v is the area of a feedback pressure of a valve.

For an electromagnetic force F_c of a solenoid, the equation of motion of a pressure valve can be expressed as follows (Tanaka, 1987).

$$m\ddot{x_v} + b\dot{x_v} = F_c - A_v p \tag{14}$$

where m is the inertial mass of a moving rod of a cylinder and b is the coefficient of viscous damping.

5 The position control system of a pneumatic cylinder using a pressure proportional valve

5.1 A block diagram of a pneumatic servo system

The solenoid's electromagnetic force F_c can be approximated by the following equation, denoting feedback gains of a cylinder position y and its moving velocity $\dot{y}$ by g_{fs}, g_{fv}, respectively,

$$F_c \cong \frac{a_1(a_0 y_0 - g_{fs}y - g_{fv}\dot{y})}{\tau_0 s + 1} \tag{15}$$

where a_1, a_0, τ_0 denote the electromagnetic force conversion coefficient, the voltage conversion coefficient w.r.t. reference input y_0, and the time constant of the solenoid.

Combining (10), (11) and (13)–(15), then the position control system is obtained by Figure 5, in which a cylinder position y can be maintained at the reference position y_0 under an unexpected load (or force) being added to the cylinder. In Figure 5, time constants $\tau_i\,(i = 1, \cdots, 4)$ denote $\tau_1 = \frac{k_c}{k_p}$, $\tau_2 = \frac{m}{b}$, $\tau_3 = \frac{A_v}{k_x}$, $\tau_4 = \frac{M}{B}$, respectively, and k_x is the flow gain of the valve, k_p is the pressure flow coefficient, and k_c is the compliance of air pressure. In the usual air pressure servomechanism, $\tau_0, \tau_2, \text{and} \tau_3$ may be very small and can be ignored (Tanaka, 1987). The time constant τ_4 may be changed to $(\tau_4 + \Delta)$ depending on the loaded mass.

5.2 A reduced block diagram of a pneumatic servo system

If the pneumatic servo system has the condition $\tau_4 > \tau_1$, which means its inertia characteristics are dominant than its volume characteristics in the system, the block diagram shown in Figure 5 can be reduced as Figure 6. In Figure 6, the parameters $\omega_M, \zeta_M, k_{Lp}$ denote the following values respectively.

$$\omega_M = \sqrt{\frac{\{A_v + (a_1 g_{fv} A)/B\}k_x}{bk_p\tau_4}} \tag{16}$$

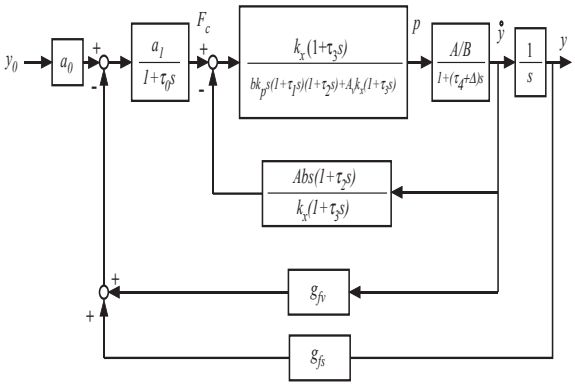

Figure 5. The position control system by a pneumatic cylinder.

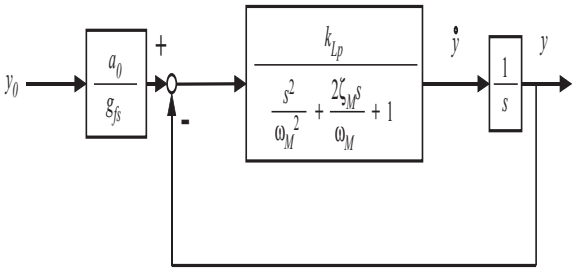

Figure 6. The reduced position control system by a pneumatic cylinder.

$$\zeta_M = \frac{b(k_p + A^2/B) + A_v k_x \tau_4}{2\sqrt{bk_v\tau_4 k_x\{A_v + (a_1 g_{fv} A)/B\}}} \tag{17}$$

$$k_{Lp} = \frac{(a_1 g_{fp} A)/B}{A_v + (a_1 g_{fv} A)/B} \tag{18}$$

The characteristics of step responce of the pneumatic servo system is analyzed theoretically and the parameter k_{Lp}/ω_M is necessary to be set 0.4 or less in order to obtain the undershoot step response (Tanaka, 1987).

5.3 A state space model for leveling control of the loading bed of a harvest cart

The loading bed of a harvest cart, which we proposed in this paper, is controlled by a pair of pneumatic cylinders as shown in Figure 7, which is appeared in later section. The structure of dynamics of the proposed level control system is shown in Figure 8.

The rods of pneumatic cylinder (a) and (b) are connected to the loading bed with rotation and bottoms of cylinders are connected to the base of the harvest cart with the angle θ of inclination. The angle θ is assumed to be fixed, i.e. $\sin\theta$ is to be constant. The height z_a, z_b of the both ends of the loading bed are controlled by the position of the rod y_a, y_b, respectively, as

$$z_a = y_a \sin\theta, \;\; z_b = y_b \sin\theta \tag{19}$$

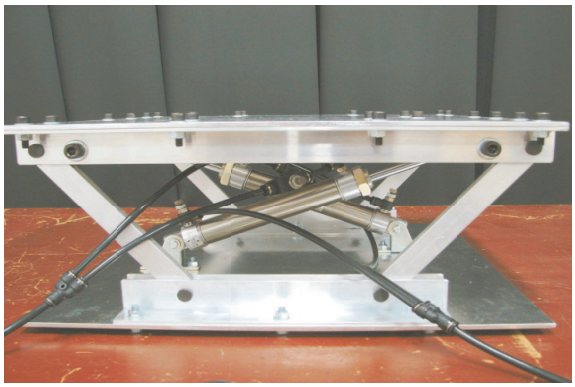

Figure 7. The experimental device for level control of the loading platform.

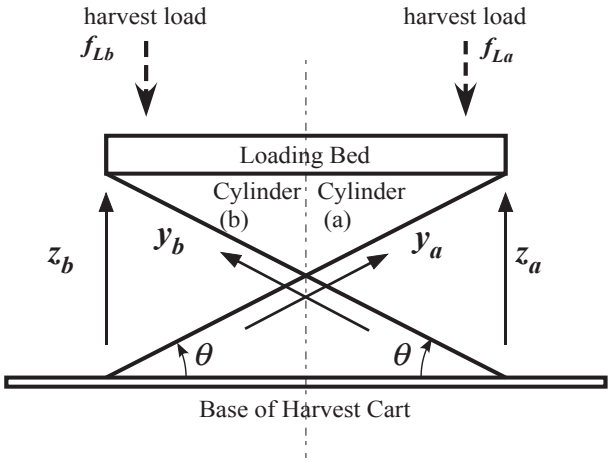

Figure 8. The structure of a dynamic model for level control of the loading bed.

with the state space model as follows: $(i = a, b)$

$$\frac{d}{dt}\begin{bmatrix} y_i \\ \dot{y}_i \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 0 & -\frac{2B}{M} \end{bmatrix}\begin{bmatrix} y_i \\ \dot{y}_i \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{2A}{M} \end{bmatrix} p_i + \begin{bmatrix} 0 \\ \frac{2A}{M} \end{bmatrix} f_{Li}, \tag{20}$$

where p_i is the control input and f_{Li} is the harvest load. The objective of level control of the loading bed is, therefore, maintain the difference $z_a - z_b$ to be minimized. That is the difference v defined by

$$v = \sqrt{(z_a - z_b)^2} = \sqrt{(y_a - y_b)^2}\sin\theta \tag{21}$$

to be reduced as soon as possible.

5.4 Simulation results of the level control system

The harvest is loaded on the loading bed (Figure 8) of the harvest cart unevenly from the farm. We have simulated the level control of the loading bed under (a) the periodical loading from the both ends with different weights and a phase difference and (b) the random impulsive loading from the both ends with different weights and a phase difference. Figure 9 shows the external harvest loadings f_{La}, f_{Lb} and the difference v of the loading bed (21) for the case (a). Figure 10 shows the external harvest loadings f_{La}, f_{Lb} and the difference v of the loading bed (21) for the case (b). In Figures 9, 10 amplitudes of f_{La}, f_{Lb}, v are normalized and scaled.

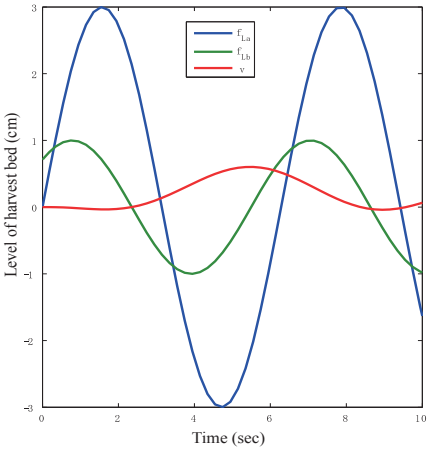

Figure 9. A state of level of the harvest bed under periodical loading.

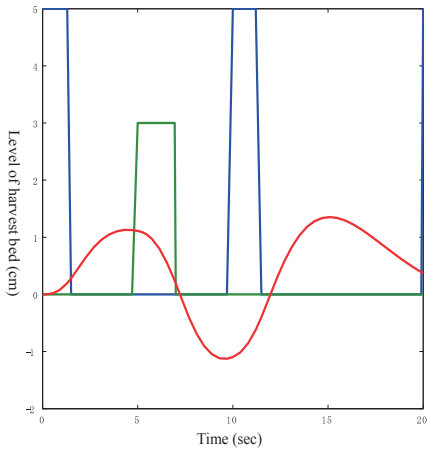

Figure 10. A state of level of the harvest bed under random impulsive loading

6 Leveling control of the harvest bed on the terrain farm land

The harvest vehicle usually moves on rough terrain to carry crops to the cargo-pickup point at the farm. In this section, we consider the control problem to maintain the level of a harvest bed under the existence of pitching motion of the suspension. Let's assume there is a pitching

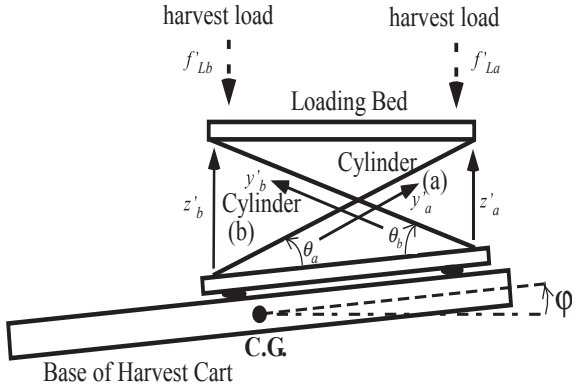

Figure 11. The model of a harvest bed on the platform of the vehicle on rough terrain.

angle φ, while the harvest vehicle moves. Then the model of a harvest bed under pitching motion is shown in Figure 11.

The height z'_a, z'_b of the both ends of the loading bed are controlled by the position of the rod y_a, y_b, respectively, as

$$z'_a = y'_a \sin\theta_a, \;\; z'_b = y'_b \sin\theta_b \tag{22}$$

with the state space model as follows: $(i = a, b)$

$$\frac{d}{dt}\begin{bmatrix} y'_i \\ \dot{y}'_i \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 0 & -\frac{2B}{M} \end{bmatrix}\begin{bmatrix} y'_i \\ \dot{y}'_i \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{2A}{M} \end{bmatrix} p_i + \begin{bmatrix} 0 \\ \frac{2A}{M} \end{bmatrix} f'_{Li}, \tag{23}$$

where p_i is the control input and f'_{Li} is the harvest load. There is the incline of the base of a harvest vehicle, caused by the pitching angle φ. Therefore, we have to compensate for the incline in order to control the level of the harvest bed. The difference between z'_a and z'_b is

$$\Lambda = l_r \sin\varphi \tag{24}$$

where l_r is the distance between the center of gravity (C.G.) and the rear axle of the vehicle (Figure 2).

The objective of level control of the loading bed for this case is, therefore, maintain the difference $z'_b - z'_a$ to be equalized to the incline height Λ, as soon as possible. That is the difference $|\Lambda| - |v'|$ defined by

$$v' = \sqrt{(z'_a - z'_b)^2} = \sqrt{(y'_a \sin\theta_a - y'_b \sin\theta_b)^2} \tag{25}$$

to be reduced as soon as possible. It is not clear in this general case for the solution to level control of the harvest bed of the cart.

7 Conclusions

The autonomous harvest cart with level control of loading platform has been proposed in this paper. Crops can be stored in an uneven cultivated land so that reduction in commodity value may not be produced by using the proposed harvest cart. The pneumatic cylinder servo control system is used to control the level of loading platform. The proposed harvest cart is designed so that it can maintain the level of loading platform while loading of crops and following a bumpy road from a farmland.

Creating Social-aware Evacuation Plans based on a GIS-enable Agent-based Simulation

Kasemsak Padungpien and Worawan Marurngsith
Department of Computer Science, Thammasat University, Thailand, wdc@cs.tu.ac.th

Abstract

In disaster preparedness, agent-based simulation (ABS) is an effective tool for aggregating information on evacuees affected by disasters. An agent usually imitates a household; and its actions are normally specified by decision models based on risk perception and social elements. Assigning socially connected households to the same shelters can better utilise resources. However, by pre-assigning specified regions to shelters, social connections are often omitted when developing evacuation plans at policy level. Thus, this paper presents a method to create social-aware evacuation plans. A GIS-enabled ABS is used to estimate evacuation demand and group evacuees according to their social connection data prior to assign them to the nearest shelters. The evacuation plans generated by the proposed method are compared against the travel-cost optimisation plans solved by using a linear model. The results obtained from a case study show that the social-aware evacuation plans offer a slightly better utilisation of shelter capacity; take similar time to evacuate households; yet could save nearly three hours to achieve complete evacuation. These results seem to confirm the competitiveness of social-aware evacuation plans as an option for evacuation planning at policy level.

Keywords: agent-based simulation, social connection, K-means clustering, linear programming, evacuation and shelter planning, GeoMASON

1 Introduction

Evacuation and shelter planning is essential to decrease the severity of loss and damage caused by either natural or man-made disasters. Evacuation studies may be classified into three groups: disaster models, traffic models, and traffic disaster evacuation models (Bae et al., 2014). Previous studies from 1985 – 2014 as reviewed in (Bae et al., 2014; NaBanerjee, 2015) confirmed that agent-based simulation (ABS) is the most popular tool used for gaining aggregated information of an evacuation. A finding has pinpointed that an evacuation decision is determined by a combination of household characteristics and by both capacity-related and hazard-related factors (Lim et al., 2016).

The first step in evacuation planning, is to forecast the number of people to be evacuated and the time to start evacuation, *i.e*. the demand estimation. ABS models were successfully used in (FlötterödLämmel, 2010; NaBanerjee, 2015; Yin et al., 2014) to gain insight into the evolution of evacuation demand when considering both risk factors and social elements. Proactive agents, *i.e.* goal-oriented agents searching for safe places or performing tasks to prepare for evacuation, were used to model households (NaBanerjee, 2015), individuals (FlötterödLämmel, 2010) and patients (Yin et al., 2014). The agents take actions based on the decision models integrated into a simulation (Gama et al., 2016; Lei et al., 2012; Lim et al., 2016; Yin et al., 2014). These models are mainly probabilistic decision models derived from human behaviour in response to hazards and evacuees' demographic characteristics (e.g. sex, age, education, social connection, and economical status) collected from historical records and interviews.

Evacuation plans obtained from aggregated results of ABS are not only determined by the shortest routes, but also by the behaviour of households based on their social connections (*i.e.*, how friends and relatives might influence a household). Research efforts have successfully integrated some social connection factors into decision models as an attempt to better understand dynamic factors in an evacuation decision (Lim et al., 2016; Yin et al., 2014). Their findings confirmed the role of social connections among evacuees in effective emergency response, as described in (Hofinger et al., 2014; Wachtendorf et al., 2013). Aggregating agents' social interaction using ABS may not be applicable when creating plans based on regional segmentation. Besides, shelter assignment techniques based on regions are usually focussed on transportation optimisation rather than social connections. Consequently, social connections are often omitted when developing evacuation plans at policy level.

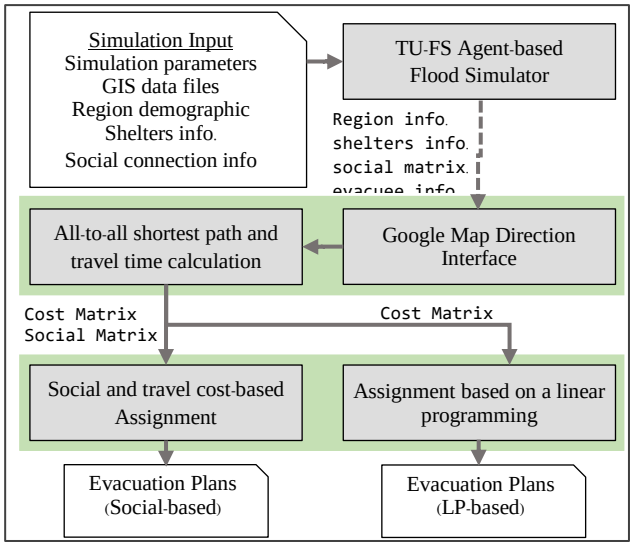

Figure 1. Overall process to generate the evacuation and shelter plans.

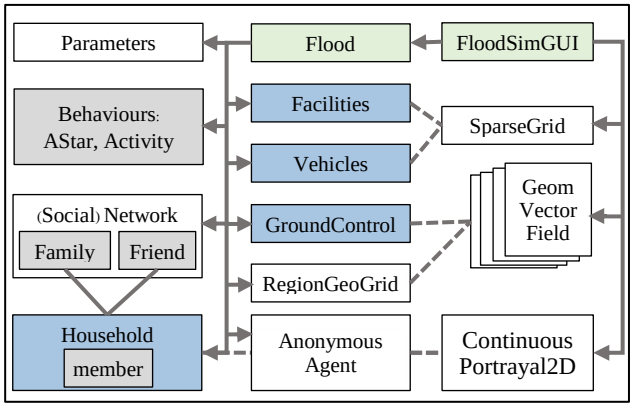

Figure 2. Classes and components in the TU-FS simulator.

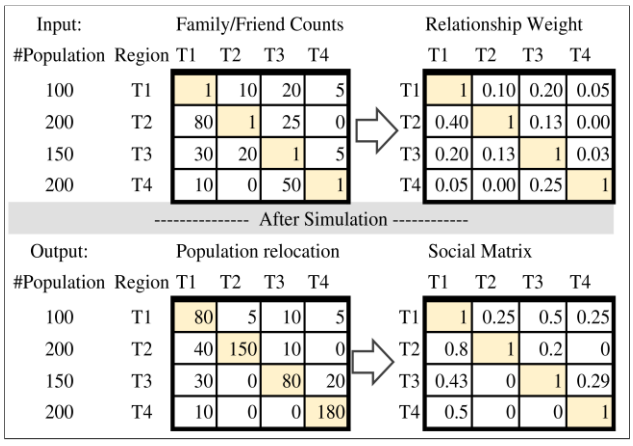

Figure 3. Example of the social connection and the social matrix.

This paper presents a method to create a social-aware evacuation plan. A GIS-enabled ABS called the TU-FS simulator (Vijitpornkul and Marurngsith, 2015), implemented on the GeoMASON framework (George Mason University, 2013), is used to estimate evacuation demand and obtain social connection data. These data are used to classify evacuees into groups and assign them to the nearest shelters. This paper makes three contributions.

(1) An estimation of evacuation demands and households' social connections using a GIS-enabled agent-based flood simulator is demonstrated.

(2) A shelter assignment method to generate social-aware evacuation plans by using the K-means clustering and realistic traffic information obtained via the Google Map Direction API (Google Developer, 2016) is proposed.

(3) A linear optimisation model for solving the capacity-aware shelter assignment problem based on minimising travel-cost is presented. Evacuation plans generated by this model were compared against the social-aware plans and this confirmed the effectiveness of the proposed social-aware method.

A case study, covering the central part of Lop Buri province in Thailand, was conducted to demonstrate the applicability of the proposed method. The results confirm the competitiveness of social-aware evacuation plans as an appropriate alternative to current policies for evacuation.

The rest of this paper is organised as follows. The next section introduces an agent-based flood simulation used in this study. Section 3 presents the proposed evacuation and shelter planning method. Section 4 analyses the efficiency gained from allocating ten shelters with the proposed method in comparison to the linear optimisation model. Finally, Section 5 brings this paper to a conclusion.

2 GIS-Enabled Agent-Based Flood Simulation

The overall process to generate evacuation and shelter plans is shown in Figure 1. Firstly, users must setup the flood scenarios by providing six inputs *i.e.*, (1) the simulation parameters, (2) the GIS data files, (3) information about the affected regions, (4) information about shelters and other facilities, (5) social connection information and (6) the household demographics. All these inputs are then passed to the TU-FS simulator to run a simulation. The TU-FS simulator gathers the amount of population in the affected regions and processes it into four output files that represent the evacuation demand. These four files contain information about the affected regions, shelters, households (evacuees), and a social matrix, respectively. Data contained in those four files is processed using the Google Map Direction interface followed by an all-to-all shortest path and travel time calculation. The process creates two matrices, namely: a cost matrix, and a social matrix. In our approach, we use both matrices to assign shelters and generate evacuation plans. In contrast, the linear model only uses the cost matrix to deal with shelter-assignment and to produce evacuation plans.

We have modified the original TU-FS simulator to be able to simulate pre-evacuation activity in different scenarios. The core simulation model and the graphical user interface of the model were implemented in two Java classes: Flood and FloodSimGUI (Figure 2). The Flood class contains objects from four `steppable` classes (`Facility`, `Vehicles`, `GroundControl`, and `Household`), four custom classes (`AStar`, `Activity`, `Family`, `Friend`) and other objects inherited from the MASON and GeoMASON libraries. The `steppable` classes implement objects whose behaviour is updated at every time step during a simulation. Custom classes are used to implement specific behaviours of the objects. For example, the `AStar` class implements an algorithm to assign a household or a vehicle to a certain travel path. Four objects extended from the Mason library are used to enable customised parameters. These are the `ContinuousPortrayal2D`, `SparseGrid`, `Network`, and `Param`. These objects are also used for creating both the social network relationship among households and the layered environments in the model. GIS data files are added into the model using two classes of the GeoMASON library, *i.e.*, the `GeomVectorField` and `RegionGeoGrid` objects. Details of the MASON simulation engine can be found in (Luke, 2015).

The `GroundControl` class manages the GIS data layers in the model. To do this, three parameters are required, namely: a list of GIS ASCII format files, the affected region and shelter location. The GIS layers of an area under study are read from the list of GIS ASCII files and placed on top of the 2D continuous space containing the households' agents. These layers represent the political boundary of a region, the ground water, the transportation (road network), and the flood map. The flood map layer consists of a set of files that are named in sequence. That map is updated at every specified simulation time step (*e.g.* every simulated hour). The TU-FS simulator uses the WGS84 (EPSG4326) coordinate reference system. The list of regions and shelter locations is stored in a CSV and fed into the simulation by the `GroundControl` class. The GPS locations are also sent to the `Facilities` class to create agents for shelters and sub-districts.

Parameters related to household demographics and social connections are also specified in the CSV-format files. The household demographics file records the number of affected regions or sub-districts under study. That information is kept in rows, where every row specifies information about the households in a sub-district as the percentage of the population having certain attributes. For example, these attributes could be personal characteristics (sex, height, average age), health status (healthy, infected, sick, dead), number of families, mobility state. The parameters used to derive social connections are in the `FriendInfo` and `FamilyInfo` files. These files contain 2D matrices that represent a Count and a Size part. Each part of the file has a 2D matrix of R×R size, where R is the number of the affected regions. Figure 3. (top left) depicts the structure of the Count part of the file. The Size part is kept in a matrix where each cell (in row i column j) represents the average of friend/family members that live in sub-district j of a person that lives in sub-district i. The `FriendInfo` and `FamilyInfo` files are used to create Household, Family, Friend and Vehicle objects to meet the specified parameters. Social network relationships are set using the MASON's social network facility.

Once all objects have been successfully initialised, the TU-FS simulator runs a simulation until either a defined step or a trigger marked in the flood map is reached. At every step in the simulation, household agents may move to join with friends or family. The simulation summarises locations of agents and other detailed information into four text files (Figure 1). At this stage, the number of households who live in sub-district *i* but have moved and stay in sub-district *j* is recorded in cell *i,j* of the population relocation matrix (see Figure 3 lower left). Data in this relocation matrix is calculated as a percentage and written into a `SocialMatrix` file (Figure 3 lower right). Finally, all four output files are used by the shelter allocation module to produce an evacuation plan.

3 Evacuation and Shelter Planning Method

3.1 Shelter Allocation Methodology

As depicted in Figure 1, the shelter allocation module takes the output of the ABS module and performs four key steps. The detail algorithm is presented in Table 1. Firstly, we use a web service from the Google Direction API to obtain three driving routes with their directions as a JASON object. The routes are extracted from the JASON object and stored in a origin/destination matrix, the OD matrix. Any unsafe roads obtained from the simulation are rejected as feasible routes.

Secondly, the travel time from all sub-districts to every shelter is calculated prior to applying the Floyd-Warshall algorithm to find the all-to-all shortest path. The calculation of travel time is based on the simple car-following evacuation model, but including the travel speed obtained from the Google Map Direction API. The RegionInfo file contains a list of vehicles that are used to calculate the length of vehicle processions for each affected region. After that, speed and distance in the OD matrix are used to calculate the overall evacuation time of all vehicle processions from each affected region to shelters. The results containing the evacuation times are stored in a new matrix called the cost matrix (C).

Table 1. Algorithm used in The Shelter Allocation Module.

Algorithm:
D: set of affected sub-districts
S: set of shelters
i,j: node index

1. **Obtain driving distance matrix** from all origin to destination (OD):
   Forall $i \in D \cup S$, and forall $j \in D \cup S$
   Obtain 3 travel routes and distance from node i to j using the Google Map Direction API
2. **Remove unsafe routes**:
   For all element in the OD matrix, remove the travel direction which contains unsafe routes
3. **Calculate all-to-all shortest path**:
   Applying the Floyd–Warshall algorithm on the OD matrix
4. **Obtain the vehicle list**:
   If a vehicle list is not provided, calculate the vehicle table based on % of households that have private cars and % of vulnerable evacuees who need an ambulance. Otherwise go to step 5.
5. **Calculate the cost matrix (C):**
   Use the vehicle list from step 4 to calculate the length of vehicle processions for all affected regions and calculate the time to evacuate all vehicles from each affected region to all shelters using the travel speed and distance in the OD matrix obtained from step 3.
6. **Combine the social matrix with the cost matrix:**
   If a social matrix is provided, concatenate all columns to the cost matrix. Otherwise go to step 7.
7. **Classify the affected regions into S centroids**:
   Pass the C matrix to the K-Means Clustering to classify the affected region into S groups
8. **Calculate the estimate evacuation demand**:
   Read the Affected Region file to obtain the % of people who decided to evacuate and calculate the evacuation demand for each region.
9. **Schedule affected regions of each centroid to the nearest shelters**:
   Allocate the affected region from the same group to the nearest shelter. If the shelter capacity is exceeded, the next nearest available shelter is selected.

3.2 Shelter Assignment based on K-Means Clustering

The third key step performs the travel-cost and social-based shelter assignment. In this step, affected regions are classified into S groups based on travel time and social connections, where S is the number of shelters. The combination of the Social matrix and the C matrix is used as the input features for the K-Means Clustering module. Ideally, all groups of an affected region will be assigned to common shelters.

To assign shelters to affected regions the number of evacuees is first estimated by applying the percentage of people that decided to go to shelters, relative to the initial population. To proceed with allocation, the system will try to assign an affected region from a group to the nearest shelter allocated to that group, *i.e.* the Our Shelter. If the Our Shelter cannot accommodate any more evacuees, the next nearest available shelter with the closest social connection will be selected, *i.e.* the Our Friend Shelter. The latter selection process is iteratively applied until an available shelter is found.

3.3 Linear Optimisation Model

The last key step in the shelter allocation is to generated alternative evacuation plans by using a linear optimisation model. To solve shelter assignment, we have implemented a linear optimisation model based on minimising travel time using the Simplex method. Parameters and decision variables in our model, are defined as follows.

S set of shelters
D set of sub-districts to be evacuated
I index of sub-district
J index of shelter
Ei the number of evacuees in sub-district i
Lj the capacity limit of shelter j
Cij the evacuation time

Decision variable:

$$x_{ij}\ is \begin{cases} x_{ij} \geq 1 \text{ and } x_{ij} \leq E_i \text{ if subdistrict i is assigned to shelter j} \\ 0 \text{ otherwise} \end{cases}$$

Objective function:

$$\min \sum_{i \in D} \sum_{j \in S} x_{ij} C_{ij} \quad (1)$$

Subject to:

$$\sum_{j \in S} x_{ij} = E_i \quad (2)$$

$$\sum_{i \in D} x_{ij} \leq L_j \quad (3)$$

In our model, the number of evacuees of sub-district i assigned to shelter j is used as a decision variable. The objective function, Equation (1), minimises total evacuation time based on travel cost to evacuate all evacuees from all sub-districts to their assigned shelters. The constraint in Equation (2) guarantees that the number of evacuees of a sub-district assigned to different shelters is equal to the total number of evacuees in that sub-district. The constrain in Equation (3), ensures that the number of evacuees from sub-districts assigned to a shelter does not exceed that shelter's capacity.

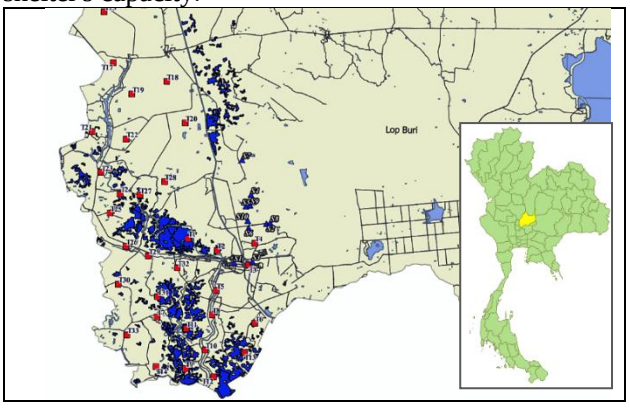

Figure 4. Screenshot showing the studied area in Lop Buri, Thailand.

4 Case Study

A case study was carried out to demonstrate the applicability of the proposed method. The case study is located in the centre of Lop Buri province, Thailand, covering 6,200 km² area. The information used in the case study is based on the Lop Buri's official evacuation and shelter plan of the year 2011. The official plan specified 33 sub-districts or Tambon (T1 – T33 shown in Table 2) with a potential flood-affected population of 149,468 people living in 8,300 households. Furthermore, there were 1,939 vulnerable people among the affected population. Ten potential public shelters were pre-defined with capacities of 500 – 3,150 people (see S1 – S10 in Table 3). Those shelters were existing public schools, hospitals, and military facilities located on high ground. Flood maps and geographical information from the Thailand Flood Monitory System provided by the Geo-Informatics and Space Technology Development Agency (GISTDA, 2016) were used to locate shelters and the affected regions (Figure 4).

The progression of the flood was simulated based on the flood map of the year 2012. To investigate advantages and drawbacks of our approach we compare the generated social-aware evacuation plans (S-plans) against their counterparts generated from the linear programming optimisation (LP-plans). We considered four scenarios (see below) that produced eight different plans: (S-A1, -A2, -B1, -B2 and LP-A1, -A2, -B1, -B2).

A1: The evacuation is performed before the inundation has progressed to the potential affected regions. Healthy evacuees use private vehicles to travel to the assigned shelters.

A2: As for A1, except that public buses are used to transport all healthy evacuees.

B1: The evacuation is started when some roads are already inundated and unsafe to use. Healthy evacuees use private vehicles to travel to the assigned shelters.

B2: As for B1, except that public buses are used to transport all healthy evacuees.

Note that ambulances were used to evacuate vulnerable evacuees in all experimental settings. The result from the ABS shows that 10 percent of the population will be evacuated. This conform with the findings in (Lei et al., 2012; Yin et al., 2014).

4.1 Shelter Utilisation

From the perspective of capacity utilisation, both the social-aware and LP- plans achieved very similar results (Figure 5) ranging from 78 – 81.5 percent. In the LP plans, we observed that some shelters were packed up to 100% to minimise the evacuation time. However, other shelters were not used at all. Thus, the social-aware plans show a slightly better (by 1%-2%) shelter utilisation.

4.2 Time to Evacuate One Household

In the generated plan, the time to evacuate one household is reported (an example of the generated plan is shown in Table 4). In all studied scenarios a household needs on average about an hour (-6 to +20 min.) to arrive at its assigned shelter (Figure 6). Although the linear optimised plans show less evacuation time per household, they have a wider range of min-max time. The most effective evacuation is observed in the S-A1 plan in which all evacuees could arrive at their assigned shelters in one hour and twenty-six minutes. The worst time is shown by the S-B1 plan as road cuts make a trip time of three hours and twenty-one minutes.

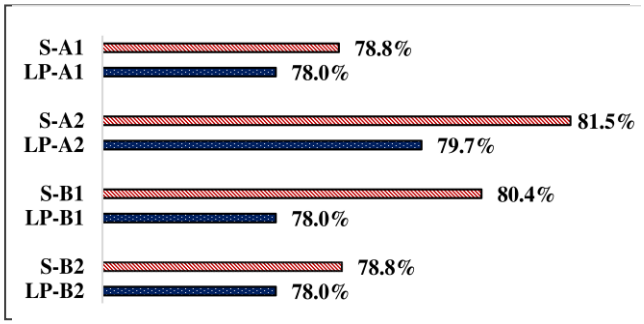

Figure 5. Average shelter utilisation of social- vs. LP-plans.

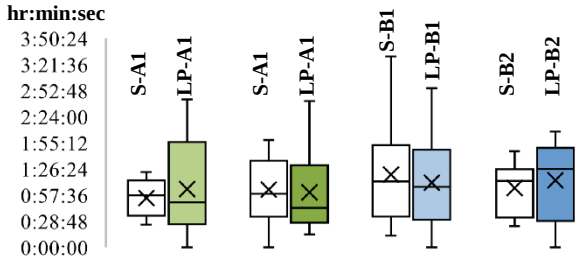

Figure 6. Time to evacuate a household to the assigned shelter.

4.3 Total Evacuation Time

The overall evacuation time is analysed from both a best case and a worst-case perspective. In the former case, termed the minimum travel time, traffic congestion was taking into account and processions of evacuees' vehicles, going to different shelters and following different routes, were scheduled in parallel. In the latter case, termed the maximum travel time, processions of evacuees' vehicles were moved in sequence to mimic heavy traffic congestion.

Travel time differences between social-aware and LP-plans are shown in Figure 7 and Figure 8. Note that positive values indicate that a social-aware plan is faster than its LP plan counterpart. Our results show that in comparison to the LP plans, all S-plans (with the exception of the minimum time of S-A1) save an average of between half an hour and up to three hours of travel time. Obviously, the travel time required for evacuation depends on the conditions of the route selected, which takes its toll in the slower minimum travel time of the S-A1 plan.

4.4 Discussion

Our approach capitalises on the detailed information on distances and available routes to produce social aware evacuation plans that seem to be more capable than simple LP plans. Note that our methodology manages to make evacuation plans even in the event of road cuts, providing that those road cuts do not cause isolation areas.

5 Conclusions and Future Work

In this paper, a GIS-enabled agent based simulation to create social-aware evacuation plans, based on estimation of household movement during flood, has been presented. The implementation of an updated version of the TU-FS simulator and the shelter assignment method have been described. A case study has been conducted to demonstrate the applicability of the proposed method. Two evacuation scenarios were considered: evacuation prior to the arrival of a flood, and evacuation during a low-level flood. The evacuation plans generated by the proposed method were compared against their linear model travel-cost optimisation counterparts. The results show that plans generated with our methodology offer a 1-2% better use of shelter capacity. The average evacuation times per household are similar to those of optimised plans with a difference between -12% to +15%. However, our evacuation plans could save nearly three hours to evacuate all regions.

Thus, the methodology presented in this paper could be an appropriate alternative to develop evacuation plans at policy level. Future work will focus on improving the social matrix model and model verification.

Abstract

In this paper, we propose a simulation model with a PI controller to analyze and control the dynamics of a multi-workstation production system. The formulation is based on dynamic modelling and control theory, and the model was implemented in Matlab and Simulink. Exploratory tests were carried out, and the results indicated some relationships between the values of the parameters of the controller and the values of the output variables, that is, the levels of work in process. They also showed that the proposed model has the potential of providing managerial directions on how to dynamically adjust the capacity, aiming to smooth the operation of the shop floor and to keep the work in process close to the desired levels.

Keywords: production systems, control theory, dynamics, simulation, planning and scheduling

1 Introduction

As known, the increasing computational capacity engendered a sound evolution of the operations management area, since it allowed the development of several tools to cope with large amounts of data related to the planning process and to ground the analysis of the decision makers. In this sense, the use of dynamic modeling and simulation techniques complements the static approaches for planning optimization of production systems and supply chains. Control theory is also a correlated area whose theories and tools have been applied to production and supply chain management. Some steps in these directions are enumerated in the literature review section of this paper.

Considering the aforementioned approaches, we present in this paper a simulation model based on state equations to depict the dynamics of a multi-workstation manufacturing system. A proportional-integral (PI) controller is applied to the model, and exploratory tests are carried out.

The model basically deals with the work in process (WIP) and capacity allocation variables (represented by the processing frequency of the stations), in a plant with job shop configuration. In general terms, the control of work in process is a classical concern in the operation of job shops, since it generates more predictable cycle/throughput times, which lead to better promises and fulfilment of delivery dates, a more stable coordination of the shop floor, and more flexibility to attend changes in the customer demand. These effects are highlighted in the literature related to various methodologies in production engineering, such as just-in-time, quick response manufacturing, workload control, factory physics, and others.

The results obtained with the simulation of the proposed model provided some indications of how its parameters influence the WIP levels, and demonstrated the potential of the proposed approach to depict the dynamic relations between capacity allocation, work in process and operations smoothness in production systems.

2 Literature Review

The effort of evolving from the static to the dynamic analysis of production and supply chain systems relies on system dynamics and control theory, as mentioned. In a broader sense, system dynamics may be defined as an area of knowledge that deals with the time-varying behavior of a system (Doebelin, 1998). This includes not only mechanical, electrical, fluid and thermal, but may also include biological, manufacturing, social and hybrid systems. Control theory, on its turn, has different subareas and a range of tools for the analysis and design of closed-loop systems, where the information of the outputs is fed back to the system in order to lead it to desired goals. In the literature reviews concerning the application of control theory to production and supply chain, the models are classified according to the area of application [(Ortega and Lin, 2004), (Sagawa and Nagano, 2015b)], the underlying control methodology (Sarimveis et al., 2008), the type of analysis that is carried out (i.e. robustness, stability, etc.) (Ivanov and Sokolov, 2013), or according to mixed criteria (Åström and Kumar, 2014).

In Table 1, we present some applications of control theory to production and supply chain systems, classified according to subareas of application and the methods underlying the models. Our intention here is not to present an extensive review, but rather to enumerate different possibilities and to provide few references in each category, as examples.

Other applications based on model predictive control or robust optimal control are not listed here, but can be found in (Sarimveis et al., 2008). Also, there are some alterna-

Table 1. Some Applications of control theory in production systems and supply chains

Area/type of application	*Applied methodologies and tools*	*References (examples)*
single-product production-inventory models and extensions to supply chain	classical control theory, block diagrams, transfer functions	(Towell, 1982; Zhou et al., 2006; Spiegler et al., 2016)

multi-echelon production-inventory models using bills of material as input	input-output analysis, Laplace or z-transform, probability distributions, NPV	(Axsäter, 1976; Grubbström and Molinder, 1994; Grubbström et al., 2010)
multiple-machine and multi-product systems based on flow models	flow models, block diagrams, transfer functions, bond graphs	(Wiendahl and Breithaupt, 2000; Kim and Duffie, 2006; Sagawa and Nagano, 2015a)
supervisory/process control of continuous production systems and its integration within the hierarchical production planning	mixed integer dynamic optimization (MIDO), mixed integer nonlinear programming (MINLP)	(Monfared and Yang, 2007; Munawar and Gudi, 2004; Du et al., 2015)
production and supply chain models with autonomous control/decentralized agents	queue length estimator (QLE), pheromone, heuristic methods, RFID	(Scholz-Reiter and Freitag, 2007; Wang and Lin, 2009; Barenji et al., 2014; Schukraft et al., 2016)

tive formulations out of the control theory area, based, for instance, in queueing systems, which are out of the scope of this paper.

In the following subsection, we present the mathematical model that was adopted as basis for the simulation model proposed in this paper.

2.1 Dynamic multi-workstation model based on electrical components

A dynamic model based on the ideal properties of electrical components is proposed in (Sagawa and Nagano, 2015a) to depict a multi-workstation system that can manufacture different families of products. The model is basically composed by machines, buffers and junction elements.

The machines are compared to resistors and their processing frequency U_i correspond to $\frac{1}{R}$, where R is an ideal resistance. Similarly, the buffers are seen as ideal capacitors with capacitance C, which corresponds to their storage capacity (Ferney, 2000). The junctions are used to couple these manufacturing elements and to depict the configuration of the production flow in the system, i.e. to represent the different process routings of each product or product family (Sagawa and Nagano, 2015a). When a given machine outputs flow to m workstations downstream, it is coupled to these workstations by means of a divergent junction that imposes the conservation of flow. Similarly, the upstream flows coming from different workstations to a given workstation are merged by means of a convergent junction that conserves the total flow (Sagawa and Nagano, 2015a; Ferney, 2000). The discussed model is continuous and deals with 3 variables: the production flow f, the production volume q and the effort e. The production volume corresponds to the integral of the flow, and the effort is used as an auxiliary variable, for coupling a machine and its precedent buffer, as well for the approximation of a discrete system as a continuous system (Ferney, 2000). The basic equation of the model is derived from the well-known constitutive equations of the ideal electrical components previously mentioned, and is shown in (1). The variables and parameters of this equation were already mentioned in the text. The index i denotes a given workstation, the index s applied to the flow or effort variables denotes the output of this station, and the index e denotes its input. Eq. (2) is based on the aforementioned integral relation between the production volume q and the flow variable f, likewise the electric charge stored in a capacitor is defined as a function of the integral of the electric current. In the context of manufacturing, $\dot{q}_i(t)$ is interpreted as a rate of material storage or consumption, expressed as the difference between the input and output flow of a workstation.

$$f_{si} = U_i \left[\frac{q_i(t)}{C_i} + \min\{1, q_i(t)\} - e_{si}(t) \right] \quad (1)$$

$$\dot{q}_i(t) = f_{ei}(t) - U_i \min\{1, q_i(t)\} \quad (2)$$

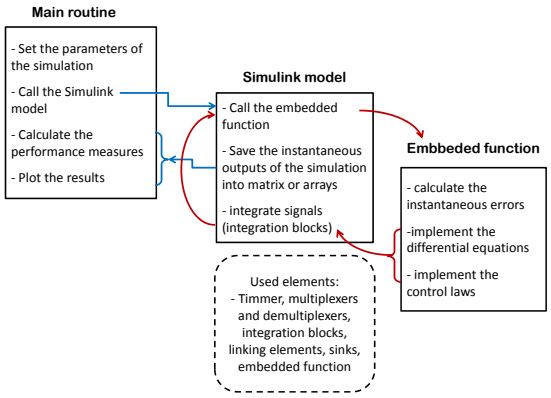

Figure 1. Schematics of the simulation model

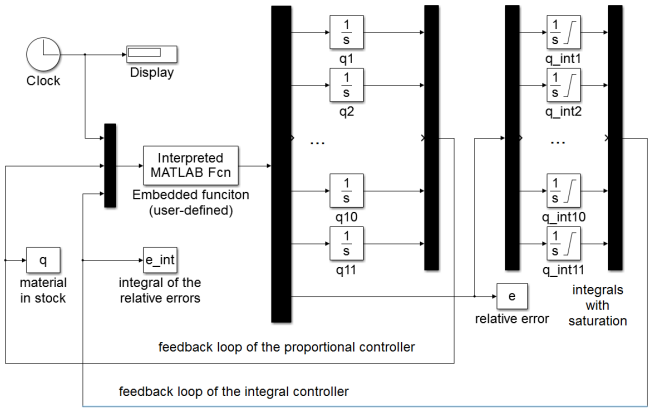

Figure 2. Schematics of the model build in Simulink®

The assumption of buffers with unlimited capacity allows simplifying (1), and the combination of (1) and (2) yields the basic state equation of a workstation, presented in (3).

$$\dot{q}_i(t) = f_{ei}(t) - U_i \min\{1, q_i(t)\} \tag{3}$$

This basic equation and the constitutive equations of the junctions were applied to a 11-workstation production system, as presented in (Sagawa and Nagano, 2015a), resulting in the state model shown in (4).

$$\begin{bmatrix} \dot{q}_1 \\ \dot{q}_2 \\ \dot{q}_3 \\ \dot{q}_4 \\ \dot{q}_5 \\ \dot{q}_6 \\ \dot{q}_7 \\ \dot{q}_8 \\ \dot{q}_9 \\ \dot{q}_{10} \\ \dot{q}_{11} \end{bmatrix} = \begin{bmatrix} -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0.4300 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0.2508 & 0.5118 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0.1538 & 0.3140 & 0 & -1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0.0170 & 0.0347 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0.0175 & 0.0020 & 0.2811 & 0.2811 & 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0.0087 & 0.0010 & 0.1399 & 0.1399 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0.0161 & 0.0018 & 0.2588 & 0.2588 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0.0200 & 0.0023 & 0.3204 & 0.3204 & 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0.2407 & 0.2407 & 0.2407 & 0.2407 & -1 \end{bmatrix} \begin{bmatrix} U_1 \min\{1, q_1\} \\ U_2 \min\{1, q_2\} \\ U_3 \min\{1, q_3\} \\ U_4 \min\{1, q_4\} \\ U_5 \min\{1, q_5\} \\ U_6 \min\{1, q_6\} \\ U_7 \min\{1, q_7\} \\ U_8 \min\{1, q_8\} \\ U_9 \min\{1, q_9\} \\ U_{10} \min\{1, q_{10}\} \\ U_{11} \min\{1, q_{11}\} \end{bmatrix} + \begin{bmatrix} U_{01} \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \tag{4}$$

3 Simulation Model with a PI Controller

A simulation model based on the presented state equations was implemented using Matlab® and Simulink®. It included a proportional-integral (PI) controller, as mentioned. The structure of this model, as well as the executed instructions, are shown in Fig. 1. As it can be seen, the relevant parameters of the simulation are defined in the main routine. After that, this routine calls the Simulink model (Fig. 2), which contains the block diagram of the dynamic model with the controller. The computation of the state equations is performed by a user-defined function embedded in the Simulink® model.

After the iterations are carried out for the total simulated time, the main routine compiles the results and calculates the performance measures. For the implementation of a proportional-integral controller, integration blocks $(1/s)$ of the first level should be applied to the instantaneous material storage rates $\dot{q}_i$, while second level integrations should be applied to the relative errors in the stock levels, as it can be seen in Fig. 2.

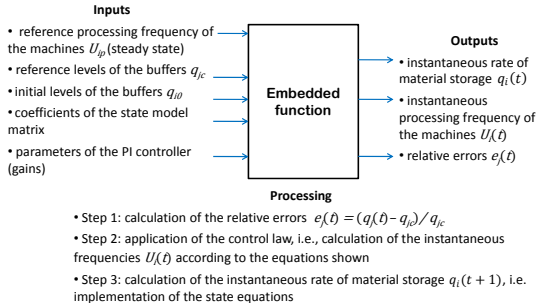

Figure 3. User-defined function implemented in the simulation model

As mentioned, the state model is implemented by means of a user-defined function. The inputs of this function are those parameters defined in the main routine, and presented in Fig. 3.

With these inputs, the function calculates, at each time t, the relative errors of the stock levels, shown in (5), and implements the control law. For an integral controller, this control law is shown in (6). With the values of the instantaneous processing frequencies of the machines U_i, resulting from the implementation of the control law, the instantaneous rates of material storage $\dot{q}_i(t+1)$ are then calculated. These rates are integrated in the integration blocks and fed back to the model

$$e'_j(t) = -e_j(t) = \frac{q_{jc} - q_j(c)}{q_{jc}} \tag{5}$$

$$U_i(t) = U_{ip}\left(1 + k_p e'_j(t) + k_i \int e'_j(t)dt\right) \tag{6}$$

where $\dot{q}_j(t)$ is the instantaneous amount of material stored in buffer j, $e'_j(t)$ is the relative error considering the actual level $\dot{q}_j(t)$ and the reference level q_{jc};U_{ip} is the reference for the processing frequency of machine i, considering the customer demand fulfillment in the steady state; k_p is the proportional gain of the controller; and k_i is the integral gain. The presented equations apply for the case where the buffer j immediately succeeds the machine i. If machine i is succeeded by more than one buffer, the minimum value of e_j is computed.

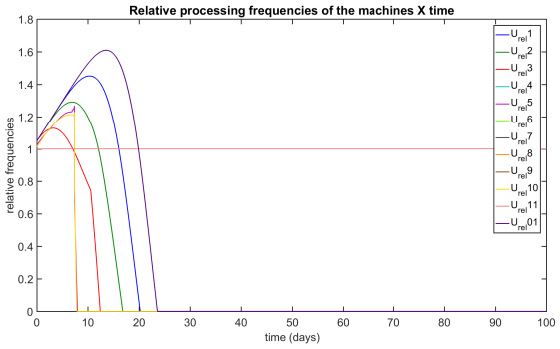

Figure 4. Processing frequencies of the machines for a test carried out with $k_p = 0.05$ and $ki = 0.05$ (whitout saturation limits).

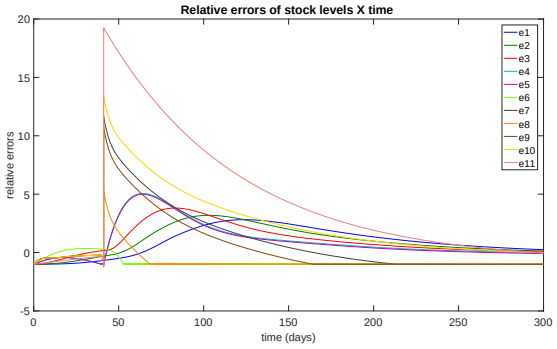

Figure 5. Evolution of the relative errors in stock levels (WIP), for saturation limits of ± 10, $k_p = 0.05$ and $k_i = 0.001$.

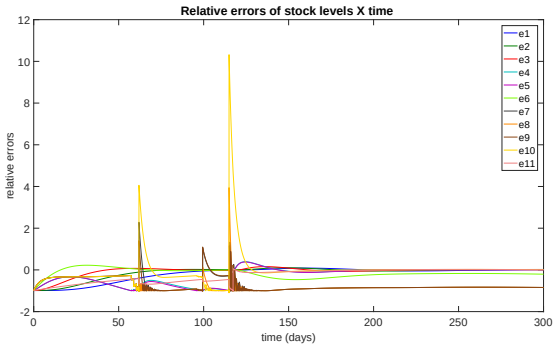

Figure 6. Evolution of the relative errors in stock levels (WIP), for saturation limits of ± 1, $k_p = 0.05$ and $k_i = 0.001$.

4 Test and Results

The proposed simulation model was applied to the 11-workstation system presented in (Sagawa and Nagano, 2015a). For an initial analysis, it was of interest to consider the warm-up of the manufacturing system and its transition to the regular operation, that is, to consider the situation where all the buffers are empty ($qi0 = 0$ for all i) and the system starts to work, aiming to attend the customer demand and to reach the desired levels of work in process. This starting condition is somewhat similar to the application of a step input, conventionally used for the study of the response in dynamic systems. In our case, however, each buffer has a different reference level, since these levels were defined as a multiple of the amount of material cumulated in each buffer when the system was simulated without control, i.e., when the open-loop system was simulated. In order to allow comparisons, we adopted a multiplication factor of 100 times, as in (Sagawa and Nagano, 2015a). As output variables of the tests, we analyzed the values of the processing frequencies of the machines $U_i(t)$ (the controlled variables); the relative processing frequencies, i.e. $(U_i(t) - U_{ip})/U_{ip}$; and the relative errors in the buffer levels (e_i) over time. This last measure indicates the variation of the work in process in the system. Depending on the selected values of the gains, the machines are led to operate with processing frequencies above the reference frequencies, in order to fulfill the buffers. In Fig. 4, the source of material works with a processing frequency that is 60% greater than the frequency that attends the customer demand in the medium term, i.e. in the steady state. This control command generates a surplus of material in the buffers. When the controller receives this information, it reduces the processing frequency of the machines. This reaction, however, is excessive, so that the machines are shutdown. The saturation of the integral controller could be a relevant parameter of influence for the control of the processing frequencies of the machines. Due to the saturation in PI controllers, the integrator may drift to undesirable values, since it tends to produce progressively larger control signs. This effect is known as windup of the integral controller (F Franklin et al., 1994; Moreno-Valenzuela, 2008). Therefore, additional tests were performed with the establishment of saturation limits for the integral controller. Some results are shown in Fig. 5-8. The values of the gains were kept constant and different saturation limits were tested.

The presented results indicate that, with narrower saturation limits, the overshoots in the WIP (represented by the relative errors) were significantly reduced. In Fig. 5, the overshoot is of 20 times the reference level and in Fig. 5, it is of 10 times. Although punctual instabilities in the control of some machines arose (Fig. 7), the operation of the system also became smoother with the estab-

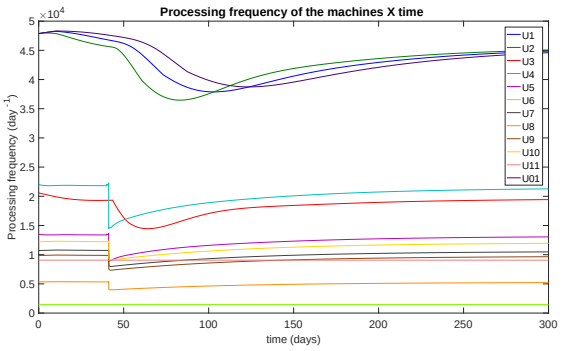

Figure 7. Evolution of the processing frequency of the machines, for saturation limits of ± 10, $k_p = 0.05$ and $k_i = 0.001$.

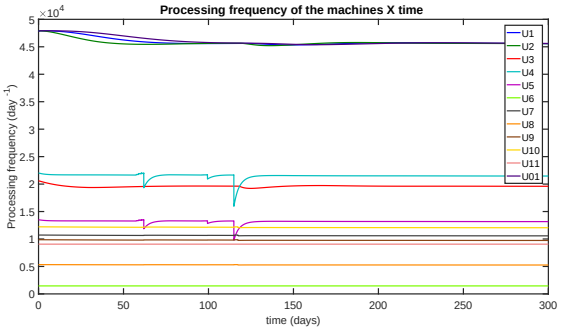

Figure 8. Evolution of the processing frequency of the machines, for saturation limits of ± 1, $k_p = 0.05$ and $k_i = 0.001$.

lishment of saturation limits.

The exploratory tests have also shown that the overshoot in the processing frequencies of the machines tend to increase with the increase of the integral gain. Hence, the results could be further improved by means of systematic experiments and the application of control tools for the optimization of these parameters (gains and saturation limits).

From the managerial perspective, the controller can lead the system to undesired operating points, depending on parameters set, because working either too far above or below the regular capacity imply higher operational costs. Moreover, there are well-known relations among WIP, cycle times and throughput rate. An increase in WIP may engender a relevant increase in the cycle time (lead time), without producing any effect in the throughput rate of the production system (Hopp and Spearman, 2001). Longer cycles times usually result in delayed jobs, rush orders, and difficulty of coordination. Based on the aforementioned reasons, it is of interest, in our model, to find the parameters that enable to reduce the overshoot of WIP and, meanwhile, to reduce the oscillations in the processing frequencies of the machines.

The variations in the processing frequencies represent, in fact, capacity additions or reductions. Thus, the proposed simulation model may provide insights on how much capacity should be increased or decreased over time in order to: 1. guarantee adequate levels of WIP, to absorb fluctuations; 2. avoid an excessive increase in the cycle/throughput times; 3. smooth operations, so that the operational costs stay low. These capacity adjustments can be implemented in various ways, i.e. overtime, subcontracting, adding/renting extra resources, or reducing the utilization of the machines.

In practice, the goal of production managers is to keep the operations stable, as much as possible, so that no extra costs are incurred (although this pursuit of stability should not unreasonably compromise the flexibility to attend customers). In MRP systems, the short term variations in the plans are usually smoothed or prevented by applying time fences to demand, planning and/or order release. This solution is efficient to keep the costs under control, but disregards the dynamics of the production systems, so that backorders and stock outs in the short term may occur. In this sense, the use of the dynamic modeling and simulation seems to be an interesting alternative or complement to other methodologies used in the production engineering area. The presented formulation is also relatively simple and easy to implement, which is an advantage in terms of use.
